Xenotransplantation of human cryopreserved parathyroid tissue isolated from parathyroid adenomas to normocalcemic rabbits

Erhan Ayşan1, Yiğit Düzköylü2, Ismail Can3, Nur Büyükpinarbaşılı4

Objective: Parathyroid allotransplantation is a new method for the treatment of permanent hypoparathyroidism. Adenoma cells are not used for transplantation because of the potential for functional or histopathologic transformation. In this study, we transplanted human adenomatous parathyroid cells to rabbits.

Material and Methods: Parathyroid adenoma tissue taken from a male patient was cryopreserved and transplanted into seven New Zealand white rabbits (mean weight, 3700±220 g; mean age, 4.5 months) under immunosuppression. The levels of parathormone, calcium and phosphorus were measured before and after transplantation, and the parathyroid cells were observed histopathologically.

Results: Mean parathyroid hormone level was 0.5 pg/dL before transplantation and 6.6 pg/dL after transplantation (p<0.05). Preoperative mean calcium level was 14.1 mg/dL, and mean phosphorus level was 3.5 mg/dL before transplantation while these values were 14.4 mg/dL and 3.3 mg/dL, respectively, after transplantation (p>0.05). Morphologic transformation was not observed in parathyroid cells after transplantation.

Conclusion: In short-term observation, adenomatous parathyroid cells can function without malignant transformation. In the future, the preliminary methodology in this study may serve as a safe alternative for allotransplantation into patients with permanent hypoparathyroidism.

Keywords: Hypoparathyroidism, xenotransplantation, parathyroid adenoma

INTRODUCTION
Hypoparathyroidism is a serious health problem that most commonly occurs as a complication of thyroid surgery. Postoperative hypoparathyroidism may be observed in three different variations such as transient (occurs within 3-6 months), protracted (occurs within 1 year) or permanent (occurs after the 1st year) (1). Because parathyroid hormone (PTH) has multiple metabolic functions, control of hypoparathyroidism symptoms with calcium (Ca) replacement therapy can be very difficult (2). Parathyroid allotransplantation for permanent hypoparathyroidism is a relatively new option for treatment (2-4). Upon extensive literature review, it is noted that donors are selected from cadavers or patients with secondary hyperparathyroidism. Primary parathyroid adenomas are the most common cases of surgical intervention indicated in the literature due to hyperparathyroidism, but these patients have not been used as donors thus far (5-7). Cells isolated from adenomatous parathyroid tissue are superior to healthy and secondary hyperplastic cells both in quantity and proliferation rate. However, because adenoma is a benign tumor, there are some concerns about its possible behavior in recipients (5, 6). The potential for functional or histopathologic transformation of adenoma cells is not yet known (5-7). In this study, we aimed to pre-evaluate the usability of this tissue with xenotransplantation from human to rabbit because it has potential to be quite valuable as a cell source.

MATERIAL AND METHODS
This research was performed in Bezmialem Vakıf University, and the research protocol was approved by the same university’s Local Animals Ethics Committee. All protocols were in accordance with the regulations governing the care and use of laboratory animals of the declaration of Helsinki.

Seven male New Zealand white rabbits (mean weight, 3700 220 g; 3700±220 g, mean age 4.5 months) without bred production were used. The rabbits were sheltered at one per cage in standard cages, with top and bottom parts made of stainless metal and sides made of woven wire. The floors of the cages were covered with wood shavings, which were changed daily. Rabbits were kept at room temperature and with adequate ventilation. Water and feeding containers were made of standard plastic, with sideways entrances. Animals were fed specially produced pellet feeds for small laboratory animals.
**Procedure for Parathyroid Tissue Donor Patient:** A 49-year-old male patient was admitted to the outpatient clinic with malignant hypercalcemia (blood calcium level >11 mg/dL). Ultrasound evaluation of the neck revealed a 3 cm diameter mass inferior to the left lobe of the thyroid tissue. Parathyroid scintigraphy (Tc 99m MIBI) indicated that the mass was a parathyroid adenoma. A small Kocher neck incision was performed, and the mass was excised and then divided into two parts. One part was used for histopathologic evaluation and the other part was cryopreserved according to the technique described below for xenotransplantation. The mass was reported as parathyroid adenoma in the histopathologic evaluation.

**Cryopreservation and Cell Preparation:** Tissue was pooled and cryopreserved in three main steps: cell isolation, cell counting (total number of cells, rate of viability) and finally cryopreservation. The cell solutions were thawed by submerging in a 37°C waterbath. After shaving and antisepsis with povidone-iodine (Beckman Coulter) was used to determine viability with the trypan blue staining method. The cells were then prepared for cryopreservation with the following steps: a 500 µl FBS 20% DMSO (400 µl FBS+100 µl DMSO) solution was prepared and gently dropped into 500 µl FBS solution containing 0.25x10⁶ cells on ice. The temperature of the solution was gradually decreased and the solution was then stored in a liquid nitrogen tank.

**Transplantation:** On the day of transplantation, 100 mg/kg prednisolon (Prednol-L 40 mg Ampul®; Mustafa Nevzat Co, Istanbul, Turkey) was used subcutaneously as an induction. On the day of transplantation, 100 mg/kg prednisolon (Prednol-L 40 mg Ampul®; Mustafa Nevzat Co, Istanbul, Turkey) was used subcutaneously as an induction. On the day of transplantation, 100 mg/kg prednisolon (Prednol-L 40 mg Ampul®; Mustafa Nevzat Co, Istanbul, Turkey) was used subcutaneously as an induction. On the day of transplantation, 100 mg/kg prednisolon (Prednol-L 40 mg Ampul®; Mustafa Nevzat Co, Istanbul, Turkey) was used subcutaneously as an induction. On the day of transplantation, 100 mg/kg prednisolon (Prednol-L 40 mg Ampul®; Mustafa Nevzat Co, Istanbul, Turkey) was used subcutaneously as an induction.

**RESULTS**

Levels of PTH, Ca and P in blood from the ear veins of the rabbits before and on the 10th day after transplantation before sacrificing are shown in Table 1. When the levels before and after transplantation were compared, the differences between the levels of PTH were statistically significant (p<0.05). While Ca levels had increased, P levels had decreased, but the differences for these two parameters were not statistically significant. Mean PTH level was 0.5 pg/dL before transplantation and 6.6 pg/dL after transplantation (p<0.05). Mean Ca level was 14.1 mg/dL, mean P level was 3.5 mg/dL before transplantation, and 14.4 mg/dL and 3.3 mg/dL, respectively, after transplantation (p<0.05).

When parathyroid cells were observed histopathologically, there were no morphologic changes before and after transplantation. Table 1 shows results under 0.5 as ‘zero’ and results over 1900 as ‘unidentified’.

**Statistics Analysis:** All statistics were performed using Statistical Package for the Social Sciences version 15.0 for Windows (SPSS Inc.; Chicago, IL, USA). Continuous variables are expressed as the means±standard deviation (SD). Significances of the measurements of serum calcium and phosphorus levels were evaluated by the Wilcoxon test. The differences were considered statistically significant if the p value was less than 0.05.

PTH: parathormone; Ca: calcium; P: phosphorus

Table 1. Serum levels of PTH, Ca and P before and on the 10th day after xenotransplantation
DISCUSSION
Because of the significant clinical symptoms of permanent hypoparathyroidism (PH), clinicians have studied various therapeutic solutions. In long-term medical treatment, oral calcium and vitamin D or its analogues can be administered. However, it is important to deliver them in appropriate doses with regards to pharmacodynamics, the potency at the tissue level, rapidity of action, and the ease of reversal of toxicity (8). Long-term treatment with calcium and vitamin D does not restore physiologic calcium homeostasis and often results in hypercalciuria, even in the face of normocalcemia, thereby increasing the risk of renal sequel (9). Additionally, the disadvantages of conventional therapy including a narrow therapeutic window, propensity for hypercalciuria and hypercalcemia, and the absence of negative feedback mechanisms have led to the investigation of new approaches, including parathyroid gland autotransplantation (8, 10, 11).

As has been shown in various studies, parathyroid gland autotransplantation is an effective approach for reducing the incidence of permanent and transient hypoparathyroidism and is best performed in the setting of total thyroidectomy (12-14). However, it is important to remember that this approach is only possible when the removal and/or devascularization of the glands is recognized by the surgeon peroperatively. Additionally, in patients who have been operated for secondary hyperparathyroidism, autograft hyperplasia may cause recurrences (15).

In recent years, surgeons have studied various therapeutic solutions for the treatment of PH based on other transplantation methods. In the literature, transplantation of parathyroid glands included in total laryngeal transplantation have been reported (16). Currently, studies involving iso-, allo-, and xenotransplantation of parathyroid tissue in human and animals indicate promising results that go far beyond the preoperative autotransplantation techniques (17, 18). The use of cultured human parathyroid cells is an essential technique for allo- and xenotransplantation because it provides better engraftment of parathyroid cells by means of better revascularization and a decrease in the expression of the major histocompatibility complex on parathyroid cells (2, 19, 20). To overcome organ rejection in parathyroid allotransplantation, a number of methods have been proposed, such as short-term immunosuppression and immune-alteration by depletion of passenger leukocytes or preoperative organ culture but unfortunately, those approaches resulted in prolonged but insufficient graft function (21-23).

At present, tissues derived from patients with hyperplastic parathyroid glands are frequently used because of their numerous cells. Parathyroid hyperplasia is a clinical condition that is often coexistent with chronic renal failure (24-26). However, because the incidences of Hepatitis C and Hepatitis B viral infections in this patient population are high which prevent researchers from performing transplantations, even this limited number of patients cannot be used effectively as donors (27-30).

In the literature, it is shown that the average lifetime of these tissues derived from this donor population is no longer than 6 months, and this interval may be further prolonged in tissues derived from parathyroid adenoma (29). In this study, we transplanted adenomatous parathyroid cells from one human patient into rabbits and evaluated functional and histopathologic features. In each rabbit, increases in PTH levels were found to be statistically significant. Ca levels were also found to be increased and P were decreased, but the increase was not found to be statistically significant. These promising results show that, similar to the results of studies with hyperplastic tissues, adenomatous transplants do not result in an uncontrolled increase in either PTH or Ca levels. In addition, morphologic differences were not detected at the end of the study.

Although there are well-known published studies concerning transplantation of healthy parathyroid tissue to humans, there has not yet been a study about transplantation of adenomatous cells because of the malignant potential of parathyroid adenomas. In our experimental study, we evaluated the development and potential malignant transformation of adenomatous human parathyroid tissue transplanted into rabbits, with a successful combination of tissue culture passage and cryopreservation with immunosuppression.
Limitations of the study
Although our results were favorable, the effects were short-term. There are two reasons for this limitation. First, long-term immunosuppression in rabbits can lead to rapid metabolic disorders, which results in early deaths. Second, the cells that were transplanted in the muscle tissue could migrate from their initial localization, which may make histopathologic assessment impossible for us.

CONCLUSION
Our results show that adenaomatous parathyroid cells function in the short-term without any morphologic transformation, which can support the consideration of a safe and alternative allotransplantation method of human adenomatous parathyroid tissue and may function as a preliminary work in this field of study.

Ethics Committee Approval: Ethics committee approval was received for this study from Bezmiâlem Vakif University Animal Experiments Local Ethics Committee (Number 2013/99).

Informed Consent: Not required in this study.

Peer-review: Externally peer-reviewed.

Conflict of Interest: No conflict of interest was declared by the authors.

Financial Disclosure: The authors declared that this study has received no financial support.
