Material and Methods: A 61-year-old male presented with changes in bowel habits. Colonoscopy revealed a circumferential mass causing luminal narrowing extending from 10 to 17 cm from the anal verge. Biopsy confirmed adenocarcinoma. Pelvic MRI demonstrated a rectosigmoid junction tumor located in the upper rectum, with limited perirectal extension. Ten locoregional lymph nodes were identified, the largest measuring 8 mm. Presacral fascial planes were preserved. Following six cycles of neoadjuvant FOLFIRINOX, imaging revealed a complete metabolic response in the perirectal lymph nodes and a partial response in the rectosigmoid tumor. Robotic low anterior resection was planned.

Results: Surgery was initiated with incision at the sacral promontory. Rectal mobilization was performed along the embryological "holy plane" using sharp dissection. Both right and left hypogastric nerves were identified and preserved during medial-to-lateral dissection. Intermesenteric anastomosis was detected and clipped. The inferior mesenteric artery was clipped approximately 1 cm distal to its origin from the aorta, with preservation of the inferior mesenteric plexus. The inferior mesenteric vein was divided below the pancreas, and dissection proceeded along the superior border of the pancreas to enter the lesser sac. Complete mobilization of the splenic flexure was achieved. Anterior pelvic dissection was initiated by incising the anterior peritoneal reflection. After completion of the anterior dissection, the posterior plane was entered and posterior pelvic dissection was completed. Following complete mobilization, rectal transection was performed using a robotic stapler. An end-to-end colorectal anastomosis was completed using a circular stapler. Anastomotic integrity was confirmed with an air leak test.

Conclusion: This video highlights that a fully robotic low anterior resection enables controlled and precise dissection in the narrow pelvic cavity, improves surgical ergonomics, and provides a safe approach to upper rectal cancer surgery after neoadjuvant chemotherapy.

Robotic resection of recurrent colorectal cancer metastasis to the seminal vesicle

Sıtkı Uğurkan Öztürk, Bülent Önal, Server Sezgin Uludağ

İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul

Objective: Robotic surgery is one of the most advanced surgical techniques in which modern medicine meets technology. The robotic system precisely replicates the surgeon's hand movements, eliminates tremor, and provides superior maneuverability in confined spaces. In this video presentation, we will demonstrate the robotic resection performed due to luxation of the seminal vesicle in a 38-year-old male patient who had previously undergone surgery for colon cancer.

Material and Methods: Robotic surgery was chosen as the surgical approach, and the recorded operative video was subsequently processed using professional editing software and prepared for presentation.

Results: Following the surgery, negative surgical margins were achieved, and no mortality or morbidity was observed. The patient remains under postoperative follow-up.

Conclusion: Compared to conventional open surgery and laparoscopic (minimally invasive) surgery, robotic surgery offers several advantages, including three-dimensional high-definition visualization, an enhanced field of view, and improved instrument dexterity. As a result, operations can be performed through smaller incisions, blood loss may be reduced, and patients generally experience a more comfortable and faster recovery process. Performing the procedure using the robotic approach provided a significant advantage to the surgeon in the pelvis, a technically challenging anatomical region, and enabled the achievement of negative surgical margins.

Robotic surgery in left colon cancer: The evolution of the minimally invasive era

İbrahim Kılınç, Tolga Dinç

Department of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Advances in minimally invasive surgery have increasingly promoted the use of robotic systems in colon cancer surgery. Robotic surgery offers technological advantages such as three-dimensional high-definition imaging, tremor filtration, and wristed instruments, which are designed to overcome the technical limitations of laparoscopy. These features allow for more precise dissection and better adherence to oncological surgical principles in left colon cancer surgery.

Material and Methods: Left colon anatomy involves technically challenging steps such as mobilization of the splenic flexure and dissection of the inferior mesenteric vessels. Robotic systems enhance maneuverability in deep and narrow anatomical spaces, facilitating dissection along proper mesocolic planes. This contributes particularly to safer high vascular ligation and lymph node dissection.

Results: In the current literature, oncological outcomes of robotic left colon resections have been compared with those of open and laparoscopic surgery. No significant differences have been reported between laparoscopic and robotic surgery in terms of adequacy of resection margins or the number of lymph nodes retrieved. Despite these advantages, longer operative times and higher costs remain the main limitations associated with this approach.

Conclusion: Robotic surgery stands out as a safe and effective minimally invasive option in the treatment of left colon cancer. In this context, the aim of this video, which presents a patient operated on with a robotic approach for left colon cancer, is to demonstrate the anatomical structures and anatomical dissections involved in left colon surgery.

Keywords: Robotic surgery, colon cancer, colectomy, lymph node dissection

Robotic low anterior resection and pelvic nerve preservation

Halil Kirazkaya, Mahmut Said Değerli, Nurettin Şahin, Turgut Dönmez, Ahmet Sürek

Department of General Surgery, University of Health Sciences Türkiye, Bakırköy Dr. Sadi Konuk Training and Research Hospital, İstanbul

Objective: Total mesocolic excision is considered the gold standard in rectal cancer. Preserving the hypogastric nerves and pelvic plexuses within the narrow pelvic anatomy improves postoperative functional outcomes. This video presentation describes a case in which pelvic nerves were identified using the Da Vinci Xi robotic surgical system.

Material and Methods: A 76-year-old male patient diagnosed with upper rectal adenocarcinoma and who had completed neonatal and juvenile treatment was scheduled for robotic low anterior resection. A medial-to-lateral approach was preferred during the operation. As the mesorectal dissection progressed, the bilateral hypogastric nerves and plexuses were visualized and preserved in the pelvic lateral walls.

Results: The operation was successfully completed using nerve-sparing principles. The articulation capability of the robotic arms also helped preserve the integrity of the neurovascular structures. The operation lasted 200 minutes. The patient was discharged on the 5th day after the operation. No urinary dysfunction was observed during the patient's stay in the ward.

Conclusion: Robotic surgery has high potential for identifying and preserving important functional structures due to its articulation ability in the narrow pelvic space. Clear visualization and precise dissection of pelvic autonomic nerves also minimize postoperative functional morbidity.

Keywords: Nerve-sparing surgery, rectum cancer, robotic surgery

Postoperative functional outcomes of transanal transection and single-stapled anastomosis technique after low anterior resection in rectal cancer

Yavuz Gürhan Mert, Anıl Özen, Volkan Doğru, Muhittin Yaprak

Akdeniz University Faculty of Medicine Hospital, Antalya

Objective: Anal stenosis (stricture) and functional disorders (incontinence, obstructive defecation) observed after low anterior resection (LAR), one of the sphincter-preserving methods in rectal cancer surgery, are significant factors affecting patients' quality of life. The aim of this study is to evaluate early postoperative anal stenosis and functional outcomes in five patients who underwent LAR using the transanal transection and single-stapled (TTSS) anastomosis technique for rectal cancer at our clinic.

Material and Methods: In this study, the data of five patients who underwent the LAR + TTSS procedure with a diagnosis of rectal cancer were retrospectively reviewed. Patients were evaluated in terms of postoperative anal stricture severity (none, mild, moderate, severe), obstructive defecation score (Altomare-ODS), St. Mark's (Vaizey) incontinence score, and LAR syndrome (LARS) score. Patients with a functioning protective ileostomy were excluded from functional scoring and were analyzed only for the presence of stricture.

Results: In the postoperative evaluation of the five patients included in the study; anal stricture: no anal stricture "none" was detected in 80% (n=4) of the patients, while "moderate" stricture was observed in 20% (n=1). Ileostomy status: protective ileostomies were present in two patients (40%), whereas three patients (60%) were without a stoma. Functional outcomes (n=3): In the functional assessment of the three patients without a stoma; obstructive defecation: a "low score" (<10) was identified in two patients, and a "moderate score" (10-15) was found in one patient (mean score: 9.3). Incontinence: St. Mark's (Vaizey) scores were recorded as 12, 8, and 13, respectively. LARS distribution: minor LARS was detected in one patient, and "major LARS" was identified in two patients.

Conclusion: Based on the preliminary results of our limited case series, it was observed that postoperative anal stricture rates in patients undergoing the TTSS technique were within acceptable levels. Regarding functional outcomes, obstructive defecation symptoms in patients without a stoma were found to be at mild-to-moderate levels; however, monitoring of incontinence scores and LARS remains of clinical significance. Larger patient cohorts and long-term follow-up are necessary to further clarify the functional outcomes of this technique.

Keywords: Rectal cancer, TTSS

Recurrent rectal prolapse, rectocele, and cystocele: Laparoscopic mesh rectopexy with sigmoid colectomy

Fahri Yetişir[1], Mete Yarkın Yetişir[2]

[1]*Clinic of General Surgery, Acıbadem Bayındır Söğütözü Hospital, Ankara*

[2]*Başkent University Faculty of Medicine, Ankara*

Objective: In this case presentation, we aimed to evaluate the role of the anatomic characteristics of the sigmoid colon in the treatment of our patient with recurrent rectal prolapse and rectocele causing obstructed defecation, and to assess the contribution of sigmoid colon resection to surgical success in recurrent prolapse cases.

Material and Methods: A 43-year-old female patient presented with the main complaints of difficulty in defecation, the need for manual assistance during defecation, and a protrusion from the bowel approximately the size of an orange during defecation. She also reported frequent urination and urinary incontinence. She stated that her symptoms started after a traffic accident. Investigations performed due to these complaints led to the diagnoses of rectal prolapse, rectocele, and cystocele. With these diagnoses, approximately one year earlier, the patient had undergone a laparoscopic anterior mesh rectopexy. However, from the third postoperative month onward, her symptoms increased again and she was re-evaluated. Clinical assessment and imaging studies revealed recurrent rectal prolapse and an advanced rectocele. Based on these findings, surgical intervention was planned for the recurrent prolapse.

Results: During the operation, the sigmoid colon was found to be redundant and folded onto itself in a "W-shaped" configuration. Considering that this condition may have contributed to the recurrence of prolapse, rectopexy was performed together with sigmoid colon resection. During the surgical procedure, the bowel was positioned appropriately in its anatomical location, and to prevent recurrence of the prolapse, the rectum was fixed to the sacral promontory using mesh material. In the postoperative period, the patient remained clinically stable, and a marked decrease in her previous complaints was noted. At the sixth-month postoperative follow-up, her symptoms had significantly improved; no rectal prolapse was observed, and normal defecation function was documented.

Conclusion: This case highlights the importance of the structural characteristics of the sigmoid colon in recurrent rectal prolapse. Rectopexy combined with sigmoid colon resection may be an effective approach in the treatment of prolapse. However, in such complex cases, appropriate patient selection and correct application of surgical techniques are critical to increasing success rates.

Keywords: Rectal prolapse, rectopexy

[V-069]

Inguinal hernia repair with single-port total extraperitoneal (STEP) approach: Our experience

Yaşar Özdenkaya, Sıla Duru, Tunahan Yıldırım, Dilara Alp

Department of General Surgery, İstanbul Medipol University Faculty of Medicine, İstanbul

Objective: Laparoscopic total extraperitoneal (TEP) approach is a widely used minimally invasive method in inguinal hernia surgery. In recent years, with the development of single-incision laparoscopic surgical techniques, single-port total extraperitoneal (STEP) applications have come to the forefront; however, this technique is applied in a limited number of centers, and there are a limited number of reports in the literature, particularly from our country. This video presentation aims to present the surgical stages and technical details of inguinal hernia repair performed using the STEP technique.

Material and Methods: A 46-year-old male patient diagnosed with unilateral (right) indirect inguinal hernia was prepared under general anesthesia in the supine, 30-degree, Trendelenburg position. Following injection of a local anesthetic (bupivacaine) at the incision site, a 2.5 cm infraumbilical incision was made to access the anterior fascia of the rectus muscle. A 2 cm incision was then made to cut the anterior fascia. The rectus muscle was then pulled laterally. A single-port GelPOINT® mini advanced access platform (applied medical, USA) was inserted, and a partial extraperitoneal space was created through blunt dissection via the port. Three trocars were used through the single-port. CO_2 was insufflated into the created space at a pressure of 12 mmHg. Sufficient extraperitoneal space was obtained through blunt dissection. Dissection was performed according to standard TEP surgery principles. A 16*12 cm, right anatomical, 3D, propylene mesh was placed in the preperitoneal space. The implanted mesh was securely fixed to the preperitoneal space at three points using an absorbable fixation system.

Results: The operation was completed without complications. There was no need for intraoperative conversion or additional ports. The operation time was recorded as 35 minutes. No early postoperative complications were observed. The patient was mobilized early and discharged without problems on the first postoperative day. A single-incision was observed to offer advantages in terms of both cosmetic results and postoperative pain.

Conclusion: The STEP approach is a safe and feasible alternative method in selected patients undergoing inguinal hernia surgery. Using a single-incision can reduce potential complications associated with additional ports and offer cosmetic advantages. Sharing the surgical stages of the technique via video presentation is expected to contribute to the learning process of this method.

Incarcerated Amyand's hernia: Preoperative diagnosis and surgical approach

Emine Sena Cünük[1], Elif Tutar[1], Zennure Şahin[1], Mehmet Demir[1], Enis Dikicier[2]

[1]*Sakarya Training and Research Hospital, Sakarya*

[2]*Sakarya University Faculty of Medicine, Sakarya*

Objective: Amyand's hernia is a rare condition defined as the presence of the vermiform appendix within the inguinal hernia sac. Although generally diagnosed intraoperatively, preoperative diagnosis is currently possible with advanced imaging modalities. The aim of this video presentation is to present a case who applied with a painful swelling in the right groin, was diagnosed preoperatively by computed tomography (CT), and was treated via a laparoscopic approach.

Material and Methods: The diagnostic, treatment, and surgical processes of a 69-year-old male patient who presented to our clinic with a complaint of painful swelling in the right groin were recorded. The patient's demographic data, physical examination findings, laboratory parameters, and radiological images were evaluated, and the surgical procedure was prepared in a video presentation format.

Results: A 69-year-old male patient presented with a 4-day history of painful swelling in the right groin. Physical examination of the patient, who had a history of left inguinal hernia repair, revealed a non-reducible incarcerated inguinal hernia on the right side. Laboratory results showed a WBC of 6.18 10^3/µL (normal) and a CRP of 65 mg/L (high). Due to the discrepancy between clinical and laboratory findings, an abdominal CT was performed, which revealed the vermiform appendix within the hernia sac in the right inguinal canal (Amyand's hernia). During laparoscopic exploration, the presence of the appendix and mesoappendix in the right inguinal canal was confirmed, and they were reduced into the abdominal cavity. The mesoappendix was dissected, and an appendectomy was performed by applying a homolock clip to the base. The surgical site was irrigated, and a JP drain was placed. Due to the risk of infection, no repair was performed on the inguinal ring (hernia defect), and the procedure was terminated. The patient had an uneventful postoperative course and was discharged on the first postoperative day.

Conclusion: Although Amyand's hernia is rare, it should be considered in the differential diagnosis of incarcerated hernias. In inflammatory cases presenting with high CRP levels, as in this case, the laparoscopic approach is a safe option as it allows for both the exploration of the entire abdomen and the atraumatic reduction of the appendix from the hernia sac.

Spleen-preserving laparoscopic distal pancreatectomy and simultaneous endoscopy-assisted laparoscopic gastric wedge resection: Minimally invasive surgery for synchronous gastric and pancreatic neuroendocrine tumors

Mehmet Zafer Sabuncuoğlu[1], İsa Sözen[2], İsa Karaca[2], Mehmet Siraç Koşan[2], Batuhan Burak Ersoy[2], Serdar Acar[2], Kübra Olgunçelik[1]

[1]*Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya*

[2]*Department of General Surgery, Süleyman Demirel University Faculty of Medicine, Isparta*

Objective: The presence of synchronous lesions in gastroenteropancreatic neuroendocrine tumors (GEP-NETs) is rare but carries significant importance for surgical planning. In this video report, we aimed to present the technique of spleen-preserving laparoscopic distal pancreatectomy combined with simultaneous gastric wedge resection in a case with synchronous NETs located in the stomach and pancreatic tail.

Material and Methods: A 58-year-old female patient with a history of hypothyroidism and diabetes mellitus presented to our clinic. Following an upper respiratory tract infection, she experienced a sensation of obstruction in the throat. Endoscopic examination revealed a gastric mass, prompting further evaluation. Dynamic pancreatic computed tomography (CT), endoscopic ultrasonography, Ga-68 DOTATE PET-CT, and endoscopic biopsy were performed. After a multidisciplinary evaluation, the patient was scheduled for a spleen-preserving laparoscopic distal pancreatectomy combined with simultaneous gastric wedge resection.

Results: The procedure was successfully completed entirely via a laparoscopic approach, with preservation of the spleen. No major intraoperative complications were encountered. Postoperatively, the patient remained hemodynamically stable, and early oral intake and ambulation were initiated without incident.

Conclusion: Spleen-preserving laparoscopic distal pancreatectomy represents a safe and effective minimally invasive approach for small pancreatic tail NETs, offering the added benefit of preserving immune function. In the presence of a synchronous gastric neuroendocrine tumor, combined laparoscopic resection constitutes a feasible surgical option. This video presentation demonstrates the key steps of the surgical technique along with practical procedural details.

Robotic intersphincteric low anterior resection and coloanal anastomosis technique

Yiğit Ata Öztürk, Emin Amiraslanov, Ertuğrul Filiz, Süleyman Utku Çelik, Cihangir Akyol, Mehmet Ali Koç

Department of General Surgery, Ankara University Faculty of Medicine Hospital, Ankara

Objective: Sphincter-preserving surgical techniques in distal rectal cancer are essential for maintaining quality of life without compromising oncological safety. Intersphincteric resection represents an alternative to abdominoperineal resection in very low rectal tumors. Robotic surgery facilitates these complex procedures by providing enhanced visualization and superior maneuverability within the confined pelvic space. In this study, we aimed to present the technique of robotic intersphincteric low anterior resection with coloanal anastomosis performed in a patient with distal rectal cancer.

Material and Methods: A patient with a T2N0 distal rectal tumor located 1 cm proximal to the dentate line, showing near-complete regression after neoadjuvant chemoradiotherapy, underwent robotic intersphincteric low anterior resection with diverting ileostomy. Following standard robotic surgical principles, ligation of the inferior mesenteric vessels, splenic flexure mobilization, total mesorectal excision, and intersphincteric dissection were performed. The rectum was transected transanally at the level of the dentate line, followed by hand-sewn coloanal anastomosis. A diverting ileostomy was created in the right upper quadrant.

Results: The operation was completed without intraoperative complications. Final pathological examination revealed T2N0M0 disease with negative surgical margins.

Conclusion: Robotic intersphincteric low anterior resection with coloanal anastomosis is a safe and feasible sphincter-preserving option in selected patients with distal rectal cancer. The technical advantages of robotic surgery contribute significantly to precise dissection in the narrow pelvis while maintaining oncological principles.

Keywords: Intersphincteric resection, rectal cancer, robotic surgery

An incisionless approach in robotic colorectal surgery: Transanal specimen extraction

Mertcan Kayıkçı, Yiğit Ata Öztürk, Can Yahya Boztuğ, Cihangir Akyol

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: This video presentation aims to demonstrate the management of an intraoperative rectal injury that occurred during robotic low anterior resection in a patient with mid-to-low rectal cancer, while preserving minimally invasive surgical principles.

Material and Methods: A patient diagnosed with rectal adenocarcinoma located just above the Houston valve and staged as cT2N0M0 was discussed in a multidisciplinary tumor board and scheduled for surgical treatment. Robotic low anterior resection was performed in the Lloyd-Davies position following the principles of total mesorectal excision. During distal dissection at the level of the levator muscles, an iatrogenic rectal injury occurred. As distal transection with a stapler was considered unsafe, an alternative approach was adopted. The rectum was transected distal to the tumor, and the proximal rectal stump was closed. The specimen was extracted transanally, and an anvil was secured extracorporeally. An end-to-end colorectal anastomosis was then created using a circular stapler.

Results: The integrity of the anastomosis was confirmed using air and fluid leak tests. The procedure was completed with a protective loop ileostomy. No additional abdominal incision was required. The postoperative course was uneventful. Final pathology revealed T2N0M0 disease, and the patient was followed without adjuvant therapy. The loop ileostomy was closed at the third postoperative month.

Conclusion: Intraoperative complications during robotic rectal surgery can be safely managed with appropriate surgical strategies while maintaining minimally invasive principles. Transanal specimen extraction and circular stapled anastomosis represent an effective alternative approach in selected cases without the need for additional abdominal incisions.

Keywords: Robotic rectal surgery, anastomotic technique, transanal specimen extraction

Video-based education with surgical-specimen correlation: Step-by-step laparoscopic splenectomy

Mert Ercan[1], Barış Eker[1], Murat Güner[2], Erdinç Kamer[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir*

Objective: Laparoscopic surgery, by providing magnified images and a high-resolution visual field, enables clearer visualization of surgical anatomy and allows step-by-step observation of surgical procedures. With these features, laparoscopic approaches offer a more instructive environment for surgical education compared to open surgery. Laparoscopic splenectomy, however, is among the procedures with a long learning curve due to anatomical variations and the complex structure of the splenic ligaments. Accurate identification of intraoperative anatomical structures and the development of three-dimensional perception are of great importance in surgical education. Real-time specimen correlation stands out as an innovative educational method that can support this process by enabling simultaneous comparison of live surgical images with resected tissues.

Material and Methods: In this educational study, a structured training material was created based on a case in which step-by-step laparoscopic splenectomy was performed using standard port placement in the right lateral decubitus position. A total of 38 surgical residents were included and divided into two groups according to their duration of residency: ≤2 years (n=20) and >2 years (n=18). Splenic ligaments (gastrosplenic, splenorenal, splenocolic, splenophrenic, and pancreatosplenic) were identified on the surgical specimen,and a hybrid visual teaching method was employed by providing animation-assisted demonstration of the ligaments and dissection planes on specimen photographs synchronized with the operative video footage (Figure 1). The anatomical recognition levels of the surgical residents regarding the splenic ligaments were analyzed using a structured, 0-10 point evaluation form administered before and after the training. Total performance scores were calculated as percentages. Pre-training and post-training comparisons were performed using paired t-tests, while intergroup comparisons were conducted using independent t-tests.

Results: Before the training, the total anatomical recognition success was 52.0±10.8% in the ≤2-year group and 64.2±9.1% in the >2-year group (Table 2), with a significant difference between the groups ($p<0.001$). After the training, the total success rate increased to 82.0±9.6% among all participants (Table 3), and the intergroup difference was no longer observed ($p=0.219$). When pre-training and post-training change scores were evaluated, the increase in total success was more pronounced in the ≤2-year group compared to the >2-year group (29.0±11.2% vs. 18.8±8.9%; $p=0.003$). The most prominent improvements were observed in the identification of the gastrosplenic, splenorenal, and splenophrenic ligaments (Table 4). In the evaluation of the training method, three-dimensional anatomical perception and understanding of surgical dissection planes were rated significantly higher (Table 5) in the ≤2-year group ($p=0.006$, and $p=0.041$, respectively).

Conclusion: Video-based laparoscopic splenectomy training supported by real-time surgical-specimen correlation significantly improves the anatomical recognition of splenic ligaments. This method appears to be particularly effective in enhancing anatomical perception and shortening the learning curve in surgical residents with ≤2 years of experience. Integrating video-specimen correlation-based training approaches into the education of surgical residents for other laparoscopic procedures may further enhance the effectiveness of surgical training.

Pilot application of EPSiT in the office setting

Ahmet Ali Aktaş, Abdullah Boğa, Özgen Işık

Department of General Surgery, Acıbadem Mehmet Ali Aydınlar University Atakent Hospital, İstanbul

Objective: Endoscopic pilonidal sinus treatment (EPSiT) was introduced approximately a decade ago and has rapidly gained acceptance in clinical practice. Traditionally, the procedure is performed using the Meinero fistuloscope, an 8-degree angled instrument measuring 3.2×4.8 mm in diameter and 18 cm in length, connected to a videoendoscopy unit. The fundamental rationale of EPSiT is the identification of the sinus anatomy under direct visualization, complete removal of hair and debris, and effective ablation. Beyond the advantages of direct vision, the ability to perform the procedure under local anesthesia, avoidance of a large surgical incision, same-day discharge, low risk of major complications, and recurrence rates comparable to other techniques have contributed to its clinical value. The concept of this study arose from the hypothesis that a fiber operoscope, originally designed for office-based procedures such as hysteroscopy or cystoscopy, could be applied to EPSiT with the same rationale while offering additional practical benefits.

Material and Methods: The fiber operoscope used is a self-contained device powered by a disposable battery, equipped with an integrated LCD screen and handle. It has a 4.2 mm diameter, a working length of 310 mm, and a central 5.5 Fr working channel. A miniature camera and cold light source are located at its tip, and two separate ports allow infusion and drainage. Unlike the classical fistuloscope, it functions independently without requiring an external unit, while images can be simultaneously transmitted to a standard monitor or recorded.

Results: The procedure begins with the patient in the prone position, the buttocks separated by adhesive bands, followed by local anesthesia. The external openings of the pilonidal sinus are enlarged using a 4 mm punch biopsy blade, and the diagnostic phase proceeds as in classical EPSiT. Isotonic saline (0.9% NaCl) is infused through the scope to explore the sinus cavity, secondary tracts, and any abscesses. In the operative phase, hair and debris are removed with forceps introduced through the working channel. Additional sinus openings are similarly explored, irrigated, and cleaned. Tracts are curetted with a brush and ablated using a ball-tip cautery. Final inspection ensures complete clearance and adequate ablation before termination of the procedure.

Conclusion: This pilot application suggests potential advantages over conventional EPSiT. The absence of operating room requirements, ease of use, and high-resolution imaging support the feasibility of EPSiT as an office-based procedure. Furthermore, integration with classical microsinusectomy may enhance tract clearance and improve overall efficacy. Further studies are warranted to evaluate these potential benefits.

Keywords: Pilonidal disease, EPSiT, office procedures

Surgical repair of Grade 3c and 4 obstetric anal sphincter injuries

Ahmet Anıl Sahar[1], Abdullah Boğa[2], Ahmet Ali Aktaş[2], Özgen Işık[1]

[1]*Department of General Surgery, Acıbadem Mehmet Ali Aydınlar University Faculty of Medicine, İstanbul*

[2]*Department of General Surgery, Acıbadem Mehmet Ali Aydınlar University Atakent Hospital, İstanbul*

Objective: Obstetric anal sphincter injuries (OASIS) are a frightening complication of vaginal delivery. According to the Sultan classification, Grade 3c and 4 injuries involve sphincter involvement. When early intervention and appropriate anatomical repair are not performed, these injuries are associated with long-term anal incontinence. The purpose of this video presentation is to demonstrate the systematic and layered anatomical repair technique used in grade 3c and grade 4 OASIS through two case studies.

Material and Methods: In two patients consulted after vaginal delivery, clinical and digital rectal examinations revealed grade 3c injury involving the sphincter complex in one case and grade 4 injury involving the sphincter complex along with the rectal mucosa in the other case. The patients were taken to the operating room under emergency conditions and underwent surgery.

Results: Patients were placed in the lithotomy position to allow perineal exploration. In the patient with a grade 4 injury, the rectal mucosa and wall were identified, followed by identification of the external and internal anal sphincter muscle fibers. Dissection and exposure of the sphincter ends, repair with overlapping sphincteroplasty, perineal body reconstruction, and repair of the perineal muscles and vagina were performed. After checking with a rectal touch and air test, the subcutaneous tissue and skin were closed according to the appropriate plan, and the repair was completed. In the stage 3c patient, the steps mentioned above were performed exactly as described, except for rectal repair. No postoperative complications developed, and the patients were discharged on the second day. No continence problems were observed in the patients followed up at 3 months.

Conclusion: In grade 3c and 4 OASIS, layered repair performed early on, under operating room conditions and in accordance with anatomical principles, is the fundamental approach for preserving anal continence. The video presented offers an applicable and instructive surgical approach for these rare but severe OASIS cases.

Ex situ liver with inferior vena cava resection and autotransplantation for hepatic alveolar echinococcosis infiltrating the vena cava

Fatih Feratoğlu[1], Emre Aray[1], Ali Hajali[2], Selma Başyiğit[4], Kaan Karayalçın[3], Deniz Balcı[1]

[1]*Department of Hepatopancreatobiliary and Liver Transplantation Surgery, Bahçeşehir University Medicalpark Göztepe Hospital, İstanbul*

[2]*Department of General Surgery, Marmara University Faculty of Medicine, İstanbul*

[3]*Department of Hepatopancreatobiliary Surgery, Ankara University Faculty of Medicine, Ankara*

[4]*Department of Anesthesiology and Reanimation, Bahçeşehir University Medical Park Göztepe Hospital, İstanbul*

Objective: Alveolar echinococcosis is a rare, parasitic disease that behaves locally similar to a malignant tumor. Due to its infiltrative nature, it may invade major vascular and biliary structures, resulting in technically challenging or conventionally unresectable disease. In advanced cases, advanced hepatobiliary and liver transplantation techniques may be required for cases involving hilar vascular and biliary structures, inferior vena cava (IVC), hepatic vein confluence. In these scenarios *ex situ* liver resection and autotransplantation provide an alternative for achieving curative resection in selected patients.

Material and Methods: Here we present a case to demonstrate the feasibility and surgical strategy of *ex situ* liver resection and autotransplantation in an otherwise unresectable case of advanced hepatic alveolar echinococcosis. Alveolar echinococcosis infiltrating the vena cava, hepatic vein confluence.

Results: A 63-year-old male with chronic hepatitis B presented with abdominal pain aggravated by the Valsalva maneuver. Imaging revealed a cystic-calcific infiltrative lesion involving segments IV, VII, and VIII of the liver, causing obliteration of the right and middle hepatic veins and significant narrowing of the retrohepatic IVC and left hepatic vein, resulting in atrophy in the right lobe and hypertrophy and congestion in the left lobe of the liver. The adjacent diaphragm was also invaded. Total hepatectomy, retrohepatic IVC resection, and partial diaphragmatic resection were performed. A dacron interposition graft was used for vena cava reconstruction, followed by portocaval shunt reconstruction. After backtable resection, quilt venoplasty was performed using autologous vein patch for intraparenchymal left hepatic vein. Liver graft was implanted on IVC interposition graft. Portal vein, hepatic artery, and duct-to-duct bile anastomosis was made. The diaphragm was reconstructed using a prosthetic mesh. The postoperative course was uneventful, and the patient was discharged on postoperative day seven.

Conclusion: *Ex situ* liver resection and autotransplantation is a safe and feasible surgical option that can provide curative treatment in selected patients with advanced alveolar echinococcosis deemed conventionally unresectable, when performed in experienced centers.

Keywords: Alveolar echinococcosis, autotransplantation, *ex situ* liver resection

A foreign body migrating to the hepatoduodenal area following silent duodenal perforation mimicking malignancy: A laparoscopic approach

Mert Şahin Öztürk, Halil Aydoğmuş, Mehmet Zafer Sabuncuoğlu

Akdeniz University Faculty of Medicine Hospital, Antalya

Objective: Most gastrointestinal foreign bodies pass spontaneously without causing complications. However, long, thin, and sharp objects such as toothpicks carry a high risk of perforation and may rarely lead to serious intra-abdominal complications. Due to its retroperitoneal location and close anatomical relationship with adjacent organs, duodenal perforations may occur without free intraperitoneal contamination, resulting in silent clinical courses accompanied by localized inflammation and migration. In such cases, pseudotumoral masses mimicking malignancy may develop and lead to misleading findings on advanced imaging modalities. In this study, we present a rare case of a foreign body migrating to the hepatoduodenal area following silent duodenal perforation and discuss the diagnostic and therapeutic role of laparoscopic surgery.

Material and Methods: A 67-year-old female patient with a history of intermittent right upper quadrant pain for several years was evaluated. Ultrasonography, magnetic resonance imaging, and PET-CT revealed a hypermetabolic mass lesion adjacent to the inferomedial segment of the left hepatic lobe and the duodenum, raising suspicion of malignancy. Due to increased FDG uptake on PET-CT, cholangiocarcinoma was considered among the primary differential diagnoses. After interventional radiology suggested the possibility of a foreign body, laparoscopic surgical exploration was planned for diagnostic and therapeutic purposes.

Results: Laparoscopic exploration revealed dense inflammatory adhesions between the duodenum and the liver. Careful sharp and blunt dissection exposed a foreign body migrating from the duodenum into the hepatoduodenal area. The foreign body was identified as a toothpick and was completely removed. A leak test using patent blue dye revealed no evidence of duodenal leakage. The procedure was completed without complications, and the patient had an uneventful postoperative course.

Conclusion: Duodenal foreign bodies may rarely cause silent perforation and migration, leading to pseudotumoral lesions that mimic malignancy on imaging studies. Foreign body migration should be considered in the differential diagnosis of unexplained hepatoduodenal masses with malignant features. Consistent with the literature, laparoscopic surgery provides a safe and effective minimally invasive approach, offering both accurate diagnosis and definitive treatment in such cases.

Keywords: Foreign body, duodenum, laparoscopy

Median arcuate ligament syndrome (MALS): A case report and literature review using a laparoscopic decompression approach

Erkan Karacan, Halim Kale, Ömer Faik Ersoy

Karabük Training and Research Hospital, Karabük

Objective: Median arcuate ligament syndrome (MALS) is a rare vascular syndrome resulting from extrinsic compression of the celiac artery by the median arcuate ligament at the diaphragmatic hiatus. Typical clinical findings include postprandial epigastric pain, weight loss, nausea, and gastrointestinal complaints. Diagnosis is usually based on imaging methods such as CTA (CT angiography) and duplex ultrasonography, and diagnosis is often delayed. This video report aims to present the surgical steps of the laparoscopic median arcuate ligament decompression technique performed in a patient diagnosed with MALS and to review the current literature.

Material and Methods: In the presented case, the patient, who was followed up with prolonged postprandial pain and weight loss, was diagnosed with MALS after detailed radiological evaluation. Using a laparoscopic approach, the gastrohepatic ligament was opened to expose the celiac trunk; the median arcuate ligament and perivascular nerve fibers were dissected, completely eliminating the extrinsic compression on the celiac artery.

Results: No complications developed during laparoscopic decompression, and the patient showed rapid postoperative recovery. In the postoperative period, the patient's complaints significantly decreased, and a control CT angiogram revealed a marked reduction in the external compression on the celiac artery. The patient was discharged without complications.

Conclusion: The clinical and radiological improvement findings are consistent with the results of laparoscopic MALS surgery reported in the literature. Current studies show that the laparoscopic approach provides low morbidity, rapid recovery, and high symptom control rates. This case supports that laparoscopic median arcuate ligament decompression is a safe and effective treatment option with appropriate patient selection.

Keywords: Median arcuate ligament syndrome, laparoscopic decompression, celiac artery compression

Transanal transection single-stapled (TTSS) anastomosis in rectal cancer: Video presentation and evidence-based evaluation of the laparoscopic approach

Erkan Karacan, Hüseyin Güven, Ömer Faik Ersoy

Karabük Training and Reserch Hospital, Karabük

Objective: Ensuring a safe distal margin and reducing the risk of anastomotic leakage are key determinants of surgical success in distal rectal cancer. The aim of this video report is to present the laparoscopic transanal transection single-stapled (TTSS) anastomosis technique performed in a patient with rectal cancer located 2 cm proximal to the anal canal who underwent surgery after total neoadjuvant therapy (TNT), and to evaluate the advantages of this method over conventional very low anterior resection and manually performed coloanal anastomoses in light of the literature.

Material and Methods: Laparoscopic total mesorectal excision was performed in a patient with a tumor lesion 2 cm proximal to the anal canal who had completed the TNT protocol. The distal rectum was transected in a controlled manner via the transanal route, and a TTSS anastomosis was created using a single stapler line. Anastomotic integrity was assessed intraoperatively, and the surgical steps were presented on video.

Results: The surgical procedure was completed without complications. Creating an anastomosis using a single stapler line with the TTSS technique eliminated the risk of ischemic areas and leaks associated with multiple stapler lines seen in classic ultra-low anterior resection. No intraoperative leaks were observed in the anastomosis line. Compared to manually performed coloanal anastomoses, the TTSS technique provided advantages in terms of shorter operation time, less pelvic dissection, a more homogeneous anastomosis line, and preservation of sphincter function. The patient had an uneventful postoperative course, with no anastomotic leakage or major morbidity observed.

Conclusion: The TTSS coloanal anastomosis technique in ultra-low rectal cancer surgery is a rational approach that aims to create a more homogeneous anastomosis line by eliminating staple line intersections. The TTSS technique applied with laparoscopic TME, presented in this video poster, is considered a safe alternative in terms of technical feasibility and early clinical outcomes. Consistent with the current literature, the TTSS approach has a noteworthy potential to reduce the risk of anastomotic leakage; however, prospective and randomized studies with high-level evidence, including long-term oncological and functional outcomes, are needed to demonstrate the true superiority of this method over the standard double-stapled technique.

Endoscopic resection in gastric gastrointestinal stromal tumors-video presentation

Onur Can Yenen[1], Yiğit Doğanay Atalay[2], Efe Özkan[1], Fevzi Cengiz[1]

[1]*İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

[2]*Akçadağ Şehit Gökhan Aslan State Hospital, Malatya*

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract and may arise at various locations, most frequently in the stomach. With the widespread use of endoscopy and endoscopic ultrasonography (EUS), an increasing number of gastric GISTs are detected at an early stage, allowing complete resection. Laparoscopic surgery is considered the standard treatment for gastric GISTs smaller than 5 cm. Compared with laparoscopic surgery, endoscopic resection has been shown to provide similar surgical success and postoperative complication rates, while offering advantages such as reduced intraoperative blood loss, shorter operative time, and shorter hospital stay. Therefore, endoscopic resection has been accepted as an alternative treatment option for gastric GISTs originating from the muscularis propria.

Material and Methods: A 44-year-old female patient underwent endoscopy due to dyspeptic complaints, which revealed a lesion measuring approximately 1.5 cm located on the greater curvature at the corpus–antrum junction. Abdominal CT demonstrated an intraluminal mass of approximately 2 cm at the same location without evidence of invasion. No additional intra-abdominal pathology was detected. The patient underwent endoscopic submucosal resection. Histopathological examination was consistent with GIST, with a tumor size of 3 cm, mitotic count of 3/50 HPF, and no necrosis or atypia.

Results: GISTs are the most common mesenchymal neoplasms arising from the muscularis propria of the stomach and are malignant in approximately 10-30% of cases. According to NCCN guidelines, all GISTs larger than 2 cm should be resected. For GISTs smaller than 2 cm without high-risk features on EUS, endoscopic surveillance may be considered; however, long-term follow-up difficulties and the risks associated with repeated endoscopy limit this approach.

Conclusion: Endoscopic resection is an effective and safe treatment option for selected patients with gastric GISTs, providing comparable surgical success and complication rates, along with reduced operative time, intraoperative blood loss, and length of hospital stay.

Keywords: Endoscopic resection, gastrointestinal stromal tumor

[2]*Department of Cardiovascular Surgery, University of Health Sciences Türkiye, Bakırköy Dr. Sadi Konuk Training and Research Hospital, İstanbul*

Objective: Chronic mesenteric ischemia (CMI) is a rare and underdiagnosed clinical condition associated with postprandial pain due to progressive mesenteric artery narrowing. However, it should not be overlooked that it is more common with age. This condition, explained by inadequate perfusion of the gastrointestinal tract, most often results from atherosclerosis. We aim to share our experience with a case, of which there are very few examples in the literature, of a patient who experienced impaired blood supply and dramatic weight loss following stenosis of the celiac and superior mesenteric arteries, and who underwent surgical treatment with simultaneous bypass surgery between the aorta, celiac, and superior mesenteric arteries.

Material and Methods: A 59-year-old male patient with a medical history of coronary artery disease presented with severe pain or episodes of severe diarrhea approximately half an hour after oral intake for about two years. Abdominal CT angiography revealed occlusion of the celiac artery and superior mesenteric artery, and endovascular intervention was deemed unsuitable. Following examination and investigations, surgical treatment was planned.

Results: The patient underwent surgery under general anesthesia. Following routine abdominal exploration, access to the bursa omentalis was gained through the medial aspect of the lesser curvature, and dissection was continued to expose the hiatal region, celiac trunk, and surrounding areas. The gastrocolic ligament was opened to expose the pancreas and suprapancreatic area. After identifying the celiac artery and related structures, the superior mesenteric artery was exposed in the inframecolic space with sharp dissection. Subsequently, a retropancreatic tunnel was created with the help of dissections performed on the supra- and infrapancreatic edges, and prepared to allow the passage of an 8 mm Dacron graft. After aortotomy, end-to-end anastomosis of the aorta and graft, followed by end-to-end graft-SMA anastomosis, and finally end-to-side anastomosis of the celiac graft were performed using 6.0 prolene sutures. Following general control and hemostasis, the patient experienced no significant problems during follow-up in the ward, and oral tolerance was observed. The patient was discharged after recovering.

Conclusion: Simultaneous aorta-celiac aorta-SMA bypass surgery is quite rare in the literature. It may be preferred in patients where interventional approaches have failed or are unsuitable. It can be safely performed in patients with significant symptoms of chronic mesenteric ischemia, allowing them to return to optimal nutritional status, thus leading to positive outcomes in terms of psychology and quality of life.

Central pancreatectomy and pancreaticogastrostomy for a cystic tumor located at the pancreatic head/neck: A video-assisted surgical technique presentation

Jahad Jabıyev, Oğuzhan Özşay, Kağan Karabulut

Department of General Surgery, Ondokuz Mayıs University Faculty of Medicine, İzmir

Objective: Central pancreatectomy is a parenchyma-sparing surgical option for selected benign and low-grade malignant tumors located at the pancreatic head-neck junction. In contrast to standard pancreaticoduodenectomy, this approach preserves pancreatic endocrine and exocrine function while maintaining gastrointestinal continuity. Various reconstruction techniques have been described following resection. In this report, we present our surgical reconstruction technique using pancreaticogastrostomy after central pancreatectomy, accompanied by an operative video.

Material and Methods: A 67-year-old female presented with epigastric abdominal pain to the General Surgery clinic of Ondokuz Mayıs University Faculty of Medicine. She had no comorbidities or prior surgical history. Body mass index was 27 kg/m^2. Laboratory parameters, including serum amylase, lipase, and CA 19-9, were within normal limits. contrast-enhanced computed tomography revealed a 38 × 22 mm multiloculated cystic lesion with a solid component at the pancreatic head-neck junction. Distal to the lesion, irregularity of the main pancreatic duct and focal dilatation up to 5 mm were observed. Magnetic resonance cholangiopancreatography demonstrated no communication between the cystic lesion and the main pancreatic duct. Endoscopic ultrasonography showed normal cyst fluid glucose, carcinoembryonic antigen, and amylase levels. The patient underwent open central pancreatectomy with preservation of the duodenum. Intraoperative frozen-section analysis confirmed negative margins and absence of malignancy. The proximal pancreatic stump was closed with a stapler. Reconstruction was achieved via double-layer duct-to-mucosa pancreaticogastrostomy between the distal pancreatic remnant and the posterior gastric wall. The postoperative course was uneventful, and the patient was discharged on postoperative day five.

Results: Final histopathology confirmed serous cystic neoplasm.

Conclusion: In selected patients with benign or low-grade malignant lesions at the pancreatic head-neck junction, central pancreatectomy combined with pancreaticogastrostomy represents a safe and function-preserving alternative to more extensive resections. This technique maintains gastrointestinal continuity while preserving pancreatic parenchyma and may also be adapted to minimally invasive approaches in experienced centers.

New oncoplastic technique in tumors of the lower inner quadrant: Dogan Technique personel procedure

Yunus Emre Bölükoğlu, Lütfi Doğan, Mehmet Furkan Sağdıç

Department of Surgical Oncology, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Oncoplastic techniques defined in breast cancer treatment not only expand the indications for breast-conserving surgery but also enable improved cosmetic outcomes. Breast tumors located in the lower inner quadrant, however, pose additional challenges for oncoplastic surgery due to the scarcity of breast tissue and the frequent need for skin resection. In our study, we defined a new oncoplastic technique that prioritizes patient satisfaction for tumors in the lower inner quadrant, aiming to overcome the oncoplastic challenges associated with tumors in this location.

Material and Methods: Preoperatively the medial and inferior borders are determined using the breast fold inferiorly and the sternum medially. A triangular pyramid is designed with its base resting on the breast fold. The intersection of the apex of the triangular pyramid with the superior border of the tumor is one of the key points of the drawing. This defined pyramid is divided into two parts. After division, a parallelogram and a triangle are obtained. The remaining triangular area is where the de-epithelialization process is performed. The remaining parallelogram is designed to be the resection area. Following resection, a glandular flap is created in the superior region. To completely close the resulting defect, the glandular flap is sutured to the superior part of the de-epithelialized area. The incision is sutured along the superior skin line and the inferior border of the de-epithelialized area. This creates a hidden suture line in the inframammary fld.

Results: Multiple techniques are described for lower quadrant tumors. The Dogan Technique can be considered an important alternative in the literature at this point. In the postoperative period, the appropriate incision scar on the fold and the absence of another incision on the remaining breast tissue support cosmetic satisfaction. In tumors of the inner quadrant, the need for centralization in NAK arises in incisions made in the vertical plane, but in incisions made in the horizontal plane, such as our incision, the natural position of NAK is preserved. Not performing surgical procedures on the areola and surrounding area eliminates the risk of ischemia and hypesthesia for NAK. This differs from studies in the literature on this subject.

Conclusion: We applied this technique to five of our patients with lower inner quadrant tumors (2025-2026). We are very satisfied with the oncological and aesthetic results. We anticipate that this technique will be recognized in the literature as a safe, effective, and widely used oncoplastic technique in the future.

Laparoscopic creation of permanent access for recurrent benign biliary stricture after open whipple procedure

Orkhan Verdiyev, Cüneyt Kayaalp

Acıbadem Kadıköy Hospital, İstanbul

Objective: Pancreatoduodenectomy is a highly invasive surgery. Although mortality has decreased to approximately 1%, postoperative complications remain common. While early complications have decreased, late-onset benign hepaticojejunostomy stricture (BHS) remains a significant clinical issue. BHS causes recurrent cholangitis, intrahepatic stones, jaundice, and liver abscess, requiring invasive treatments. Thanks to advanced equipment, endoscopic retrograde cholangiography (ERC) is increasingly successful even in altered anatomies. However, when endoscopic access is impossible, alternative permanent surgical strategies are needed. In this video presentation, we present the laparoscopic creation of a permanent access loop to facilitate ERC in a patient who developed a biliary stricture following an open Whipple procedure.

Material and Methods: A 75-year-old female patient presented with late-onset complications following a Whipple procedure performed for benign reasons in 2005. Her medical history included recurrent cholangitis and liver abscesses since 2007. Throughout this period, multiple percutaneous transhepatic cholangiography interventions, balloon dilatations, and "stent-in-stent" metallic biliary stent placements were performed at external centers. Due to increasing symptoms over the last year, double-balloon enteroscopy was attempted; however, the hepaticojejunostomy (HJ) anastomosis could not be reached due to excessive looping and a long afferent limb. Interventional radiological assessment revealed that the stents were completely occluded and lithogenic. To reduce the morbidity of recurrent invasive procedures and ensure permanent endoscopic access, the laparoscopic creation of a permanent access loop was planned for the patient.

Results: Pneumoperitoneum was established via an open technique for camera trocar insertion; intra-abdominal exploration revealed dense adhesions secondary to the previous Whipple procedure. Following meticulous adhesiolysis, the segment identified as the biliopancreatic limb was mobilized from the transverse colon mesentery and surrounding structures. Intraoperative endoscopy was performed, advancing through the gastroenterostomy site. However, endoscopic air insufflation did not result in dilatation of the targeted loop, and laparoscopic transillumination of the endoscope light was localized at a different site, allowing for the correct identification of the true afferent limb. After identifying the appropriate segment, a facial defect was created in the right upper quadrant, and the prepared jejunal loop was fixed to this area as a "permanent access loop." To facilitate future radiological interventions, the loop was marked with a radiopaque band.

Conclusion: Managing benign biliary strictures after an open Whipple is challenging. Laparoscopic creation of a permanent access loop in this altered anatomy is a rarely reported strategy. The created permanent access loop provides a comfortable gateway for percutaneous or endoscopic interventions, offering a minimally invasive and effective solution in stricture management.

[V-088]

A breath to acute mesenteric ischemia: Case series of embolectomy of the superior mesenteric artery

Eda Gül Doğan, Ramazan Onuş, Mehmet Gök, Deniz Kütük, Şener Balas, Erhan Güven

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Acute mesenteric arterial occlusion is a general surgical emergency with high morbidity and mortality, accounting for approximately 65-97% of acute mesenteric ischemia. When caused by embolism, it usually occurs 3 to 10 centimeters distally to the superior mesenteric artery (SMA) origin point.

Material and Methods: In this case series, we evaluated the outcomes of SMA embolectomy performed following explorative laparotomy in 6 patients who presented to the emergency department with acute mesenteric ischemia secondary to SMA embolism.

Results: A total of six patients, 3 males and 3 females, with a mean age of 67.8 years (range: 43-88 years), were included in this study. All patients presented to the emergency department with acute abdominal pain. Computed tomography revealed occlusion at the origin or mid-segment of the superior mesenteric artery (SMA) in all cases. Laboratory evaluation demonstrated a mean white blood cell count of 15.5×10^3/μL (range: $9\text{-}27\times10^3$/μL) and a mean serum lactate level of 2.9 mmol/L (range: 1.49-5.2 mmol/L). All patients were taken to surgery due to acute mesenteric ischemia. Preoperatively, three patients were evaluated by interventional radiology, in two cases no endovascular intervention was deemed appropriate, one patient underwent an endovascular attempt without effective results. All patients subsequently underwent emergency surgical intervention. After assessment of intestinal ischemia and necrosis, the SMA was exposed via a transperitoneal inframesocolic approach. The SMA and jejunal branches were isolated and looped, and SMA embolectomy was performed using a Fogarty catheter after arteriotomy. Intestinal perfusion was then reassessed, necrotic bowel segments were resected, and a planned second-look laparotomy was scheduled to evaluate potential ongoing ischemia. Postoperatively, 2 patients died before a second-look laparotomy could be performed. Two patients required additional bowel resection during the second-look, and at third-look exploration, no pathological findings were observed, allowing for abdominal closure. In the other 2 patients, no pathological findings were detected at second-look laparotomy, and the abdomen was successfully closed. The mean length of hospital stay was 8.5 days (range: 2-20 days). Two patients died on postoperative day 1. Although ischemia was initially controlled in four patients, two subsequently died due to sudden cardiac arrest on postoperative days 3 and 4, while two patients were discharged in good clinical condition.

Conclusion: Acute mesenteric ischemia, which is associated with high mortality, intraoperative SMA embolectomy may contribute to preservation of intestinal reserve and improved survival outcomes. Therefore, this is an effective treatment option in appropriately selected patients.

Keywords: Embolectomy, mesenteric ischemia, vasculary surgery, superior mesenteric artery

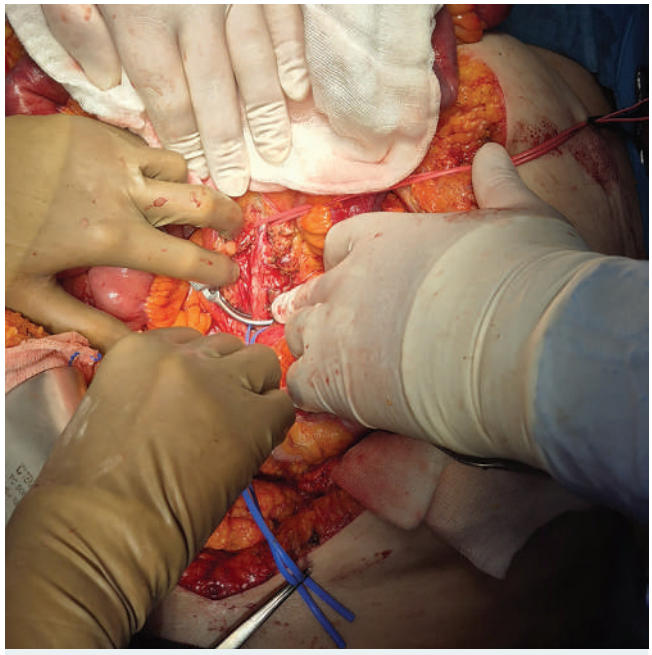

Figure 1. Superior mesenteric artery is exposed and looped.

Table 1. Patient distribution according to the results

	Age-gender	Computed-tomography	Interventional radiology	Operation	Mortality
Patient 1	59-Male	SMA proximally occluded	Ineffective procedure	Abdominal closure after second-look	Sudden cardiac arrest at postoperative day 4
Patient 2	69-Female	SMA occlusion at origin point	No intervention deemed appropriate	Abdominal closure after second-look	Sudden cardiac arrest at postoperative day 3
Patient 3	66-Male	SMA proximally occluded	No intervention deemed appropriate	Abdominal closure after third-look	Discharged
Patient 4	82-Female	SMA occlusion at origin point	-	Second-look couldn't performed	Exitus on postoperative day 1
Patient 5	43-Male	SMA proximally occluded	-	Abdominal closure after third-look	Discharged
Patient 6	88-Female	SMA mid-segment occlusion	-	Second-look couldn't performed	Exitus on postoperative day 1

Laparoscopic and thoracoscopic distal esophagectomy for distal esophageal adenocarcinoma: A video presentation

Türker Kaymak, Ertuğrul Gazi Alkurt, Bahadır Kartal

Department of General Surgery, Hitit University Faculty of Medicine, Çorum

Objective: Minimally invasive approaches have become increasingly common in the surgical management of distal esophageal adenocarcinoma with growing experience. Laparoscopic and thoracoscopic esophagectomy allows preservation of oncologic principles while potentially reducing surgical morbidity in appropriately selected patients. This video presentation demonstrates the technique of laparoscopic and thoracoscopic distal esophagectomy performed for distal esophageal adenocarcinoma.

Material and Methods: A patient with distal esophageal adenocarcinoma who was deemed suitable for surgery after preoperative evaluation underwent a minimally invasive approach. The abdominal phase was performed laparoscopically in the supine position. The omentum majus was dissected along the greater curvature, the gastrohepatic ligament was opened, and abdominal lymph node dissection was carried out. The left gastric artery was ligated and divided, and a gastric conduit was created. The staple line was reinforced with intracorporeal suturing. During the thoracoscopic phase, the esophagus was mobilized, the azygos vein was clipped and divided, and the gastric conduit was delivered into the thoracic cavity. Esophagogastric anastomosis was performed using a side-to-side technique with an endoscopic linear stapler.

Results: The procedure was completed successfully using a minimally invasive approach. No intraoperative complications were observed. The anastomosis was constructed safely, and the operation was completed under controlled conditions. The video clearly demonstrates the essential steps and technical aspects of the procedure.

Conclusion: Laparoscopic and thoracoscopic distal esophagectomy is a safe and effective surgical option for distal esophageal adenocarcinoma when performed by experienced teams. This video presentation highlights the feasibility of the minimally invasive approach and illustrates key technical steps of the procedure.

[3]*Department of Radiology, Kütahya Evliya Çelebi Training and Research Hospital, Kütahya University of Health Sciences, Kütahya*

Objective: Small bowel tumors constitute a small proportion of all gastrointestinal system tumors. Among benign mesenchymal tumors, schwannomas are quite rare. Although they are most commonly located in the stomach (approximately 60%) and the colon (approximately 3%), the development of schwannoma in the small intestine-particularly in the jejunal region-is uncommon. In this study, a case diagnosed with jejunal schwannoma presenting with mechanical ileus is presented in the context of the literature.

Material and Methods: A 61-year-old male patient presented to the emergency department with worsening abdominal pain that had persisted for several days. Contrast-enhanced abdominal computed tomography (CT) was reported as suggestive of ileus. With a preliminary diagnosis of mechanical ileus, emergency laparotomy was performed, during which a constricting mass was identified in the distal jejunum and resection with side-to-side anastomosis was carried out. Histopathological examination revealed a benign mesenchymal tumor consistent with a peripheral nerve sheath tumor (schwannoma). The postoperative course was uneventful, and the patient was discharged on postoperative day 8.

Results: Schwannomas are benign mesenchymal tumors originating from the peripheral nerve sheath. They are most commonly located in the stomach, whereas small bowel involvement is rare and jejunal localization is particularly uncommon; therefore, they are often overlooked in the differential diagnosis. Jejunal schwannomas usually grow slowly and may remain asymptomatic for long periods. When symptomatic, they present with nonspecific findings such as abdominal pain, chronic constipation, occult gastrointestinal bleeding, or anemia. Acute mechanical small bowel obstruction is rare and usually requires emergency surgery. In our case, a history of chronic constipation one year prior supports the insidious nature of these tumors. Radiological findings are non-specific. Contrast-enhanced CT may show focal bowel wall thickening, an intramural mass, or proximal bowel dilatation; however, these findings overlap with gastrointestinal stromal tumors (GIST), adenocarcinomas, and lymphomas. Therefore, careful small bowel evaluation is essential in patients with persistent or unexplained gastrointestinal symptoms. Definitive diagnosis relies on histopathological and immunohistochemical examination. S-100 positivity supports schwannoma, while CD117 negativity is critical for excluding GIST. Complete surgical resection is curative with a low recurrence risk. Our patient recovered without recurrence during one-year follow-up.

Conclusion: Jejunal schwannomas are very rare tumors. Because they may clinically lead to ileus, it is important to consider them in the differential diagnosis, particularly in cases of unexplained small bowel obstruction.

Keywords: Benign mesenchymal tumor, GIS schwannoma, mechanical bowel obstruction

Figure 1. Upright abdominal radiograph demonstrating prominent air-fluid levels in the ileal loops; absence of gas in the distal colon is consistent with mechanical bowel obstruction.

A rare cause of recurrent small intestine obstruction: Well-differentiated ileal neuroendocrine tumor

Abdülaziz Emek, Turgay Şimşek, Orhan Tatlı, Mehmet Furkan Avcı, Enes Şahin, Mahmut Burak Kılcı, Sertaç Ata Güler, Nuh Zafer Cantürk

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Small intestine neuroendocrine tumors (NETs) are one of the common subtypes of gastrointestinal neuroendocrine neoplasms. Those located in the ileum, in particular, may remain asymptomatic for a long time due to their slow growth and submucosal localization. Clinical findings are generally nonspecific. Diagnosis is often made when complications such as mechanical ileus or mesenteric fibrosis develop. Therefore, in patients presenting with recurrent ileus attacks, small bowel NETs should always be considered in the differential diagnosis, despite their rarity.

Material and Methods: The clinical course, imaging findings, surgical approach, and histopathological results of a 52-year-old female patient presenting with recurrent mechanical ileus attacks were retrospectively evaluated.

Results: Contrast-enhanced abdominal computed tomography (CT) at the patient's initial presentation revealed findings consistent with ileus. The patient was managed conservatively and discharged after clinical improvement. Two months later, the patient presented again with complaints of severe abdominal pain, nausea, vomiting, and inability to pass gas or stool. An upright abdominal X-ray showed air-fluid levels. A current contrast-enhanced CT scan showed asymmetric wall thickening in a 2 cm segment of the ileal loop. A nodular lesion was detected in the adjacent mesenteric fatty tissue, and there was marked bowel dilatation proximally. The patient underwent surgery with a preliminary diagnosis of mechanical ileus. A mass lesion narrowing the intestinal lumen was observed approximately 100 cm proximal to the ileocecal valve. Segmental small bowel resection and primary anastomosis were performed. There were no complications in the postoperative period. The patient was discharged on the fifth day. Histopathological examination of the resection specimen was consistent with a well-differentiated NET.

Conclusion: In patients presenting with recurrent mechanical ileus attacks, especially when symptoms recur despite conservative treatment, small bowel NETs should be considered in the differential diagnosis. Segmental wall thickening on computed tomography and the presence of accompanying mesenteric nodular lesions are diagnostic indicators. Timely surgical resection ensures both a definitive diagnosis and successful clinical outcomes.

A rare case report of a trichilemmal cyst extending from the anus to the scrotum

Muhammed Özdemir[1], Zekeriya Pelen[1], Onur Alptekin Güney[1], Özgecan Gündoğar[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul*

[2]*Department of Medical Pathology, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul*

Objective: A trichilemmal cyst is a generally benign cutaneous lesion originating from skin appendages, particularly hair follicles, and is filled with keratin. It occurs in approximately 5-10% of the population, with nearly 90% of cases located on the scalp due to the high concentration of hair follicles. Although trichilemmal cysts are almost always benign, rare cases may show proliferative activity, and malignant transformation with distant metastasis has been reported in approximately 2% of cases in the literature. Therefore, complete surgical excision with clear margins is the recommended treatment.

Results: A 47-year-old male patient presented to our clinic with swelling starting laterally to the anus and ending laterally to the scrotum. Magnetic resonance imaging revealed a subcutaneous cystic lesion approximately 20 cm in length, with no connection to the spermatic cord or scrotum. Microbiological culture of aspirated cyst fluid showed no pathogenic growth. Rectosigmoidoscopy demonstrated no communication between the lesion and the rectum. The lesion was completely excised with clear surgical margins and preservation of cyst integrity for diagnostic and therapeutic purposes. Histopathological examination confirmed a non-proliferative trichilemmal cyst. The postoperative course was uneventful, and no additional pathology was detected during follow-up.

Conclusion: Although trichilemmal cysts are most commonly located on the scalp, this case highlights the importance of considering trichilemmal cysts in the differential diagnosis of anal and perianal masses. Definitive diagnosis relies on histopathological examination following complete surgical excision with clear margins.

Oncoplastic approach in giant phyllodes tumor: Goldilocks mastectomy and nipple-sparing technique

Muharrem Sarkın, Zeki Demirok, İsmail Zihni, Veli Vural, Cumhur Arıcı

Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya

Objective: Phyllodes tumors are rare fibroepithelial neoplasms of the breast. Particularly, "malignant" and "giant" (over 5 cm) forms may require mastectomy to ensure negative surgical margins. Reconstruction after mastectomy is critical for the patient's quality of life. Here, we aim to present a case of a giant phyllodes tumor recurrence treated with a left nipple-sparing mastectomy and dermal flap reconstruction (goldilocks mastectomy).

Material and Methods: A 46-year-old female patient, who was operated on three years ago for a "Borderline Phyllodes Tumor" in the left breast and subsequently lost to follow-up, presented with breast asymmetry and a giant mass.

• **Physical examination:** A tense, palpable mass filling the entire left breast was noted, accompanied by a significant increase in venous vascularity on the skin.

• **Imaging:** Contrast-enhanced mammography and MRI revealed a lobulated, heterogeneous solid lesion (BI-RADS 4c) measuring approximately 26x22 cm, filling all quadrants and extending into the axillary tail.

• **Pre-op diagnosis:** Following a tru-cut biopsy result of "Borderline Phyllodes Tumor", surgery was planned.

Results: • **Surgical procedure:** The patient underwent a left "Nipple-Sparing Mastectomy" combined with "Dermal Flap Reconstruction" (Goldilocks Mastectomy).

• **Intraoperative observations:** No pectoral fascia invasion was found.

• **Specimen:** The excised specimen measured 30 cm.

• **Pathology:** Postoperative histopathological examination confirmed a "Malignant Phyllodes Tumor" with a tumor size of 25 cm, atypia in stromal cells, 7/10 HPF mitosis, and a 40% Ki-67 index.

• **Surgical margins:** Margins were negative (5 mm distance).

• **Follow-up:** The case was evaluated by the oncology board, and 4 cycles of cisplatin + adriamycin chemotherapy were planned. Satisfactory cosmetic results were observed at the 1-month postoperative follow-up.

Conclusion: Wide resection and oncologically safe margins are indispensable in the surgical treatment of giant phyllodes tumors. The Goldilocks mastectomy technique is an effective oncoplastic method, especially for large-volume breasts, as it eliminates the need for implants or free flaps by providing an acceptable breast volume using the patient's own dermal tissue. This case demonstrates that aesthetic results can be optimized in giant masses without compromising oncological principles

[P-015]

Migration to a distant contralateral region following breast wire localization: A rare complication in the literature

Zeyneddin Ali Muhammed, Onur Öztel, Ece Canpolat, Safa Nacar, Tanju Tütüncü, Emin Yılmaz

Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Wire-guided localization is a widely used and reliable method for the surgical treatment of non-palpable breast lesions. However, rare but potentially serious complications such as wire displacement, breakage, or migration to extra-mammary anatomical sites have been reported. While literature indicates that wire migration typically occurs within the same breast or to the ipsilateral thoracic wall, migration to contralateral and distant anatomical regions is extremely rare. This case report presents an extraordinary instance where a localization wire migrated from the right breast to the left shoulder joint following stereotactic marking and was subsequently removed surgically.

Material and Methods: A 52-year-old female patient, scheduled for right breast-conserving surgery and sentinel lymph node biopsy (SLNB) due to right breast malignancy, was referred to the radiology department for preoperative stereotactic localization on the day of surgery. Following the localization procedure, the patient was taken to the operating room; however, the operation was cancelled due to an active herpes simplex infection on her lip identified during the anesthesia evaluation. The patient was discharged with medical treatment as per dermatological recommendations. Three days after discharge, she presented to the emergency department complaining that the wire tip had retracted under the skin and was subsequently admitted.

Results: Imaging revealed that the wire placed in the right breast had unexpectedly migrated to the contralateral side, advancing into and embedding within the left shoulder joint region. Following the trajectory of the wire under ultrasound (USG) guidance, the wire was successfully removed through a surgical incision in the left shoulder. No complications occurred during the procedure.

Conclusion: Although wire migration following localization is rare, surgical delays can increase this risk. This case highlights that a localization wire can migrate beyond the breast tissue to contralateral and distant anatomical sites. In cases of surgical delay following wire localization, reevaluating the position of the wire and adopting a multidisciplinary approach are of paramount importance for the effective and safe management of potential complications

Breast cancer developing six years after prophylactic bilateral simple mastectomy: A case report

İsmet Canpunar, Saygın Altıner, Ahmet Çağrı Büyükkasap, Hüseyin Göbüt, Aydın Yavuz, Kürşat Dikmen, Hasan Bostancı

Department of General Surgery, Gazi University Faculty of Medicine, Ankara

Objective: Breast cancer is the most common malignancy among women. Advances in genetic testing, screening programs, and multidisciplinary management enable prevention and early diagnosis, leading to improved disease-free survival. Genetic predisposition is a major risk factor, with *BRCA2* mutations among the most common. In mutation carriers, prophylactic mastectomy and routine mammographic screening after age 40 within national programs facilitate early detection and improve survival. Although prophylactic mastectomy significantly reduces cancer risk, malignancy may still develop, as demonstrated in this case.

Material and Methods: A 35-year-old woman underwent genetic testing in 2019 due to breast cancer in her two older sisters and was found to carry a *BRCA2* mutation. Breast ultrasonography showed a BI-RADS 2 lesion. She underwent prophylactic bilateral simple mastectomy with implant reconstruction; pathology was benign. She was followed with semiannual ultrasonography. In June 2025, lesions measuring 26×14 mm and 16×12 mm were detected in the right breast. Core needle biopsy was unsuitable because of the implant; incisional biopsy revealed invasive lobular carcinoma, estrogen- and progesterone-receptor positive, HER2 negative, with a Ki-67 index of 12%. PET-CT demonstrated right breast lesions and suspicious right axillary lymph nodes. After four cycles of neoadjuvant chemotherapy, follow-up imaging showed resolution of uptake.

Results: The patient was evaluated multidisciplinary. In October 2025, right subcutaneous mastectomy and sentinel lymph node biopsy were performed, followed by expander placement in collaboration with plastic surgery. Isosulfan blue was injected for mapping. Sentinel lymph node biopsy and subcutaneous mastectomy, including the nipple-areola complex to the pectoral fascia, were completed without implant damage. The specimen weighed 148 g. The implant was replaced with a tissue expander. She was discharged on postoperative day one without complications.

Conclusion: Patients with *BRCA2* mutations who undergo prophylactic mastectomy should continue close imaging surveillance. As shown in this case, breast cancer may arise in residual tissue despite risk-reducing surgery.

Keywords: Breast cancer, BRCA-2 mutation, prophylactic mastectomy

Giant thyroid metastasis of renal cell carcinoma emerging fifteen years later: A rare case mimicking primary tumor

Hakan Ataş[1], Eda Nural[2], Betül Günbey Yılmaz[3], Huban Sibel Orhun[4], Barış Saylam[1]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[2]*Clinic of General Surgery, Kahramanmaraş State Hospital, Kahramanmaraş*

[3]*Department of Pathology, Ankara Yıldırım Beyazıt University Faculty of Medicine, Ankara*

[4]*Clinic of Pathology, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

Objective: Renal cell carcinoma (RCC) is known as the "great mimicker" due to the unpredictable biological behavior of tumor cells and its potential for hematogenous spread. Although thyroid metastases are clinically rare (1.1-3%), RCC is the most frequently detected primary focus in such cases. The most characteristic feature of RCC metastases is their ability to emerge years after the resection of the primary tumor; latent periods of up to 20 years have been reported in the literature. This poses a significant diagnostic challenge, particularly because it can be confused with primary clear cell neoplasms of the thyroid. This case presents a rare metastasis presenting as a 10.2 cm giant mass 15 years after nephrectomy.

Material and Methods: A 54-year-old male patient presented with a sense of pressure in the neck and a rapidly growing swelling. His medical history revealed a nephrectomy 15 years ago due to left RCC. Radiological examination showed a giant nodule, 10.2 cm in size with heterogeneous signal intensity, nearly completely filling the parenchyma of the right thyroid lobe (Figure 1). Total thyroidectomy was performed due to clinical suspicion and significant compressive symptoms in the patient, whose cytological findings were reported as "atypia of undetermined significance".

Results: Histopathological examination revealed a tumoral structure infiltrating the thyroid tissue, consisting of cells with extensive clear-eosinophilic cytoplasm and prominent nucleoli. Immunohistochemical staining showed that the tumor cells were strongly positive for PAX-8, CD10, and vimentin, while testing negative for TTF-1 and thyroglobulin (Figure 2). This immunoprofile and morphological findings confirmed the diagnosis of "Clear Cell RCC Metastasis".

Conclusion: Although the rich vascularization of the thyroid seems favorable for metastasis, high iodine content and rapid blood flow are factors that make metastatic settlement difficult. This case highlights the metastatic capacity of RCC, which can reach giant sizes exceeding 10 cm even after a long latent period of fifteen years. The greatest diagnostic challenge is that RCC morphologically mimics the clear cell variants of primary thyroid tumors. Consequently, in patients with a history of RCC, the possibility of metastasis must always be excluded in thyroid masses, even if decades have passed since the nephrectomy. In differential diagnosis, the use of specific markers such as PAX-8 and CD10 is vital to prevent incorrect radioactive iodine treatment and to determine the correct oncological surgical strategy. Appropriate surgical resection is the most effective method for providing local control and long-term survival in these cases.

Keywords: Renal cell carcinoma, thyroid metastasis, giant nodule, pathology

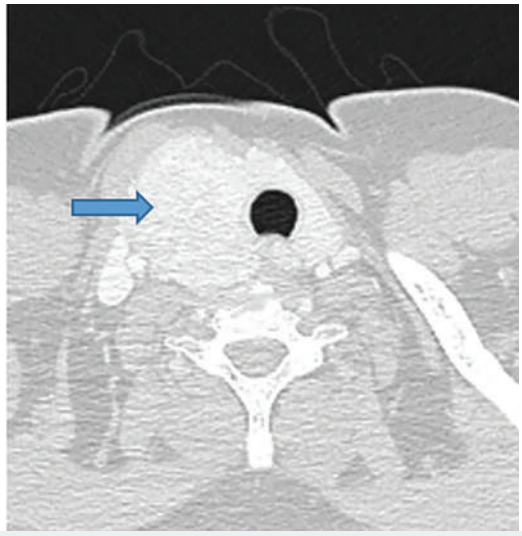

Figure 1. A 10 cm metastatic mass causing tracheal compression and deviation (axial CT scan).

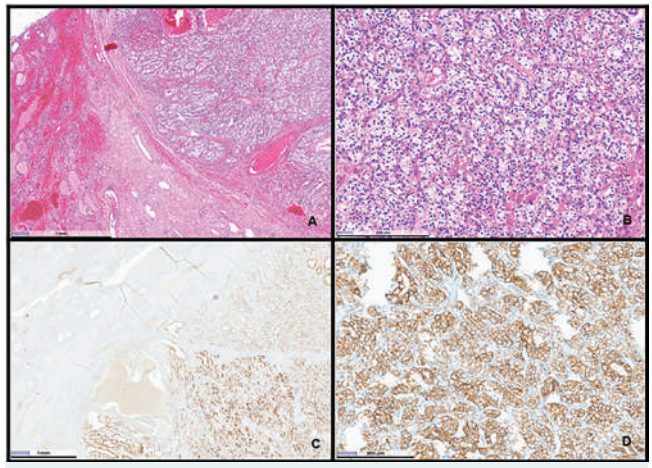

Figure 2. Metastasis of clear cell renal cell carcinoma showing a solid nodular pattern within the thyroid parenchyma (**A**). Tumor area consisting of clusters and sheets of cells with abundant clear cytoplasm belonging to clear cell renal cell carcinoma (**B**). Immunohistochemically, a positive immune reaction is observed in tumor cells with the RCC antibody. This antibody is negative in the thyroid parenchyma (**C**). The CA-IX antibody applied immunohistochemically shows a 'box-like' pattern of positive immune reaction in tumor cells (**D**).

Persistent hyperparathyroidism requiring three stage surgery

Berat Başdan, Serhat Gizlenci, Edip Akpınar

Department of General Surgery, University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Primary hyperparathyroidism is most commonly caused by a parathyroid adenoma and is typically cured with surgical treatment. However, in a subset of patients, biochemical remission cannot be achieved after surgery, resulting in persistent disease. The most frequent causes of persistent hyperparathyroidism include multiglandular disease, supernumerary glands, and ectopic parathyroid tissue. In such cases, reoperative neck surgery may be required, and accurate localization becomes crucial. We present a case requiring three-stage surgical intervention due to persistent hyperparathyroidism.

Material and Methods: A 42-year-old male patient presented to the emergency department with hypercalcemic crisis. Laboratory evaluation revealed a parathyroid hormone (PTH) level of 400 pg/mL. Serum calcium levels were approximately 20 mg/dL both preoperatively and between surgical interventions. Preoperative Imaging Before the First Surgery Tc-99m sestamibi parathyroid scintigraphy demonstrated MIBI retention in the posterior inferior aspects of both the right and left thyroid lobes, suggestive primarily of parathyroid pathology (adenoma/hyperplasia). Based on these findings, the patient underwent the first surgery, and the suspected parathyroid tissue was excised. The pathological specimen measured approximately 4×2×1.2 cm, consistent with parathyroid adenoma. Due to the absence of postoperative biochemical improvement, a second surgery was planned. Right total thyroidectomy and left superior parathyroidectomy were performed. Despite this intervention, serum calcium and PTH levels remained markedly elevated. Preoperative Imaging Before the Third Surgery Repeat parathyroid scintigraphy demonstrated focal increased uptake in the right upper paratracheal region, compatible with a parathyroid adenoma. Based on these findings, a third surgical exploration was undertaken.

Results: During the third operation, meticulous exploration revealed ectopic parathyroid tissue located between the esophagus and trachea. The ectopic gland was excised. Following the final surgery, serum PTH and calcium levels normalized, and the patient had an uneventful postoperative course.

Conclusion: In cases of persistent primary hyperparathyroidism where biochemical remission is not achieved after initial surgery, repeat localization studies are critically important. Cervical imaging modalities should be reassessed, and reoperative neck exploration should be carefully and systematically planned according to the obtained findings. With accurate localization and an experienced surgical approach, biochemical cure can be achieved.

Keywords: Hyperparathyroidism, parathyroid neoplasms

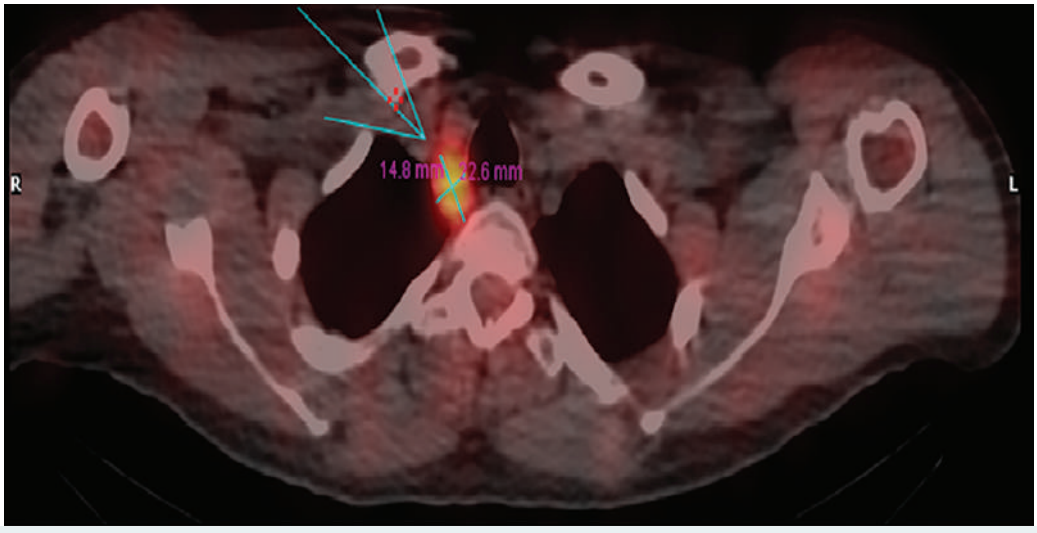

Figure 1. Scintigraphic image after the second surgery. Scintigraphy shows a focus consistent with parathyroid adenoma in the right paratracheal region.

Gallbladder duplication: A rare case report

Kadir Serkan Türel, Erdem Bedur

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Congenital anomalies of the gallbladder are rare, and a wide range of anatomical malformations affecting its shape, size, number, and position have been described. Septate gallbladder is among the malformations that has not been well documented, because it is usually asymptomatic or discovered accidentally during the evaluation of jaundice or at postmortem examination. Variations in the cystic duct and vasculature in the portal triad have also not been well described. These anomalies are important to know for surgeons because of associated anatomical variations of main bile duct and hepatic artery and increased risk of common bile duct injury.

Results: We report the case of a double gallbladder in a forty-two year old man. He presented with recurrent episodes of biliary colic. Laboratory analysis of liver function was normal. Her blood values were within normal range. Preoperative ultrasound imaging confirmed the gallbladder filled with stones. There was no information about the number gallbladder, presence of septa, cystic arteries, and cystic ducts. A laparoscopic cholecystectomy was planned for the patient. During intraoperative exploration, anatomical variations were identified, including a double cystic artery and a double cystic duct. Due to these findings and concerns regarding operative safety, the procedure was converted to open surgery. Following a right subcostal incision, further exploration was performed. The common bile duct was identified and found to be normal. Two separate cystic ducts originating from the common bile duct and two cystic arteries arising from the hepatic artery were clearly visualized and carefully dissected. After precise identification of all biliary and vascular structures, a safe cholecystectomy was successfully completed without complications. Gross examination of the surgical specimen revealed a duplicated gallbladder separated by a septum. Histopathological evaluation confirmed the presence of a double gallbladder associated with double cystic duct and double cystic artery origins.

Conclusion: Duplication of the gallbladder is a rare congenital abnormality, which requires special attention to the biliary ductal and arterial anatomy. Accurate diagnosis and careful surgical planning are critical in managing double gallbladder cases to avoid iatrogenic injuries.

Keywords: Cholecystectomy, congenital malformation, double gallbladder

[P-020]

Distal pancreatectomy with en bloc celiac axis, partial superior mesenteric vein-portal vein resection and supraceliac aorta and common hepatic artery anastomosis with interposed saphenous vein graft case report

Kerime Yaşaran Uysal[1], Tarkan Ünek[1], Tufan Egeli[1], Mücahit Özbilgin[1], Cihan Ağalar[1], Çağla Dinler Şensöz[1], Akın Alp Akansel[1], Mehmet Necati Katran[1], Şevket Baran Uğurlu[2]

[1]*Department of General Surgery, Dokuz Eylül University Faculty of Medicine, İzmir*

[2]*Department of Cardiovascular Surgery, Dokuz Eylül University Faculty of Medicine, İzmir*

Objective: Pancreatic ductal adenocarcinoma is an aggressive solid tumor where the 5-year survival rate rarely exceeds 10%, despite advances in surgical techniques and systemic therapies. Tumors located in the pancreas body and neck are often considered "locally advanced" at diagnosis due to their proximity to critical vascular structures like the celiac trunk (CTr). The modified Appleby procedure (distal pancreatectomy with en bloc celiac axis resection, DP-CAR) is an aggressive approach developed to improve survival in patients responding to neoadjuvant chemotherapy. This technique relies on retrograde hepatic perfusion provided by the superior mesenteric artery (SMA) via pancreaticoduodenal arcs and the gastroduodenal artery (GDA) to allow R0 resection. When this arc is insufficient, hepatic arterial revascularization is required.

Material and Methods: A 59-year-old female with hypertension presented with epigastric and back pain. Contrast-enhanced Computed Tomography revealed a 45x39 mm hypodense lesion in the pancreas body, invading the CTr branching level and causing splenic vein thrombosis. CA19-9 was 402 U/mL. Endoscopic ultrasonography confirmed that the mass invaded the CTr, as well as the splenic artery and vein. Biopsy confirmed pancreatic adenocarcinoma. Following 6 cycles of FOLFIRINOX, regression was observed. And modified Appleby procedure was planned. Preoperative celiac angiography demonstrated hepatic arterial flow via the GDA through the pancreatoduodenal arcade.

Results: During surgery, no metastases were observed. The tumor invaded the retroperitoneum and posterior stomach. Upon clamping the common hepatic artery (CHA), Doppler ultrasound showed arterial flow from the SMA to the liver via the GDA, but acceleration time was prolonged. Consequently, DP-CAR was performed alongside splenectomy, partial gastric resection, retroperitoneal lymph node dissection, and partial resection of the superior mesenteric vein (SMV) and portal vein (PV). An end-to-end anastomosis was performed between the distal SMV and proximal PV. Subsequently, an end-to-end anastomosis was created between the supraceliac aorta and the CHA using an interposed saphenous vein graft. Hepatic flow was confirmed via Doppler.

Conclusion: DP-CAR is a procedure that provides a survival advantage in selected patients with unresectable pancreatic cancer; however, it is associated with high morbidity and mortality rates. The most common causes of mortality are gastric/hepatic ischemia, and post-pancreatectomy hemorrhage. As DP-CAR is an invasive procedure, patients must be selected with extereme care. The feasibility of DP-CAR depends on the presence of adequate collateral flow to both the liver and the stomach to avoid ischemia. Therefore, it is essential to evaluate the patency of the GDA and the pancreatoduodenal arcade to determine the necessity of preoperative celiac axis embolization or arterial reconstruction.

Keywords: Arterial reconstruction, modified appleby procedure, pancreatic adenocarcinoma

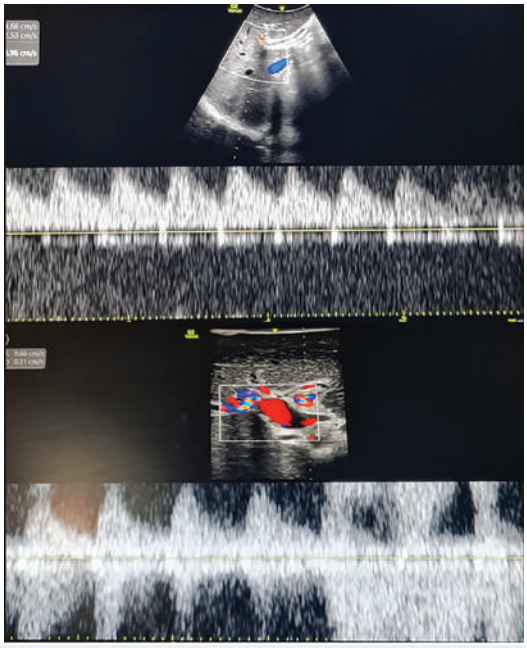

Figure 1. Intraoperative Doppler USG.

Intraoperative Doppler ultrasonography images: The upper image shows a prolonged acceleration time in the hepatic artery prior to anastomosis. The lower image demonstrates the restoration of normal arterial waveform and flow parameters following arterial reconstruction.

Ileal ureter reconstruction after long-segment ureteral resection due to recurrent sigmoid colon adenocarcinoma: A case report

Mehmet Sercan Candan[1], Enis Mert Yorulmaz[2], Farida Mustafayeva[1], Cengiz Tavusbay[1], Fevzi Cengiz[1]

[1]*Department of General Surgery, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

[2]*Department of Urology, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

Objective: Long-segment ureteral defects may arise due to iatrogenic injury, radiation fibrosis, or malignancy. When the defect exceeds the limits suitable for primary anastomosis, Boari flap, or psoas hitch reconstruction, ileal ureter substitution becomes a viable alternative. Ileal ureter replacement was first introduced by Shoemaker in 1906 and later popularised by Goodwin in 1959. We present a case of recurrent sigmoid colon adenocarcinoma requiring long-segment ureteral resection and successful ileal ureter reconstruction.

Material and Methods: A 60-year-old male patient, who underwent anterior resection surgery for sigmoid colon adenocarcinoma four years prior, was diagnosed with moderately differentiated adenocarcinoma (pT3N2BM0) and received postoperative chemotherapy. Three years postoperatively, a local recurrence mass invading the left ureter was detected in the same area. Following a multidisciplinary evaluation, surgical resection was planned. During the operation, the tumor was found to infiltrate a long segment of the left ureter, and, in accordance with oncological principles, the affected ureteral segment along with the tumor was resected en bloc. Since primary ureteral anastomosis was not possible due to the length of the defect, continuity was achieved through ileal reconstruction (Figure 1).

Results: The postoperative course was uneventful. Renal function remained stable, and the patient was discharged uneventfully on postoperative day 16. In the 1st postoperative month, radiological examinations revealed that the anastomosis was intact (Figure 2).

Conclusion: Management of long-segment ureteral defects remains complex. Reconstruction options depend on defect length and location. Complete tumor excision must be balanced with preservation of renal function. Ileal ureter substitution provides a tension-free reconstruction in cases where alternative techniques are not feasible. In our case, the long-segment defect following oncologic resection precluded primary repair. Ileal substitution allowed restoration of urinary continuity without compromising oncologic principles. No early complications were observed. Ileal ureter reconstruction is a reliable option for extensive ureteral defects following oncologic resection of locally recurrent colorectal cancer. Multidisciplinary planning and meticulous technique are key to favourable outcomes.

Keywords: Ileal ureter, ureteral reconstruction, colorectal cancer recurrence

Emergency laparoscopic low anterior resection due to sigmoidal colon trauma secondary to high pressureized compressed air; case report

Tuğberk Tok

Clinic of General Surgery, Karadeniz Ereğli State Hospital, Zonguldak

Objective: Transanal insufflation with high-pressure compressed air is a rare but potentially life-threatening cause of colorectal barotrauma. Patients may rapidly develop severe abdominal pain, distension, pneumoperitoneum, and—if perforation occurs—fecal peritonitis. Injury most commonly involves the rectosigmoid region and sigmoid colon, and timely recognition with appropriate surgical management is critical to prevent morbidity and mortality.

Material and Methods: A 30-year-old man presented to the emergency department with abrupt-onset severe abdominal pain and marked distension that began approximately 2 hours after co-workers directed an industrial high-pressure air device toward his anal area over clothing as a practical joke. He reported no immediate anal pain or bleeding. He had no prior abdominal surgery, comorbidities, allergies, or regular medications. Vital signs were stable except for minimal tachypnea. Physical examination revealed diffuse abdominal tenderness with peritoneal signs. Digital rectal examination showed no bleeding or palpable rectal wall abnormality. Chest radiography showed no thoracic injury, while an abdominal radiograph demonstrated pneumoperitoneum. Abdominal CT revealed generalized free intraperitoneal air, prompting emergency diagnostic laparoscopy. Prior to abdominal surgery, anoscopy was performed and showed no laceration, hemorrhage, or rectal wall defect.

Results: Emergency laparoscopy revealed minimal hemorrhagic fluid in the pelvis without active bleeding and no fecal contamination. Multiple serosal defects (approximately 1-3 cm) were observed in about 15 areas involving the upper rectum and sigmoid colon; minimal hematomas were noted on the sigmoid appendices epiploicae without active hemorrhage. No pathology was identified in other colonic segments or solid organs. No clearly visible full-thickness perforation was identified intraoperatively; however, given the extent of serosal injury and the risk of occult perforation, laparoscopic low anterior resection was performed, selecting a secure distal margin beyond the rectal serosal defects. After specimen extraction with the proximal segment intact, intraluminal air insufflation of the resected segment confirmed a ~1 cm full-thickness perforation on the posterior aspect of the sigmoid colon. Resection was completed and a coloanal anastomosis was performed laparoscopically. The postoperative course was uneventful.

Conclusion: Colorectal barotrauma from high-pressure compressed air can produce extensive serosal injury and an occult perforation that may not be apparent on initial laparoscopic inspection. In hemodynamically stable patients without shock, significant fecal contamination, or major rectal destruction, laparoscopic resection with primary anastomosis can be an effective treatment option. Early diagnosis and prompt operative management are essential, and workplace safety measures are key to prevention.

Keywords: Colorectal barotrauma, compressed air, laparoscopic low anterior resection, pneumoperitoneum, sigmoid colon perforation

[P-034]

Small bowel intussusception secondary to colonic diverticular perforation: A rare cause of acute abdomen

Ersin Kılıç

Clinic of General Surgery, Gebze Fatih State Hospital, Kocaeli

Objective: Adult intussusception is rare and usually associated with an underlying organic pathology. Invagination of a small bowel loop into the rectum is exceptionally uncommon. We present a case of acute abdomen caused by a strangulated small bowel loop protruding from the rectosigmoid junction into the rectum.

Material and Methods: A 75-year-old male presented with rectal bleeding, nausea, vomiting, and abdominal pain for three days. Physical examination revealed generalized guarding and rebound tenderness. Digital rectal examination detected hematochezia and a palpable mass. Laboratory tests showed leukocytosis (17,000/mm³) and elevated CRP (154 mg/L). CT demonstrated dilated small bowel loops and pelvic free fluid. Emergency rectosigmoidoscopy revealed a strangulated small bowel loop 5 cm from the anal verge.

Results: During emergency laparotomy, a 10-cm strangulated small bowel segment was found protruding through a diverticulitis-related perforation on the anterior rectosigmoid wall. After reduction, necrosis was identified and resected with anastomosis. Hartmann's procedure was performed. The patient was discharged on postoperative day five.

Conclusion: Although rare, small bowel intussusception into the rectum should be considered in patients presenting with rectal bleeding or prolapse-like symptoms. Early surgical intervention is essential to reduce morbidity and mortality.

Keywords: Intussusception, small bowel strangulation, colonic diverticular perforation

Synchronous squamous cell carcinoma and adenoid cystic carcinoma of the breast: A rare case

Zeynep Betül Yıldız, Fatma Ümit Malya

Department of General Surgery, University of Health Sciences Türkiye, Kanuni Sultan Süleyman Training and Research Hospital, İstanbul

Objective: Squamous cell carcinoma (SCC), adenoid cystic carcinoma (ACC) of the breast are exceedingly rare histopathological subtypes among breast malignancies. Both tumors frequently demonstrate hormone receptor-negative profiles, their biological behavior and clinical course may differ significantly. The aim ofthis study is to present the clinical, pathological, and therapeutic features of a rarecase in which synchronous SCC and ACC of the breast were identified.

Material and Methods: A 41-year-old female patient presented to our clinic with a palpable breast mass. On physical examination, irregularly bordered mass measuring approximately 2 cm was detected in the right breast at the 1 o'clock position, located 3-4 cm from the areola. No additional pathology was identified inthe left breast or bilateral axillary regions. Mammography and ultrasonography revealed a solid lesion categorized as BI-RADS5. Tru-cut biopsy was performed, and the histopathological diagnosis was SCC. Staging work-up for distant metastasis was negative. Following multidisciplinary breast tumor board evaluation, the patient was scheduled for surgery. The patient underwent segmental mastectomy with SLNB in accordance with oncoplastic principles. Resection was performed with clear surgical margins, and the SLNB were reported as benign. However, histopathological examination of the surgical specimen revealed twodistinct tumor. In addition to SCC, ACC, a subtype of triple-negative breast cancer known for its favorable prognosis, was identified. Surgical margins were negative, and no metastasis was detected in the sentinel lymph nodes. Immunohistochemical analysis demonstrated that both tumor components were negative for ER-PR-HER2. Considering that breast-conserving surgery had been performed and taking into account the histopathological findings, the patient was referred for adjuvant radiotherapy. Chemotherapy was not administered due to negative surgical margins and absence of lymph node involvement. The decision regarding systemic therapy was made through a multidisciplinary evaluation based on patient characteristics and tumorbiology.

Results: SCC accounts for less than 0.1% of all breast cancers and is generally associated with an aggressive clinical course. In contrast, ACC, although rare in the breast, typically demonstrates an indolent clinical behavior and favorable prognosis. The synchronous presence of these two rare tumor types within the same breast has been reported only in a very limited number of cases inthe literature. Although both tumors may pose challenges in treatment planning, it is well recognized that ACC may exhibit a biological behavior distinct from that of conventional triple-negative breast cancers. Therefore, treatment strategies should not rely solely on immunohistochemical profiles but must also be individualized according to histopathological subtype and clinical characteristics. Given the potential for rapid progression in SCC, close postoperative surveillance is warranted in suchpatients. The coexistence of these two distinct tumor types further underscores the importance of a multidisciplinary approach in treatment planning.

Conclusion: Synchronous coexistence of SCC and ACC in the breast is an extremely rare condition. In this case, negative surgical margins were achieved with breast-conserving surgery, and the decision regarding adjuvant therapy was made based on the histopathological characteristics of the tumors. This case highlights the importance of managing the diagnostic, therapeutic process of rare breast tumors through a multidisciplinary approach.

Gestational gigantomastia: A rare pregnancy-related breast disorder

Baran Mollavelioğlu[1], Dila Udum[1], Erol Kozanoğlu[2], Bora Edim Akalın[2], Selman Emiroğlu[1], Mustafa Tükenmez[1], Neslihan Cabıoğlu[1], Mahmut Müslümanoğlu[1]

[1]*Department of General Surgery, İstanbul University, İstanbul Faculty of Medicine, İstanbul*

[2]*Department of Plastic, Reconstructive and Aesthetic Surgery, İstanbul University, İstanbul Faculty of Medicine, İstanbul*

Objective: Gestational gigantomastia (GG) is a rare condition characterized by excessive, often bilateral, breast tissue enlargement that usually appears toward the end of the first trimester of pregnancy. Patients typically present with rapid and extreme breast enlargement, back pain, dyspnea, mobility limitation, and breast skin complications such as pain, ulceration, bleeding, scaling, and sensory loss. Most affected patients are young, multiparous women without significant medical, surgical, or family history. Due to the severe impact on quality of life, surgical treatment is widely considered the gold standard. Medical therapies targeting hormonal effects include anti-estrogens and dopamine agonists, while diuretics and corticosteroids may reduce tissue and skin edema.

Material and Methods: A 24-year-old woman, approximately 24 weeks pregnant, presented to our breast surgery clinic with a 5-month history of rapid breast enlargement, back pain, and neck pain. She reported menarche at the age of 14, a 12 pack-year smoking history, and a diagnosis of multiple sclerosis with cervical spinal involvement. There was no significant family history of malignancy. On physical examination, the breasts were markedly enlarged, symmetrical, and tender, with edematous skin. Breast ultrasonography revealed dilated superficial veins, bilateral ductal ectasia, numerous bilateral anechoic cysts, and a few benign-appearing solid lesions. Considering her pregnancy and personal preference, an initial conservative approach with close follow-up was adopted.

Results: Three months later, the patient delivered a healthy infant. Postpartum evaluation considered cabergoline (a D2 receptor agonist) and tamoxifen 20 mg/day for three months; however, due to the persistence of severe symptoms, surgical treatment was chosen. Bilateral reduction mammoplasty was performed using a superomedial pedicle technique, and the nipple-areolar complexes were prepared as grafts. The excised tissue measured 29.5×18.5×5 cm from the right breast and 30×19.5×4.5 cm from the left breast. Histopathological examination revealed dilated cutaneous lymphatics, stromal edema, fibrosis, and fibroadenomas. The postoperative course was uneventful, and the patient was discharged on the second postoperative day.

Conclusion: While medical therapy may be considered in the management of gestational gigantomastia, surgical intervention remains the definitive treatment in the majority of patients with advanced breast enlargement, providing effective and lasting symptom relief.

A rare lesion mimicking malignancy: Two cases of syringomatous tumor of the nipple

Gamze Kulduk[1], Seniha Deniz Şahin[2], Arzu Akan[2]

[1]*Department of Pathology, University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul*

Objective: Syringomatous tumor of the nipple is a rare benign neoplasm with locally infiltrative behavior. It is most commonly observed in young and middle-aged women. Because it can clinically and radiologically mimic malignancy, definitive diagnosis relies on histopathological examination. Wide local excision is recommended for treatment. We aimed to present two cases diagnosed in our clinic.

Material and Methods: Case 1A 40-year-old female patient presented with discharge from the left nipple. Ultrasonography revealed dense microcalcifications in the left nipple. Parenchymal distortion was observed in the periareolar region at the 12 o'clock position of the left breast. In the left axilla, 2-3 lymph nodes measuring 12.5×6 mm with preserved central hilum and mildly thickened cortex were detected. Breast magnetic resonance imaging (MRI) demonstrated intense contrast enhancement in the left nipple and retroareolar region, along with diffusion restriction in a 15×9 mm area. Radiologically, the findings were suspicious for malignancy. Tru-cut biopsy findings, when evaluated together with the retroareolar localization of the lesion, were primarily consistent with "Syringomatous Tumor of the Nipple". Case 2A 70-year-old female patient presented with retraction of the left nipple. Mammography demonstrated a 7.5 mm low-density nodular opacity located 14 mm from the nipple (BI-RADS 0). Breast MRI revealed a relatively irregularly marginated heterogeneous solid mass measuring 32×27 mm in the retroareolar region of the left breast, causing nipple retraction (BI-RADS 4C). Histopathological examination of biopsy sections showed an infiltrative pattern composed of squamous differentiation and syringomatous structures within a collagenized spindle-cell stroma. The histopathological findings were considered in the differential diagnosis of "Low-Grade Adenosquamous Carcinoma (Metaplastic Carcinoma)" and "Syringomatous Tumor of the Nipple".

Results: Both patients underwent lumpectomy. The excised surgical specimens were submitted for histopathological evaluation. Final pathology in both cases confirmed syringomatous tumor of the nipple. Surgical margins were negative in both patients.

Conclusion: Syringomatous tumor of the nipple is a rare benign neoplasm with locally infiltrative characteristics that frequently mimics invasive carcinoma clinically and radiologically. Although perineural invasion may be observed, no metastatic potential has been reported. Complete excision with negative surgical margins is curative. Accurate histopathological evaluation is crucial to prevent unnecessary radical surgery.

[P-038]

A rare form of goiter: Amyloid goiter - case presentation

Muhammed Alperen Taş, Ahmet Faruk Arlier, Muhammed Taha Zengin, Yalçın Sönmez, Mehmet Fatih Ekici

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Amyloid goiter is characterized by the accumulation of an insoluble protein formed as a result of abnormal folding called amyloid, leading to a marked enlargement of the thyroid gland. The definitive diagnosis is made by pathological evaluation. Thyroid malignancies should be excluded in the differential diagnosis. Immunohistochemical evaluation should be performed to determine the subtype of the accumulated amyloid. Amyloid goiter rarely occurs as an isolated condition; there is usually an underlying systemic disease. Primary amyloidoses are associated with plasma cell dyscrasias, while secondary amyloidoses are associated with FMF, RA, chronic osteomyelitis, tuberculosis and IBD. The incidence of amyloid goiter is remarkably high in patients who develop amyloidosis associated with FMF and undergo hemodialysis due to renal failure.

Material and Methods: In this case, the diagnosis, treatment and follow-up process of a patient who underwent bilateral total thyroidectomy and tracheostomy due to amyloid goiter at our clinic was evaluated.

Results: A 44-year-old patient with known HT, FMF and secondary amyloidosis-related renal failure who underwent renal transplantation two years ago experienced sudden cardiac arrest at home. After 30 minutes of CPR, the patient was intubated and placed on inotropic support in the intensive care unit for follow-up during the post-CPR period. A tracheostomy was planned, but due to a massive goiter in the neck, the tracheostomy could not be performed and a thyroidectomy was planned instead. A neck ultrasound performed prior to thyroidectomy revealed solid nodules filling both lobes almost completely and intermingling with each other. A neck CT scan showed a deviated trachea to the left and a multinodular goiter appearance. The patient underwent bilateral total thyroidectomy and a tracheostomy was performed. The patient died on the 4th postoperative day due to general deterioration. Widespread amyloid deposition was observed in the examined thyroidectomy material.

Conclusion: Patients typically present with a progressive and rapidly advancing, hard, painless mass in the neck. Secondary to compression, dyspnea, dysphagia and dysphonia may occur. The vast majority of patients are euthyroid. Ultrasound, CT and MRI can be used as imaging methods. The primary and most effective treatment for amyloid goiter is thyroidectomy. There are three main strategies in treatment: relieving compression symptoms, establishing a definitive histopathological diagnosis and most importantly, managing the underlying disease. Amyloid goiter is rare but has an important place in clinical practice because it is a harbinger of an underlying systemic disease. Amyloid goiter may not only be a disease of the thyroid but also a potential indicator of a systemic process requiring a multidisciplinary approach.

Keywords: Amyloid, goiter, thyroidectomy

Delayed tracheal perforation after retrosternal thyroid surgery: A rare complication

Zeyneddin Ali Muhammed[1], Hakan Ataş[1], Ebru Menekşe[2], Onur Öztel[1], Ece Canpolat[1], Safa Nacar[1]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[2]*Clinic of General Surgery, Private Koru Hospital, Ankara*

Objective: Thyroidectomy is a widely performed and generally safe surgical procedure for treating both benign and malignant thyroid diseases. While common complications include vocal-cord paralysis, hypoparathyroidism, hypocalcemia, and cervical hematoma, tracheal injuries are exceedingly rare, occurring in only approximately 0.06% of cases. Tracheal damage is typically identified and repaired intraoperatively. However, "delayed" tracheal necrosis and perforation arising from prolonged mechanical compression, tissue ischemia, or secondary infection carry significant morbidity risks. This report discusses a rare case of delayed perforation developing on the 11th postoperative day in a patient operated on for a giant- retrosternal goiter and its subsequent conservative management.

Material and Methods: A 49-year-old male presented with a heterogeneous thyroid mass showing significant retrosternal extension. Preoperative CT imaging revealed that the lesion displaced the trachea to the right, extended to the first-degree branches of the aorta in the mediastinum, and narrowed the tracheal lumen to approximately 10 mm. The patient underwent bilateral total thyroidectomy, and no complications were observed during the early postoperative period. However, on the 11th postoperative day, following an uncontrolled coughing fit, the patient returned with complaints of discharge and air-leakage from the cervical incision line. Physical examination revealed significant mobility of the neck skin flaps during expiration and air leakage synchronized with respiration. A fistula tract of approximately 2 cm was observed on the Kocher incision scar (Figure 1).

Results: Flexible laryngoscopic evaluation showed the left vocal-cord fixed in a paramedian position, while the right vocal-cord remained mobile. Radiological assessment identified a tracheal defect accompanied by pneumonia foci in the right lung (Figure 2). A conservative treatment plan was implemented instead of surgical revision: rifampicin and boric acid powder were applied to the incision line. Air-leakage was controlled using a pressure bandage with a sterile gauze-ball placed over the defect. Broad-spectrum intravenous antibiotic therapy was administered for 10 days. The patient was discharged following clinical improvement monitored through daily dressing changes. Long-term follow-up revealed no development of tracheal strictures or permanent hoarseness. The pathology report was "multifocal papillary microcarcinoma limited to the thyroid".

Conclusion: Delayed tracheal necrosis and perforation is an extremely rare but potentially life-threatening complication following thyroidectomy. In cases with preoperative tracheal compression, preventing intraoperative vascular and thermal damage is vital. Vigilance is required for signs such as sudden-onset dyspnea, subcutaneous emphysema, or air-leakage from the incision line postoperatively. Early diagnosis, aggressive infection control, and a multidisciplinary approach can yield successful outcomes with conservative treatment in selected cases.

Late-onset enterocutaneous fistula and recurrent retroperitoneal abscesses following spilled gallstones during laparoscopic cholecystectomy: A rare case report

Mete Varoğlu, Utku Öztürk, Yiğit Kağan Zeren, Aydın Yavuz

Department of General Surgery, Gazi University Faculty of Medicine, Ankara

Objective: Iatrogenic gallbladder perforation and the subsequent spilling of gallstones into the peritoneal cavity is an intraoperative complication reported in up to 40% of laparoscopic cholecystectomy (LC) cases. Although these stones usually remain asymptomatic, they can cause serious morbidity, such as abscesses, foreign body granulomas, or complex fistulizations years later, particularly in patients with immune-modifying comorbidities like diabetes mellitus. This report discusses the surgical management of a rare case presenting with a retroperitoneal abscess and enterocutaneous fistula seven years after an LC procedure.

Material and Methods: A 44-year-old male with insulin-dependent diabetes mellitus presented with purulent drainage in the right lumbar region and a history of recurrent intra-abdominal abscesses. His medical history revealed gallbladder perforation and spilled stones during an LC in 2017. MRI findings showed 1.5 cm loculated abscess foci extending to the psoas muscle posterior to the right kidney, fistula tracts opening to the skin at the L3-L4 levels, and a mesenteric abscess focus adjacent to the anterior left lobe of the liver. A multidisciplinary operation was performed by general surgery and orthopedics teams. Laparoscopic exploration identified an enterocutaneous fistula line between the colon and the peritoneum, which was resected using a 45 mm endo-GIA. Subsequently, the patient's position was changed to excise the lumbar fistula tract and debride necrotic tissues near the psoas. Following a progressive oral intake protocol, the patient was discharged recovered on the 16th postoperative day. At the one-month follow-up, the patient remained asymptomatic with complete healing.

Results: Literature indicates that symptoms arising from "lost gallstones" can manifest up to 20 years postoperatively; the 7-year latent period in our case supports this data. The migration of stones into the retroperitoneal space can lead to challenging conditions like psoas abscesses and enterocutaneous fistulas. In diabetic patients, impaired leukocyte function enhances the tendency for foreign body reactions to combine with infection, facilitating fistulization. While MRI is the gold standard for mapping tracts, definitive treatment requires the complete surgical excision of all stones and the fistula tract rather than simple drainage.

Conclusion: Spilled gallstones represent a rare but significant source of morbidity that can present as complex fistulas years after surgery. For clinical success, it is critical to meticulously document intraoperative stone spillage, thoroughly investigate surgical history in chronic fistula cases, and implement early postoperative enteral nutrition to optimize healing.

Splenic abscess due to *Brucella melitensis* mimicking a malignant cystic lesion: A challenging diagnostic case

Berde Ünyıldız, Süleyman Atalay, Uğur Arda, Ercan Önder, Ertan Bülbüloğlu, Adem Akçakaya

Bezmialem Vakıf University Faculty of Medicine, İstanbul

Objective: Splenic abscess is a rare but potentially life-threatening clinical condition. In endemic regions, *Brucella* species should always be considered among infectious etiologies. However, radiological findings and elevated tumor marker levels may mimic malignant splenic lesions and complicate the diagnostic process.

Material and Methods: This is a case report of a splenic abscess caused by *Brucella melitensis* mimicking a malignant cystic lesion.

Results: A 26-year-old male patient presented with complaints of fever and abdominal pain. Laboratory investigations revealed elevated inflammatory markers and markedly increased CA 19-9 levels. Imaging studies demonstrated a large, thick-walled cystic lesion originating from the spleen; the lesion was initially considered compatible with a hydatid cyst or mucinous neoplasm. Endoscopic ultrasound-guided fine-needle aspiration yielded necrotic and infected material. Microbiological culture grew *Brucella melitensis*. Due to the large size of the lesion, its close relationship with adjacent organs, and persistent suspicion of malignancy, the patient underwent laparoscopic splenectomy and cyst excision. The postoperative course was uneventful.

Conclusion: This case demonstrates that splenic abscesses secondary to brucellosis may closely mimic malignant cystic splenic lesions both radiologically and biochemically, particularly in the presence of markedly elevated tumor markers. CA 19-9 levels can be significantly elevated in infectious and inflammatory processes and should not be interpreted as definitive evidence of malignancy. In endemic areas, brucellosis must be included in the differential diagnosis of cystic splenic lesions. In selected patients, surgical management provides both definitive diagnosis and effective treatment and remains a safe therapeutic option. Splenic abscesses due to brucellosis may mimic malignant cystic lesions in terms of both radiological and laboratory findings. Elevated tumor marker levels do not always indicate malignancy. In selected cases, surgical treatment remains a safe and definitive approach.

Keywords: Splenic abscess, brucellosis, CA 19-9, cystic splenic lesions

[P-058]

Chronic self-inflicted rectal trauma leading to superior rectal artery pseudoaneurysm: Successful endovascular management in an elderly patient on antiplatelet therapy

Hacı Vural Soyer, Samed Sayar, Sinan Aslan

University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: Superior rectal artery pseudoaneurysm (SRAP) is an extremely rare but potentially life-threatening cause of lower gastrointestinal bleeding. Reported etiologies include pelvic trauma, colorectal interventions, inflammatory processes, and radiation injury. Because of its rarity, diagnosis may be delayed. Contrast-enhanced computed tomography angiography (CTA) and digital subtraction angiography are essential for early detection. Endovascular embolization has increasingly replaced surgical intervention in hemodynamically stable patients. We present a case of SRAP secondary to chronic repetitive rectal trauma and provide a focused review of previously reported cases.

Material and Methods: A single-patient case was retrospectively analyzed, including clinical presentation, imaging findings, interventional procedure details, and follow-up outcomes. Additionally, a focused literature review of reported SRAP cases between 2000 and 2024 was performed using PubMed-indexed publications to evaluate etiology, management strategies, and outcomes.

Results: An 82-year-old male presented with acute massive rectal bleeding. His medical history included hypertension, coronary artery disease, previous coronary artery bypass grafting, pacemaker implantation, and ongoing clopidogrel therapy. He reported a 3-4-year history of chronic constipation and repetitive manual rectal evacuation using a metallic spoon. CTA demonstrated a 5-mm pseudoaneurysm arising from a distal branch of the left superior rectal artery. Selective angiography confirmed the lesion, and coil embolization was successfully performed. Hemostasis was achieved without ischemic complications. The literature review identified fewer than 20 reported SRAP cases. Most were associated with trauma or iatrogenic injury. Endovascular embolization demonstrated high technical success with low complication rates, whereas surgical management was reserved for unstable patients.

Conclusion: SRAP should be considered in patients with acute rectal bleeding, particularly in the presence of chronic rectal trauma or antiplatelet therapy. CTA enables rapid diagnosis. Selective coil embolization is a safe and effective first-line treatment. Awareness of this rare entity may reduce diagnostic delay and improve outcomes.

Keywords: Superior rectal artery pseudoaneurysm, lower gastrointestinal bleeding, endovascular coil embolization, computed tomography angiography

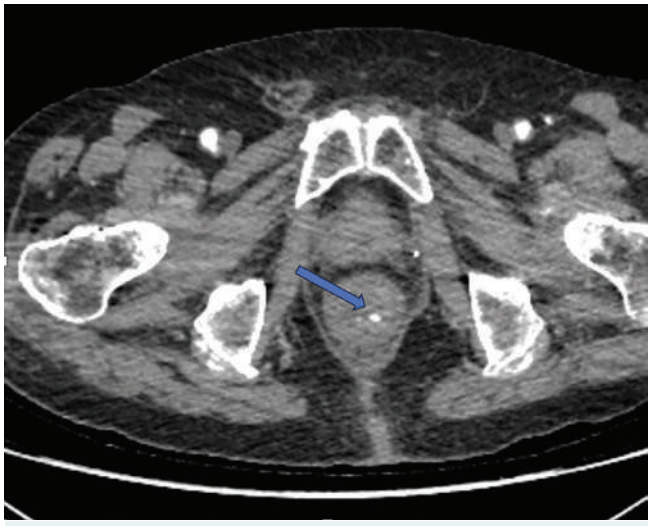

Figure 1. Contrast-enhanced CTA at admission. Demonstrating a 5-mm pseudoaneurysm arising from a distal branch of the left superior rectal artery (arrow), identified as the source of active lower gastrointestinal bleeding.

Figure 2. Pre-embolization digital subtraction angiography. Inferior mesenteric artery confirming the pseudoaneurysm in the distal branch of the superior rectal artery (arrow) prior to endovascular treatment.

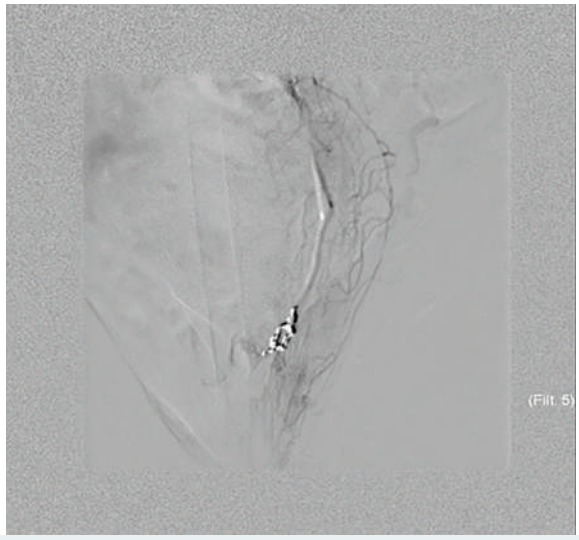

Figure 3. Post-embolization digital subtraction angiography. Complete occlusion of the pseudoaneurysm following selective coil embolization, with preservation of distal collateral perfusion and no evidence of contrast extravasation.

Rectal mass presenting at young age: Diffuse high-grade B-cell non-Hodgkin lymphoma

Gürel Neşşar, Eren Kavcı, Muhammet Emin Ceylan

University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Non-Hodgkin lymphoma (NHL) is a malignancy primarily affecting lymph nodes but capable of extranodal involvement. The gastrointestinal system is the most common extranodal site, although rectal involvement is rare and often clinically mistaken for adenocarcinoma. This case report presents diffuse high-grade B-cell NHL initially manifesting with constipation and bleeding.

Material and Methods: A 23-year-old male patient presented with lower gastrointestinal bleeding and constipation. Physical examination and colonoscopy were performed. Biopsies were obtained from the rectal lesion and sent for histopathological examination. Staging was completed with cross-sectional imaging and PET-CT. Clinical, endoscopic, pathological, and radiological findings led to diagnosis, followed by multidisciplinary tumor board evaluation of treatment options.

Results: History revealed fever, fatigue, night sweats, and 10 kg weight loss over two months. Physical examination identified multiple lymph nodes (>1 cm) in bilateral cervical, axillary, and inguinal regions. Digital rectal examination detected a posteriorly localized, mucosa-elevating, relatively smooth-surfaced, bleeding mass occupying half the lumen in the lower and middle third of rectum. Tumor marker CA 125 was elevated (62 U/mL, n <30). Computed tomography revealed multiple enlarged lymph nodes in thoracic, abdominal, and pelvic regions, with an approximately 11 cm mediastinal mass lesion consistent with widespread lymphomatous involvement. Rectal protocol MRI staged the tumor as cT4bN2bM1. Histopathological examination of biopsy material showed diffuse infiltration by atypical lymphoid cells. Immunohistochemical analysis confirmed high-grade B-cell NHL diagnosis, and the patient was referred to medical oncology.

Conclusion: Presentation of diffuse high-grade B-cell NHL as a rectal mass in young patients is extremely rare. This case emphasizes that lymphoma should be considered in the differential diagnosis of rectal tumors.

Keywords: Non-Hodgkin lymphoma, rectal neoplasm, lower gastrointestinal bleeding

A rare diagnostic dilemma after breast-conserving surgery: Differential diagnosis of titanium clip-induced hypersensitivity reaction and radiation dermatitis

Hakan Ataş[1], Eda Nural[2]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[2]*Clinic of General Surgery, Kahramanmaraş State Hospital, Kahramanmaraş*

Objective: Marking the tumor bed with titanium clips following breast-conserving surgery (BCS) is a standardized procedure to facilitate accurate target volume definition and precision of the boost dose in adjuvant radiotherapy (RT). Titanium is widely preferred in medical implants due to its biocompatibility and favorable biomechanical properties. However, emerging literature suggests that these clips may trigger localized type IV delayed-type hypersensitivity reactions, particularly in patients with nickel cross-reactivity or specific metal sensitivities. The clinical presentation often overlaps with post-RT radiation dermatitis or cellulitis, posing a significant diagnostic challenge for clinicians.

Material and Methods: A 62-year-old female patient presented with a 17 mm mass in the lower-inner quadrant of the right breast. Following BCS and sentinel lymph node biopsy, histopathological analysis revealed a stage I (pT1N0M0) mixed invasive ductal carcinoma with a 90% mucinous component (ER+, PR+, CerbB2: +1). Four titanium clips were placed in the excision cavity during surgery. The patient, who reported a history of contact dermatitis to non-gold metals, received hypofractionated RT (40 Gy in 15 fractions to the whole breast plus a 10 Gy boost) starting four weeks post-surgery. Following RT, persistent erythema, induration, and increased local temperature were observed at the operative site.

Results: Initial treatments targeting radiation dermatitis and infection, including topical/systemic steroids and antibiotics, yielded no clinical improvement. Subsequent dermatological evaluation via patch testing revealed a strong positive reaction to nickel sulfate. The clinical condition was interpreted as a secondary allergic reaction to the titanium clips (possibly due to trace nickel content or titanium itself). Consequently, surgical intervention was planned. The clips were localized using stereotactic wire guidance and surgically excised. Postoperatively, the patient's symptoms rapidly regressed, and complete clinical resolution was achieved. The patient remains on hormonal therapy (letrozole).

Conclusion: This case underscores the necessity of a multidisciplinary approach in managing chronic skin reactions following BCS. In cases of "radiation dermatitis" that remain refractory to standard therapies and are localized to the surgical site, hypersensitivity to implanted metallic materials must be considered in the differential diagnosis. For patients with a known history of metal allergy, utilizing biopolymer clips or alternative marking techniques during surgical planning may minimize the risk of such complications.

Keywords: Breast cancer, titanium clip hypersensitivity, nickel allergy, radiation dermatitis, surgical excision

Figure 1. Clinical appearance of marked erythema and local inflammation in the surgical field following radiotherapy, refractory to standard treatments.

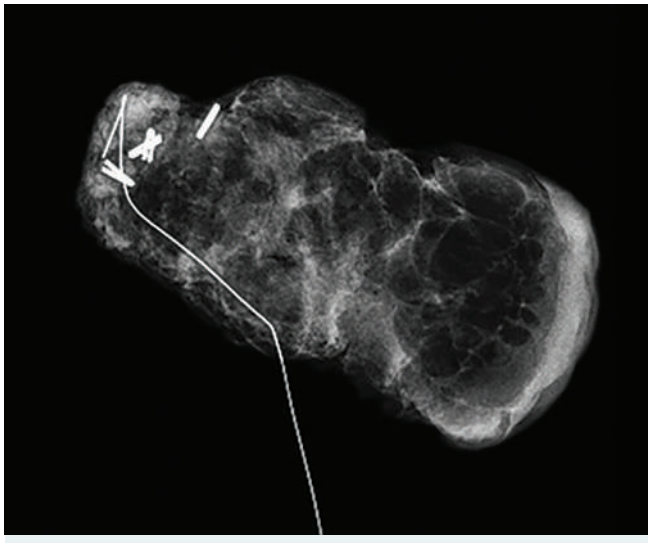

Figure 2. Mammographic image showing stereotactic wire localization of the titanium clips for surgical excision as the source of the allergic reaction.

Gastric fistulization into a mastectomy site: A rare and challenging clinical entity

Alper Varman, Ömer Kişi, Arslan Hasan Kocamaz

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: Gastrocutaneous fistulas are rare but serious complications typically associated with surgery, malignancy, or interventional procedures. A gastro-mammary fistula draining into a mastectomy site represents an exceptionally rare clinical entity. We present an unusual case with a complex clinical course.

Material and Methods: An 81-year-old female patient underwent modified radical mastectomy for invasive breast cancer approximately 4.5 years earlier, followed by adjuvant chemotherapy and radiotherapy. About 1.5 years prior, percutaneous radiofrequency ablation was performed for liver metastasis. Following the procedure, the patient experienced recurrent hospitalizations due to abdominal pain and abscess formation at the mastectomy site. During the most recent admission, discharge resembling gastric contents was observed from the mastectomy site. Contrast-enhanced computed tomography demonstrated a fistulous tract between the stomach and the mastectomy scar region. The patient was transferred to the general surgery department and evaluated in a multidisciplinary setting.

Results: Due to advanced age and comorbidities, endoscopic management was initially preferred. Endoscopic clipping of the internal fistula opening was attempted but was unsuccessful. Subsequently, placement of a percutaneous endoscopic gastrostomy tube through the fistula tract was performed to achieve controlled fistula drainage; however, leakage persisted. Surgical intervention was therefore undertaken, consisting of gastric wedge resection and wound debridement. On postoperative day three, the patient developed sudden cardiac arrest and was declared deceased despite resuscitative efforts.

Conclusion: Gastro-mammary fistula is an extremely rare and challenging clinical condition. Prior surgical history and interventional procedures may contribute to fistula development. Advanced age and comorbidities significantly influence treatment decisions. A multidisciplinary approach is essential in the management of such atypical fistulas.

Keywords: Gastrocutaneous fistula, breast cancer, radiofrequency ablation

Occult papillary thyroid carcinoma lymph node metastasis detected during surgery for tertiary hyperparathyroidism: A case report

Aysel Beyza Mavi Yıldız, Beyza Sümeyya Budak, Halil Yıldız, Yunus Emre Başpınar, Emre Kocabaş, Adam Uslu

Department of General Surgery and Organ Transplantation, University of Health Sciences Türkiye, İzmir City Hospital, İzmir

Objective: Papillary thyroid carcinoma (PTC) is generally a malignancy with a favorable prognosis; however, in some cases, it may present with lymph node metastasis without a clinically detectable primary tumor. Particularly in immunosuppressed patients, the tumor biology has been reported to exhibit a more aggressive course. The detection of occult PTC during neck surgeries performed for tertiary hyperparathyroidism is extremely rare. In this case report, we present a PTC lymph node metastasis incidentally identified within parathyroidectomy specimens in a renal transplant recipient.

Material and Methods: A 43-year-old female patient had a history of cadaveric renal transplantation in January 2025. She was diagnosed with tertiary hyperparathyroidism due to persistent hypercalcemia refractory to medical therapy and markedly elevated parathyroid hormone levels. High-resolution thyroid ultrasonography demonstrated a 5×4 mm hypoechoic nodule with punctate microcalcifications in the right thyroid lobe, categorized as TIRADS 7. Parathyroid scintigraphy revealed a hyperfunctioning parathyroid lesion located in the inferior region of the left thyroid lobe, consistent with parathyroid adenoma or hyperplasia. The patient subsequently underwent subtotal (3/4) parathyroidectomy with concomitant excision of the thyrothymic ligament.

Results: Histopathological examination revealed parathyroid hyperplasia in the right superior and left parathyroid glands. In the tissue specimens labeled as the right inferior parathyroid gland, four metastatic lymph nodes were identified, the largest measuring 5 mm in diameter. The lymph nodes exhibited morphological features consistent with PTC, including the presence of psammoma bodies, and extranodal extension was observed in one lymph node. An additional lymph node containing psammomatous calcifications within the thyrothymic ligament was also considered metastatic. Immunohistochemical analysis demonstrated positivity for TTF-1 and HBME-1. Postoperative histopathological evaluation revealed that the specimen submitted as the right inferior parathyroid gland contained metastatic lymph nodes. Additionally, a lymph node identified within the thyrothymic ligament specimen exhibited psammomatous-type calcifications and was therefore considered metastatic. Hyperfunctioning parathyroid tissue is observed in the area corresponding to the left inferior parathyroid lodge.

Conclusion: Although central lymph node metastasis is not uncommon in cases of occult PTC, the presence of multiple metastatic lymph nodes with extranodal extension in the absence of an identifiable primary tumor is noteworthy. In renal transplant recipients, chronic immunosuppression has been implicated in the development of more aggressive tumor biology in differentiated thyroid carcinomas, potentially contributing to advanced nodal disease at presentation. This case underscores the critical importance of meticulous histopathological examination of all surgical specimens obtained during surgery for tertiary hyperparathyroidism and highlights that occult thyroid malignancies in immunosuppressed patients may present with clinically significant metastatic disease.

Parathyroid adenoma arising from autotransplanted tissue: A rare cause of primary hyperparathyroidism

İlgiz Tüzken[1], Mustafa Anıl Turhan[2], İrem Şeker[1], Ayşegül Gürsoy Çoruh[3], Mustafa Şahin[4], Volkan Genç[1]

[2]*Clinic of General Surgery, Memorial Ankara Hospital, Ankara*

[3]*Department of Radiology, Ankara University Faculty of Medicine, Ankara*

[4]*Department of Endocrinology and Metabolism, Ankara University Faculty of Medicine, Ankara*

Objective: Primary hyperparathyroidism (PHPT) is most commonly caused by a solitary parathyroid adenoma and is characterized by hypercalcemia and elevated parathyroid hormone levels. Parathyroid autotransplantation is frequently performed during thyroidectomy when gland perfusion is compromised in order to prevent permanent hypoparathyroidism. Although autotransplanted parathyroid tissue may remain viable and functional for many years, adenoma formation in grafted tissue is extremely rare. Most reported cases in the literature are associated with secondary hyperparathyroidism or multiple endocrine neoplasia syndromes. The aim of this study is to present a case of PHPT caused by an adenoma arising from autotransplanted parathyroid tissue approximately three decades after thyroid surgery.

Material and Methods: Clinical, laboratory, radiological, and surgical findings of a 60-year-old female patient presenting with hypercalcemia and elevated parathyroid hormone levels were retrospectively evaluated. The patient had previously undergone total thyroidectomy and parathyroid autotransplantation for multinodular goiter. Neck ultrasonography, Tc-99m sestamibi scintigraphy, and four-dimensional computed tomography (4D-CT) were used for lesion localization. Intraoperative PTH monitoring and histopathological findings were analyzed following surgical treatment.

Results: Initial ultrasonography and sestamibi scintigraphy were inconclusive. 4D-CT demonstrated a small arterially enhancing lesion adjacent to the right strap muscles. Targeted ultrasonography confirmed the lesion. Minimally invasive parathyroidectomy was performed under intraoperative ultrasonographic guidance. Intraoperative PTH levels decreased from 318 pg/mL to 70 pg/mL, indicating adequate resection. Histopathological examination confirmed a parathyroid adenoma arising from autotransplanted tissue. Postoperatively, serum calcium and PTH levels normalized, and the patient's symptoms improved.

Conclusion: Adenoma formation in autotransplanted parathyroid tissue is a rare but important cause of PHPT and may occur decades after thyroidectomy. Careful evaluation of prior surgical history and autotransplantation sites is essential in patients with unexplained hyperparathyroidism. Advanced imaging modalities such as 4D-CT can facilitate localization of atypically located parathyroid lesions and contribute to accurate surgical planning.

Keywords: Primary hyperparathyroidism, parathyroid autotransplantation, parathyroid adenoma

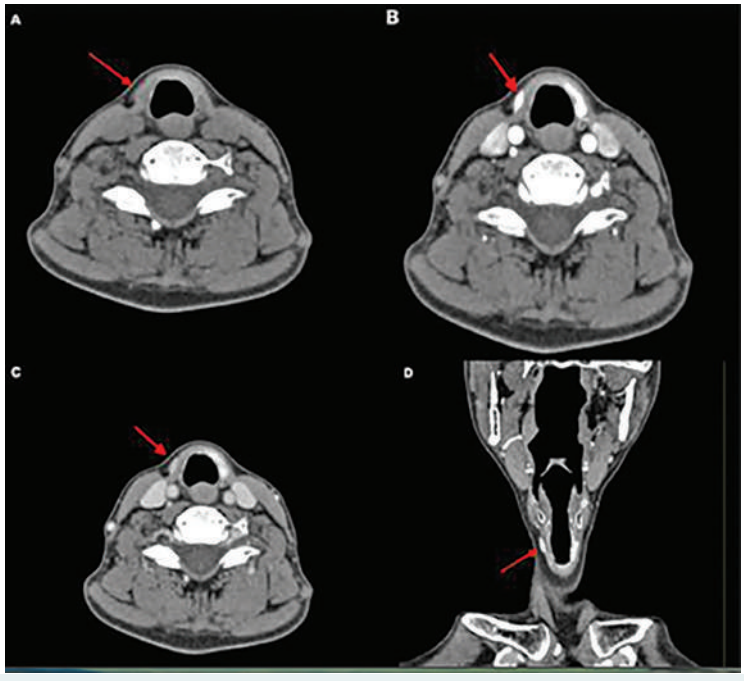

Figure 1. Four-dimensional contrast-enhanced CT imaging of the neck. (A) Non-contrast axial image shows an isodense fusiform lesion. (B) Axial arterial-phase images demonstrate a well-defined, avidly enhancing 7×5 mm lesion located anterior to the strap muscles. (C) The lesion exhibits a washout pattern on venous-phase images. (D) The arterial-phase coronal reconstructed image demonstrates an arterially hyperenhancing, tear-drop-shaped lesion located adjacent to the strap muscles, consistent with an autotransplanted parathyroid adenoma.

Laparoscopic cholecystectomy in a patient with situs inversus: Case report

Zeynel Cem Erbay, Zelal Zengin, Anıl Tugay Özcan, Ertuğrul Filiz, Şiyar Ersöz

Ankara University Faculty of Medicine, Ankara

Objective: Situs inversus totalis (SIT) is a rare congenital anomaly characterized by the mirror-like arrangement of thoracic and abdominal organs. Its incidence is reported to be approximately 1/5,000-20,000. This variation presents significant challenges, particularly in terms of orientation and ergonomics during surgery. In this study, we aimed to share our experience with laparoscopic cholecystectomy in a patient diagnosed with SIT on the background of the rare Kartagener syndrome, along with a review of the literature.

Material and Methods: A 66-year-old female patient with Kartagener syndrome (situs inversus, chronic sinusitis, bronchiectasis) presented to our clinic with complaints of abdominal pain in the left upper quadrant radiating to the back after meals. Ultrasonography confirmed cholelithiasis and the location of the gallbladder in the left upper quadrant. The patient's laboratory findings were normal. Elective cholecystectomy was planned for the patient. The operation was performed with the surgical tower and ports positioned to create a mirror image of standard laparoscopic cholecystectomy. Critical visibility was achieved by following safe cholecystectomy steps. The cystic artery and cystic duct were safely dissected and clipped, and the gallbladder was removed without any complications. No biliary tract variation anomalies were observed during the operation. No complications developed in the postoperative period. Port entry points video presentation of laparoscopic cholecystectomy performed on a patient with SIT.

Results: Laparoscopic cholecystectomy in the presence of SIT is technically challenging, especially for right-handed dominant surgeons. Various port placement and surgeon positioning strategies have been described in the literature, including mirror-image American and French techniques. Khanzada et al. reported that mirror-image positioning of the surgical team and ports improved operation time and ergonomics. In a series of 12 cases by Jani et al., the modified French technique was shown to be safe and effective; with technical adaptations, complication rates were similar to those in patients with normal anatomy. In our case, cholecystectomy was planned according to the American technique; despite the confusion and difficulty caused by the mirror image during the operation, the surgery was completed without complications, meeting all the requirements for safe cholecystectomy.

Conclusion: In conclusion, laparoscopic cholecystectomy, while technically challenging, is a safe treatment option for patients with SIT. However, detailed preoperative evaluation, appropriate surgical modifications and strategic port placement, adherence to surgical principles, and adaptability are critical for successful surgery. When performed by experienced teams, clinical outcomes similar to those seen in patients with normal anatomy can be achieved in SIT patients.

Hepatic hydatid cyst fistulized to the lung: Surgical management and a multidisciplinary approach

İbrahim Üney, Yalçın Sönmez, Alperen Taş, Faik Yaylak, Ali Cihat Yıldırım, Mehmet Fatih Ekici, Nebi Acar

Kütahya City Hospital, Kütahya

Objective: Hydatid disease is an endemic zoonotic infection caused by *Echinococcus granulosus*, predominantly affecting the liver and lungs. Although hepatic hydatid cysts are often asymptomatic, rupture may result in severe and potentially life-threatening complications. Transdiaphragmatic fistulization of a hepatic hydatid cyst into the thoracic cavity and lung is a rare but highly morbid condition. In particular, type 4 hydatid cysts with atypical radiological features may lead to delayed diagnosis. The rupture mechanism is associated with prolonged pressure exerted by the cyst, diaphragmatic erosion, alterations in intrathoracic pressure, and a history of previous surgical interventions. According to the World Health Organization classification, type 4 hydatid cysts are considered degenerative and inactive; however, their solid appearance may mimic malignancy, abscesses, or other solid lesions.

Material and Methods: A 76-year-old female patient was diagnosed with indirect hemagglutination assay (IHA) positivity in 2022. Imaging findings were consistent with a type 4 hydatid cyst. The patient was evaluated by interventional radiology and deemed unsuitable for puncture-aspiration-injection-reaspiration (PAIR) therapy. Albendazole treatment was initiated, and IHA seronegativity was observed at the 6-month follow-up. No increase in cyst size was detected during routine follow-up. Three years later, the patient was hospitalized by the pulmonology department with a preliminary diagnosis of pneumonia. Due to clinical deterioration, thoracic computed tomography was performed, revealing fistulization of the hepatic hydatid cyst into the thoracic cavity. The patient was referred to our department and underwent emergency surgery. Multiloculated cystic lesions are observed within the lung parenchyma in the right hemithorax, adjacent to the diaphragm. Cystic structures are present in the basal segments of the right lower lobe, accompanied by surrounding parenchymal changes. Disruption of diaphragmatic integrity and the presence of an inserted thoracic tube are noted.

Results: The operation was performed in collaboration with the thoracic surgery department. Intraoperatively, bilious and purulent fluid was observed in the thoracic cavity. After drainage and debridement, a fistulous tract was identified on the diaphragm. The diaphragm was incised, and the hydatid cyst cavity located at the hepatic dome was debrided. A bile duct detected at the inferior aspect of the cyst cavity was sutured and closed. Postoperatively, bile leakage from the thoracic drain was observed, and endoscopic retrograde cholangiopancreatography was performed. Following the procedure, the patient's clinical condition improved, and she was discharged uneventfully after a 30-day follow-up period.

Conclusion: This case demonstrates that hydatid cysts may cause serious complications despite serological negativization over time. Therefore, clinical and radiological findings should be evaluated in conjunction with serological tests. Although PAIR is an effective treatment option in selected cases, it is generally not recommended for type 4 or complicated hydatid cysts.

Pseudopapillary neoplasia of the pancreas in childhood: Our experience with pancreatectomy

Elif Naz Ayaz[2], Muhammed Alperen Taş[1], Hüsam İbrahimoğlu[2], İbrahim Uygun[2], Faik Yaylak[1]

[1]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

[2]*Department of Pediatric Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

Objective: Solid pseudopapillary tumors of the pancreas are rare, low-grade malignant exocrine neoplasms of the pancreas. They are known in the literature as "Frantz tumors". Although they account for only 1-3% of all pancreatic tumors, they represent 70% of pancreatic tumors in children. Typically seen in patients aged 20-30 years, 20-25% of cases occur in the pediatric population. The mass grows slowly and symptoms generally appear secondary to compression. The most common symptoms are abdominal pain and a palpable mass. Tumor markers are mostly normal in blood tests. Approximately 10% of cases are incidentally detected. In this report, we present surgical approaches for two pediatric patients with incidentally detected pancreatic masses.

Material and Methods: Two patients with pancreatic masses were evaluated in these cases, where the general surgery and pediatric surgery clinics jointly managed the diagnosis, treatment and follow-up process.

Results: Case 1: A 17-year-old female patient with no known medical history presented to the outpatient clinic due to failure to gain weight. The requested abdominal ultrasound revealed a hyperechoic lesion measuring 55x52 mm in the head of the pancreas, containing solid and cystic components. The abdominal CT scan showed a 55-mm mass in the head of the pancreas with peripheral contrast enhancement. A tru-cut biopsy was planned from the mass. No complications were observed in the postoperative period. The patient was discharged on the 8th postoperative day. No recurrence was observed during follow-up at 3 years postoperatively. Case 2: A 15-year-old female patient with no known medical history presented to the outpatient clinic with abdominal pain and a palpable mass. A solid lesion measuring 90x65x107 mm in size, with heterogeneous characteristics and internal vascularization, was observed in the body-tail section of the pancreas. The patient underwent a spleen-preserving distal pancreatectomy. The patient was discharged on the 6th postoperative day. No complications were observed during the postoperative period. No recurrence was observed during the 3-month postoperative follow-up.

Conclusion: The definitive diagnosis of pancreatic pseudopapillary neoplasm is established through pathological and immunohistochemical evaluations. In immunohistochemical staining, beta-catenin, CD10, CD56, CD99, vimentin and NSE are typically positive, while chromogranin-A is negative. Surgical resection is the only effective treatment. The extent of surgical resection varies depending on the location of the mass. Five-year survival after complete resection is over 95%. Recurrence is usually seen in 6-7% of cases within the first 4 years. It most commonly metastasizes to the liver and peritoneum. Complete resection is essential for successful treatment. In the pediatric population, success rates are increasing and complication rates are decreasing thanks to a multidisciplinary team approach to the patient.

Pancreatic head adenocarcinoma in a 19-year-old patient evaluated for suspected bile duct injury

Muzaffer Çınar, Görkem Özdemir

University of Health Sciences Türkiye, Adana City Hospital, Adana

Objective: In patients presenting with jaundice, malignancies should be kept in mind as much as benign causes. Particularly in young patients, the diagnosis of pancreatic cancer can be delayed due to its rarity in this age group. This case is presented to highlight the diagnostic challenges, as the patient was initially evaluated following a cholecystectomy with a preliminary diagnosis of bile duct injury, but was subsequently diagnosed with pancreatic head adenocarcinoma.

Material and Methods: This is a retrospective review of our patient whose treatment process was completed in our clinic.

Results: A 19-year-old female patient presented with jaundice on the 4th postoperative day following a laparoscopic cholecystectomy performed at an external center. Laboratory investigations revealed elevated cholestatic enzymes and bilirubin levels of 4.73/8.59 mg/dL. MRCP and percutaneous transhepatic cholangiography showed blunt termination of the distal common bile duct. Based on these findings, the patient was operated on with a preliminary diagnosis of bile duct injury (bismuth type E). During exploration, no injury was identified; biopsies were taken from the common bile duct and the head of the pancreas. Assuming a benign stricture in the distal common bile duct, a choledochoduodenostomy was performed. Following the report of adenocarcinoma from the diagnostic tru-cut biopsies of the pancreatic head, the patient underwent a Whipple procedure (pancreaticoduodenectomy). Pathological examination revealed a moderately differentiated adenocarcinoma, 1.7 cm in diameter. Surgical margins and oncological processes are currently being followed up with evaluations from different centers.

Conclusion: The symptoms of pancreatic cancer, such as jaundice and pain, are non-specific, and diagnostic specificity is limited by clinical findings alone. This case highlights that suspicion of malignancy must always be maintained in young patients presenting with postoperative jaundice, regardless of history or age. During intraoperative processes involving a diagnostic dilemma, biopsy and frozen section examination should not be avoided, and standard surgical principles must not be compromised.

Keywords: Bile duct injury, pancreatic cancer, Whipple procedure

Primary pancreatic lymphoma: A rare case

Dilan Yıldız, Ulaş Aday, Abdulkadir Akbaş

Dicle University Faculty of Medicine, Diyarbakır

Objective: In this case report, we aim to present a patient whose treatment was completed after a mass located in the head of the pancreas, causing obstructive jaundice, and which could not be diagnosed due to a crushing artifact in the preoperative biopsy, was diagnosed as primary pancreatic lymphoma (PPL) upon histopathological examination following pancreaticoduodenectomy.

Material and Methods: PPL is a rare disease, constituting less than 1% of extranodal lymphomas and approximately 0.2-0.5% of pancreatic tumors. According to the definition by the World Health Organization, PPL is a type of extranodal lymphoma that primarily occurs in the pancreas and should be localized in the pancreas for the majority of the disease, but lymph node and distant metastases can be seen. Due to the similarity of the clinical presentation, PPL is often confused with pancreatic adenocarcinoma during the diagnostic process. Imaging methods are insufficient for definitive diagnosis; pathological examination of tissue samples obtained by methods such as percutaneous, endoscopic, and EUS-FNA is necessary. Unlike adenocarcinoma, PPL is a disease that responds well to chemotherapy and has a better prognosis. Accurate differential diagnosis is crucial to avoid unnecessary surgical interventions.

Results: A 48-year-old female patient presented with jaundice and itching. Laboratory investigations revealed cholestasis and liver function tests above normal levels, while tumor markers were within normal limits. Radiological examinations showed dilation of the intrahepatic and extrahepatic bile ducts, an 8-mm hypointense nodular appearance narrowing the lumen posterior to the distal common bile duct, and asymmetric wall thickening in the medial part of the second duodenum. ERCP was planned. Endoscopic examination revealed coarse ulcerated and irregular mucosa at the papilla level. A biopsy yielded ulcerated, inflamed papilla samples, prompting a repeat endoscopy and biopsy. This biopsy yielded ulcerated, inflamed ampulla samples showing widespread crushing artifacts. The patient, who underwent pancreaticoduodenectomy after the cholangitis subsided and cholestasis levels reached acceptable limits, was discharged with a plan for oncological treatment after the main specimen revealed diffuse large B-cell lymphoma.

Conclusion: Accurate preoperative diagnosis is critical in the management of PPL to protect the patient from unnecessary and highly morbid surgical interventions. Data presented in the literature emphasize that chemotherapy is the primary treatment for PPL and that surgical resection does not provide a significant advantage in survival; on the contrary, it increases morbidity. Therefore, in masses that may be radiologically confused with pancreatic adenocarcinoma, histopathological confirmation must be performed before a surgical decision is made.

Laparoscopic reversal of Roux-en-Y gastric bypass with conversion to sleeve gastrectomy for dumping syndrome

Yusuf Emre Altundal, Süleyman Büyükaşık, Burak Kankaya, Halil Alış

İstanbul Aydın University, Medical Park Florya Hospital, İstanbul

Objective: Roux-en-Y gastric bypass (RYGB) may be performed following sleeve gastrectomy (SG) due to mechanical complications or severe food intolerance. However, RYGB itself may lead to significant postoperative complications such as dumping syndrome, hypoglycemia, and impaired quality of life. Reversal (takedown) of RYGB with restoration of restrictive anatomy represents a rarely reported and technically demanding revisional bariatric procedure. We present a case of laparoscopic RYGB reversal with conversion to SG performed for severe dumping syndrome.

Material and Methods: A 20-year-old male underwent laparoscopic SG in 2020 at an external center. Postoperatively, he developed reflux and solid food intolerance. In 2022, a laparoscopic revision (twist correction and partial bridectomy) was performed; however, symptoms persisted. In 2023, endoscopic and radiological evaluations revealed a stricture at the level of the incisura angularis, and an open RYGB was performed. Severe postoperative dumping syndrome subsequently developed, and the patient was referred to our center. Due to persistent and quality-of-life–limiting dumping symptoms, revisional surgery was planned and performed in 2025. During laparoscopic exploration, the gastrojejunostomy was carefully dissected and divided, the Roux limb was excluded, and intestinal continuity was preserved. The gastric pouch and remnant stomach were mobilized, and a stapled gastro-gastrostomy was created using a linear stapler to restore restrictive sleeve anatomy. During laparoscopic RYGB reversal, a gastro-gastrostomy anastomosis is created between the gastric pouch and the remnant stomach using a circular stapler. This technique restores the restrictive sleeve anatomy. Following the detection of a gastro-gastrostomy leak on postoperative day 9, an internal drainage catheter was placed endoscopically. After radiological confirmation of leak resolution, the catheter was removed endoscopically at 6 weeks.

Results: On postoperative day 9, drainage of oral intake through the surgical drain was observed. Endoscopic evaluation revealed a 0.5-1 cm defect at the gastro-gastrostomy site. A bariatric stent was initially placed but removed on postoperative day 2 due to intolerance. Internal drainage was subsequently established using a double-J catheter. Clinical and radiological follow-up demonstrated progressive resolution of the leak. After radiological confirmation of fistula closure, the catheter was removed endoscopically at 6 weeks. The patient achieved full oral intake with marked improvement of dumping symptoms and remained clinically stable during follow-up.

Conclusion: Reversal of RYGB with conversion to SG may be considered in selected patients with severe dumping syndrome. Anastomotic leakage remains a significant complication in such complex revisional procedures; however, it can be managed with appropriate advanced endoscopic interventions. Careful surgical planning and experience are essential in complex revisional bariatric surgery.

Keywords: Roux-en-Y gastric bypass reversal, conversion to sleeve gastrectomy, anastomotic leakage

Acute splenic torsion following sleeve gastrectomy: Laparoscopic splenopexy-a case report

Oğuzhan Hakan Topgül, Osman Sıbıç

University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, İstanbul

Objective: Splenic complications following sleeve gastrectomy are rare and may result from disruption of splenic suspensory ligaments, leading to abnormal splenic mobility, venous congestion, and torsion.

Material and Methods: A 31-year-old woman with a history of sleeve gastrectomy presented with acute onset left upper quadrant abdominal pain of one-day duration. Laboratory evaluation revealed normal liver and renal function tests, normal coagulation parameters, and normal complete blood count values except for mild elevation of acute-phase reactants. Previous imaging demonstrated chronic splenomegaly without torsion. Extensive etiological investigations for splenomegaly were unremarkable. Contrast-enhanced computed tomography revealed newly developed acute anterior splenic torsion associated with focal ischemic changes, splenic vein tortuosity, free fluid, and collateral vessels consistent with left-sided portal hypertension.

Results: Laparoscopic meshless splenopexy using a preperitoneal pouch technique was successfully performed for symptomatic relief. The postoperative course was uneventful, with resolution of pain and radiologic improvement.

Conclusion: Acute splenic torsion with ischemic changes may occur on a background of chronic splenomegaly after sleeve gastrectomy. In patients with preserved splenic viability, laparoscopic splenopexy represents a safe and effective spleen-preserving alternative to splenectomy.

Keywords: Splenic torsion, sleeve gastrectomy, laparoscopic splenopexy

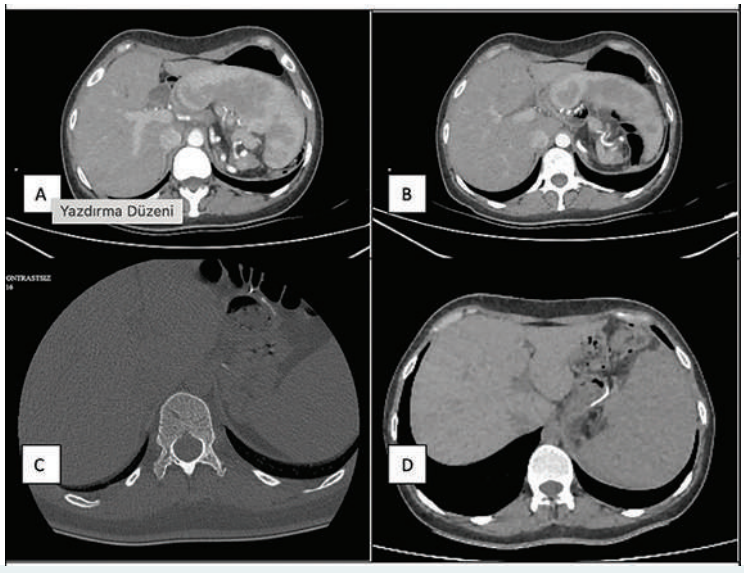

Figure 1. Radiologic findings before and after laparoscopic splenopexy. (A) Preoperative contrast-enhanced CT demonstrating anterior displacement of the spleen with heterogeneous parenchymal enhancement and patchy ischemic areas consistent with acute splenic torsion. (B) Preoperative CT showing a tortuous splenic pedicle and distorted splenic vessels, suggestive of vascular twisting and venous outflow obstruction. (C) Contrast-enhanced CT performed two years earlier demonstrating splenomegaly with the spleen located in its normal anatomical position, without evidence of torsion or vascular distortion. (D) Postoperative CT demonstrating restoration of the spleen to its normal anatomical position with reduction of the previously observed patchy parenchymal changes. The spleen remains enlarged but shows improved homogeneous enhancement.

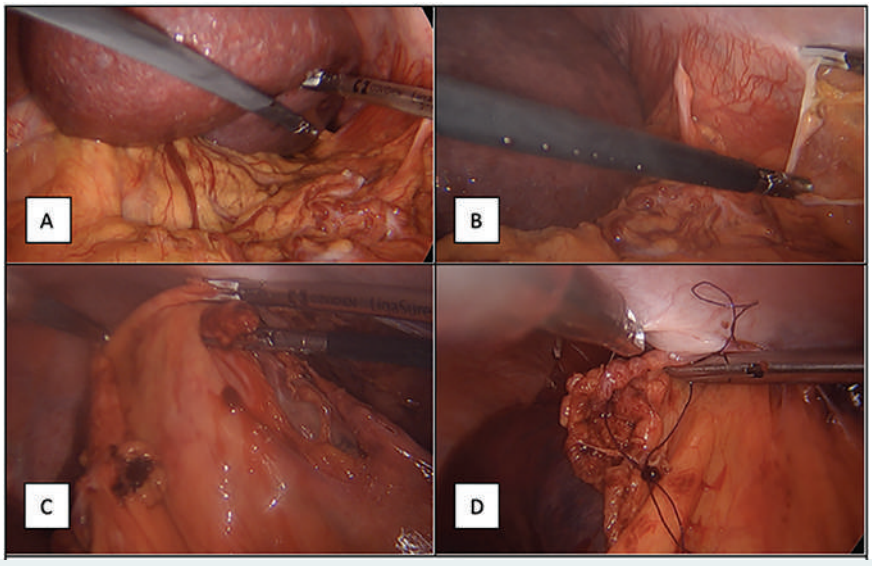

Figure 2. Intraoperative steps of laparoscopic splenopexy. (A) Intraoperative view demonstrating splenomegaly with ischemic discoloration of the splenic parenchyma. Prominent collateral vessels secondary to impaired splenic venous perfusion are visible around the spleen. (B) Creation of the preperitoneal flap for splenic fixation. (C) Placement of the spleen into the preperitoneal pouch after adequate flap mobilization. (D) Closure of the preperitoneal flap using absorbable sutures to secure the spleen in its anatomical position.

[P-072]

A case of gastric perforation presenting with silent abdomen and massive pneumoperitoneum

Edip Akpınar, Onur Yorgun, Görkem Müjde

Department of General Surgery and Organ Transplantation, Adana Faculty of Medicine; University of Health Sciences Türkiye, Adana City Hospital, Adana

Objective: Gastric perforation, classically known as "board abdomen," is an acute surgical emergency presenting with severe peritonitis. However, perforations occurring in atypical locations due to chronic non-steroidal anti-inflammatory drug (NSAID) use can present with unusual clinical outcomes. This case report describes a clinically asymptomatic case of gastric perforation due to NSAID use.

Material and Methods: Patients presenting to our hospital's tertiary emergency department undergo diagnostic, imaging, and specialist evaluation processes. After their treatment is determined, they are admitted to the relevant department if deemed necessary, and their final treatment, including surgery, is carried out.

Results: Case Report: A 32-year-old female patient presented to the main ward with complaints of significant abdominal distension and weakness. Physical examination revealed a very pale appearance, but no signs of acute illness such as tachycardia, dyspnea, or the need for positioning; vital signs were within physiological limits. Detailed history revealed chronic use of naproxen. Abdominal examination showed distension and tympanic sounds; however, no tenderness or pain was felt on palpation. Laboratory tests revealed a very low hemoglobin level (3.5 g/dL), indicating chronic anemia. Blood transfusions were initiated, and further imaging studies were planned to elucidate the etiology of the abdominal distension. Radiographic examination revealed widespread free air. Oral contrast imaging was repeated; however, no contrast leakage was observed in the peritoneal cavity, so surgery was not initially planned; the patient was kept under observation. During the follow-up period, it was observed that the pneumoperitoneum gradually increased within 6-8 hours and spread to the subcutaneous tissue of the chest and trunk. Due to this progressive condition, a decision was made to perform a diagnostic abdominal surgery (laparotomy). During the laparotomy, a hole (perforation) of approximately 5 mm in size was found on the anterior surface of the gastric fundus, and it was understood that this was the source of the massive air. There was no sign of chronic ulceration in this area of the stomach. The perforation was partially closed by the spleen. This perforation was closed with an omental patch, the abdomen was cleaned, and the surgery was concluded. The patient recovered within 3 days, started oral food intake, and was discharged from the hospital.

Conclusion: Inappropriate NSAID use can lead to atypical gastric perforations, causing unusual clinical presentations. Excessive pneumoperitoneum and subcutaneous emphysema may be indicators of this condition. This case highlights how important progressive radiological findings are for intervention decisions, even in the absence of classic symptoms.

Repair of an incarcerated scrotal hernia in an adult dwarf patient with type IV mucopolysaccharidosis (Morquio syndrome) using open preperitoneal Nyhus procedure: A case report

Sadık Peker, Ali Bekraki, Ali Levent Işık

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Type IV mucopolysaccharidosis (Morquio syndrome) is a rare metabolic disorder characterized by skeletal dysplasia, short stature, and thoracic deformities. The incidence of Morquio syndrome ranges from 1 in 250,000 to 1 in 1,000,000 live births. In these patients, the choice of anesthesia and surgical approach presents significant challenges due to skeletal, thoracic, abdominal, and cardiac abnormalities. When surgical intervention is required, laparoscopic abdominal surgery may not always be feasible. In the present case, the patient was admitted for emergency surgery with a preliminary diagnosis of incarcerated scrotal hernia, and mesh repair was performed using a preperitoneal approach through a lower midline abdominal incision.

Material and Methods: A 44-year-old immobilized male patient with a diagnosis of type IV mucopolysaccharidosis presented to the emergency department with constipation for one week and abdominal distension and pain for three days. The patient reported nausea without vomiting. His medical history included hip arthroplasty, tympanoplasty, and spinal surgery. On physical examination, the patient, who was 80 cm in height and weighed 22 kg, had a distended abdomen and an incarcerated left scrotal hernia, which was irreducible. Computed tomography revealed markedly dilated ileal loops, and ileus was diagnosed. A nasogastric tube was inserted and emergency surgery was planned. Due to anatomical and respiratory characteristics, a laparoscopic approach was considered inappropriate. The abdomen was entered through a lower midline incision and the cecum and ileal loops herniated into the scrotum were reduced into the abdominal cavity. Colon and small bowel loops were viable with preserved perfusion. The preperitoneal space was accessed through the same lower midline incision, the hernia sac was reduced, and mesh repair was performed using an open preperitoneal technique. The operation was completed without complications.The postoperative course was uneventful, and the patient was followed for six days and discharged in stable condition.

Results: In patients with type IV mucopolysaccharidosis, laparoscopic surgery and general anesthesia may carry a high risk due to short stature, thoracic deformities, and airway difficulties. The literature contains a limited number of reports regarding complicated hernia repair in this patient population. The open preperitoneal approach provides a safe and effective alternative in cases where laparoscopy is not feasible.

Conclusion: Surgical management of complicated hernias in patients with type IV mucopolysaccharidosis requires special consideration. The midline preperitoneal approach is a useful and effective technique for incarcerated scrotal hernias and allows bowel resection to be performed through the same incision when necessary. In cases where laparoscopy is not feasible, open preperitoneal mesh repair can be safely performed.

Keywords: Midline preperitoneal repair, incarcerated inguinal hernia, mucopolysaccharidosis type IV

Living-donor liver transplantation for liver-confined colorectal cancer metastases: A case with long-term follow-up

Cenk Şimşek, Murat Dayangaç, Onur Yaprak

Medipol Mega University Hospital, İstanbul

Objective: Surgical resection is the cornerstone of curative treatment for colorectal liver metastases. Nevertheless, despite advances in modern systemic chemotherapy, targeted agents, immunotherapy strategies, and liver-directed therapies, a considerable proportion of patients eventually develop unresectable disease. This challenge is particularly evident in patients with metastases confined to the liver who no longer have effective surgical options. In recent years, liver transplantation has gained increasing attention as a potentially curative strategy in highly selected patients. This report presents the detailed clinical, surgical, and oncologic outcomes of a patient with long-standing liver-confined colorectal cancer metastases treated with living-donor liver transplantation (LDLT).

Material and Methods: A 33-year-old woman was diagnosed with colon adenocarcinoma following emergency subtotal colectomy for acute intestinal obstruction and gastrointestinal bleeding in 2019. Pathological staging revealed pT3N2 disease. Initial staging demonstrated multiple liver-confined metastases without extrahepatic spread. The patient underwent systemic chemotherapy and targeted therapy followed by multisegmental liver metastasectomies and local ablative treatments, achieving disease control for approximately three years. In 2023, isolated intrahepatic recurrence occurred. Due to insufficient future liver remnant and intolerance to further chemotherapy, LDLT was planned after multidisciplinary evaluation.

Results: LDLT using a right-lobe graft was performed in May 2023. The surgical procedure included partial inferior vena cava resection and diaphragmatic resection. Postoperative recovery was uneventful, with satisfactory early graft function. No episodes of acute or chronic rejection, vascular complications, or severe infections were observed during follow-up. The patient was maintained on standard immunosuppressive therapy and enrolled in a strict oncologic surveillance program. Serial assessments included liver function tests, tumor markers, and cross-sectional imaging. At the most recent follow-up on January 2, 2026, all laboratory parameters were within normal ranges, and imaging studies demonstrated no evidence of intrahepatic recurrence or extrahepatic metastasis, indicating sustained complete remission.

Conclusion: LDLT may provide durable disease-free survival incarefully selected patients with liver-confined colorectal cancer metastases. Key advantages of the living-donor approach include optimal timing without waiting-list progression, the ability to select recipients with favorable tumor biology, and predictable graft availability. High donor safety standards, rapid postoperative recovery, and close oncologic surveillance further support the feasibility of this strategy. Meticulous patient selection, comprehensive staging, multidisciplinary decision-making, and structured long-term follow-up are essential to achieve favorable outcomes.

Keywords: Colorectal cancer, liver metastasis, long term survival

Management of incidental Meckel's diverticulum detected during colon adenocarcinoma surgery: A case report and literature review

Orhan Tatlı, Abdülaziz Emek, Mehmet Furkan Avcı, Sertaç Ata Güler, Turgay Şimşek

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Meckel's diverticulum (MD) is the most prevalent congenital anomaly of the gastrointestinal tract, arising from the incomplete obliteration of the omphalomesenteric duct. While it is a true diverticulum involving all layers of the intestinal wall, the necessity of surgical resection for asymptomatic MD discovered incidentally during unrelated procedures remains a subject of ongoing debate in the literature.

Material and Methods: A 75-year-old male patient presented with a six-month history of abdominal pain and rectal bleeding. Following a diagnosis of sigmoid colon adenocarcinoma, a laparotomy was performed. Intraoperative exploration revealed an ulcerovegetative mass in the sigmoid colon and an incidental, asymptomatic, broad-based MD, approximately 6 cm in length, located 60 cm proximal to the ileocecal valve. Localized adhesions suggested prior subclinical inflammatory episodes. Following an oncological anterior resection, a segmental small bowel resection with primary anastomosis was performed for the MD. This decision was based on the patient's advanced age and the anticipated initiation of adjuvant chemotherapy; it was determined that potential MD-related complications during immunosuppression could significantly increase morbidity and disrupt the oncological treatment course. Histopathological examination confirmed colonic adenocarcinoma (11/18 positive lymph nodes) and a benign MD with no ectopic tissue or malignancy. The patient was discharged uneventfully on the fifth postoperative day.

Results: Management strategies for asymptomatic MD vary widely in the literature. While some authors advocate for resection regardless of age due to potential complications, others recommend specific criteria such as age under 50, male gender, and diverticular length exceeding 2 cm to justify surgery. Conversely, some studies suggest that prophylactic resection may unnecessarily increase postoperative complication rates.

Conclusion: This case emphasizes that surgeons must perform a meticulous whole-abdomen exploration rather than focusing solely on the primary pathology. The approach to incidental MD should be individualized. In patients facing immunosuppression due to malignancy, prophylactic resection is a reasonable and proactive strategy to prevent future complications that could jeopardize the patient's systemic treatment.

Keywords: Meckel's diverticulum, sigmoid colon adenocarsinoma, incidental resection, prophylactic resection, surgical management

Severe anal stenosis developing after pelvic radiotherapy: A rare case report

Muhammed Emre Ersü, Furkan Güngör, Abdusselam Ağcakoyun, Ömer Faruk Özkan

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Anal stenosis is a rare but clinically significant condition caused by pathological narrowing of the anal canal, leading to difficulty or inability to defecate. It most commonly results from anorectal surgery, particularly hemorrhoidectomy, while inflammatory bowel disease, infections, trauma, and rarely pelvic radiotherapy may also be responsible. Radiation-induced anal stenosis is exceptionally rare and is attributed to chronic microvascular injury, ischemia, and progressive fibrosis. Due to its rarity, diagnosis may be delayed, especially in patients without prior anorectal surgery. This report presents a case of severe anal stenosis following pelvic radiotherapy for cervical cancer and its management.

Material and Methods: A 75-year-old female patient presented with progressive constipation, pencil-thin stools, and difficulty in defecation. She had no prior history of anal or anorectal surgery. Her medical history revealed moderately differentiated squamous cell carcinoma of the cervix diagnosed by incisional tru-cut biopsy and staged as FIGO stage IB. The patient received five cycles of chemotherapy combined with pelvic radiotherapy consisting of 28 fractions, including the anal canal within the radiation field. Approximately six months after completion of radiotherapy, a marked deterioration in bowel habits was reported. Physical examination revealed a fibrotic and markedly narrowed anal verge, and digital rectal examination could not be performed due to severe stenosis. Under spinal anesthesia, evaluation demonstrated near-complete obliteration of the anal canal by dense circumferential fibrotic tissue. Controlled radial incisions were performed using unipolar electrocautery to partially widen the anal canal, without intraoperative complications.

Results: Colonoscopy performed 48 hours after the procedure revealed diffuse fecal contamination, millimetric hematomas on the colonic walls, and mucosal elevations suggestive of ulceration at 10 cm and 40 cm from the anal verge. Retroflexion demonstrated internal hemorrhoids and a fissure line at the 7 o'clock position of the anal canal. Biopsies obtained from suspicious areas showed melanosis coli without dysplasia or malignancy, excluding radiation proctitis and secondary malignancy. No early postoperative complications occurred. The patient's constipation symptoms improved significantly, and at 1-, 3-, and 6-month follow-up visits, no evidence of recurrent stenosis or need for further dilation was observed.

Conclusion: Severe anal stenosis after pelvic radiotherapy is a rare but important complication. In patients with prior radiotherapy presenting with unexplained constipation or defecation difficulty, anal stenosis should be considered. Controlled radial electrocautery incisions may provide an effective diagnostic and therapeutic option in advanced cases, and long-term management should be individualized.

Keywords: Anal stenosis, pelvic radiotherapy, cervical cancer, radiation induced fibrosis, electrocautery incision

Complicated breast abscess developing on the background of diabetic mastopathy

Doğuhan Ergazi, Aslan Mert Demirci, İrem Kartal, Muhammed Salih Süer, Turgay Sayın, Abdullah Gıyasettin Başakıncı, Hülagü Kargıcı, Serap Erel

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Diabetic mastopathy (sclerosing lymphocytic lobulitis) is a rare, benign fibroinflammatory breast disease in patients with a long history of diabetes mellitus, which can clinically and radiologically mimic malignancy. Patients typically present with a firm mass in the breast. Although infection and abscess formation are rare, the clinical course can become complicated with poor glycemic control.

Material and Methods: This study is a case report evaluating the clinical, surgical, and metabolic processes of a patient with a complicated breast infection developing on the basis of diabetic mastopathy. Clinical, laboratory, and microbiological data, along with the surgical and medical treatments, were reviewed through the patient's medical record. The diagnosis and treatment were managed with a multidisciplinary approach involving surgery, infectious diseases, and endocrinology departments. All data were anonymized and presented in accordance with ethical guidelines.

Results: A 47-year-old female patient with a long-standing history of type 2 diabetes mellitus presented with a lesion that began as an acne-like lesion in the lower quadrant of the right breast about a week ago and rapidly progressed into an abscess. In addition to type 2 diabetes, the patient had a history of hypertension, arrhythmia, allergic asthma, obstructive sleep apnea, hypothyroidism, and HPV. Despite initial topical treatment, clinical progression was observed, leading to abscess drainage in the emergency department. Due to recurrence, the patient was admitted for inpatient care. On physical examination, a necrotic, infected wound was found in the lower right breast quadrant. The patient underwent serial surgical debridements and negative pressure wound therapy was initiated. On the 21st day of linezolid therapy, initial aspirates and tissue cultures showed no growth, but later *Acinetobacter baumannii* was isolated. Given the ongoing clinical improvement, negative acute-phase reactants, and healthy wound appearance, this finding was interpreted as colonization. An endocrinology consultation revealed the patient's HbA1c was 11.7%, indicating poor glycemic control. Insulin dosages were increased to improve metabolic regulation, and the patient was noted to be at high metabolic risk for surgical interventions. A comprehensive evaluation of clinical, surgical, and metabolic data led to the conclusion that the case was consistent with a complicated breast infection developing on the basis of diabetic mastopathy.

Conclusion: Diabetic mastopathy is a rare breast disease, but it can become complicated by severe infections in the presence of poor glycemic control. This case demonstrates that a multidisciplinary approach and metabolic regulation are as important as surgical treatment in managing breast infections in diabetic patients.

Keywords: Diabetic mastopathy, negative pressure wound therapy, sclerosing lymphocytic lobulitis

[P-079]

Retroperitoneal paraganglioma as a cause of secondary hypertension: A case detected in an etiological investigation

Sadig Shakiliyev

Private Küçükçekmece Hospital, İstanbul

Objective: Paragangliomas are uncommon neoplasms arising outside the adrenal gland, often presenting with catecholamine-secreting activity that can lead to episodic attacks or resistant hypertension. In this report, we describe a case involving a retroperitoneal mass identified during the diagnostic workup for hypertension.

Material and Methods: A 52-year-old male patient was evaluated for secondary hypertension due to persistent elevation of blood pressure despite adherence to a comprehensive medical regimen with multiple antihypertensive agents. Diagnostic investigations revealed a 62 by 59 mm retroperitoneal mass adjacent to the inferior vena cava and abdominal aorta, at the level where the left renal vein exits. A paraganglioma was suspected based on imaging findings, and the case was subsequently referred to the multidisciplinary oncology council for further assessment. Preoperative preparation was completed, and a decision was made to proceed with surgical exploration.

Results: During surgery, an 8x6 cm solid mass with cystic components, surrounded by a capsule, was observed on the left renal vein, located between the vena cava and the abdominal aorta. The mass was resected along with its capsule. Histopathological examination was consistent with paraganglioma.

Conclusion: Secondary causes should be carefully evaluated in cases of resistant or unexplained hypertension. Although retroperitoneal paraganglioma is uncommon, maintaining awareness of it is essential to avoid diagnostic delays and to guide appropriate management.

Keywords: Paraganglioma, retroperitoneal mass, secondary hypertension

Gastric metastasis of breast cancer presenting with gastric outlet obstruction

Tarık Yıldız[1], Kutay Sağlam[1], Nesrin Uğraş[2]

[1]*Department of General Surgery, Bursa Uludağ University Faculty of Medicine, Bursa*

[2]*Department of Pathology, Bursa Uludağ University Faculty of Medicine, Bursa*

Objective: Breast cancer rarely metastasizes to the gastrointestinal tract; however, such involvement is more commonly observed in the invasive lobular carcinoma (ILC) subtype. Gastric metastas is often present with nonspecific symptoms and may closely mimic primary gastric malignancies, resulting in delayed or incorrect diagnosis. Gastric outlet obstruction as the initial manifestation of breast cancer metastasis is particularly uncommon. This report aims to present a rare case of gastric outlet obstruction caused by gastric metastasis of invasive lobular breast carcinoma and to emphasize the importance of clinicopathological correlation.

Material and Methods: Clinical data, endoscopic findings, radiological imaging, histopathological examination, and immunohistochemical analyses of a patient presenting with gastric outlet obstruction were retrospectively reviewed. Upper gastrointestinal endoscopy with targeted biopsies was performed. Contrast-enhanced abdominal computed tomography was used for radiological assessment. Histopathological diagnosis was established using routine hematoxylin-eosin staining and a comprehensive immunohistochemical panel to determine the origin of the tumor.

Results: A 70-year-old female patient with a history of left-sided invasive lobular breast carcinoma presented with constipation, reduced oral intake, and symptoms suggestive of gastric emptying disturbance. Upper gastrointestinal endoscopy revealed a circumferential vegetative mass extending from the antrum to the pylorus and duodenal bulb, causing marked luminal narrowing consistent with gastric outlet obstruction. Histopathological evaluation of gastric biopsies demonstrated infiltration by atypical epithelial cells with hyperchromatic nuclei and scant eosinophilic cytoplasm. Immunohistochemical analysis showed tumor cells positive for pan-cytokeratin, CK7, and GATA-3, while CK5/6, CDX2, PAX-8, and LCA were negative, supporting the diagnosis of gastric metastasis from breast carcinoma. Contrast-enhanced abdominal computed tomography revealed diffuse gastric wall thickening, a mass lesion obliterating the antropyloric lumen, and findings consistent with peritoneal carcinomatosis, including omental cake appearance and diffuse ascites. Due to progressive obstructive symptoms, the patient underwent palliative gastroenterostomy.

Conclusion: Gastric metastasis of invasive lobular breast carcinoma should be considered in patients presenting with gastric outlet obstruction, especially in those with a history of breast cancer. Differentiation from primary gastric malignancies requires careful integration of clinical history, radiological findings, and immunohistochemical profiling. Although curative surgery is not feasible in metastatic disease, palliative surgical interventions can provide effective symptom relief and improve quality of life.

Keywords: Breast cancer, gastric metastasis, gastric outlet obstruction

Cutaneous fistula developing at the intervention site following PAIR procedure in liver hydatid cyst: A case report

Namig Gahramanov, Gökhan Gazel, Mehmet Yıldırım

Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir City Hospital, İzmir

Objective: Cystic echinococcosis (CE) is a zoonotic infection caused by *Echinococcus granulosus*, typically characterized by liver involvement. The puncture, aspiration, injection, re-aspiration (PAIR) technique, developed as an alternative to surgery in the treatment of hepatic CE, is a minimally invasive method recommended by the WHO for CE1 and CE3a stages due to its short hospital stay and low cost. However, complications such as allergic reactions and biliary fistulas may develop following PAIR. Cutaneous fistulization is a very rare complication that develops along the PAIR tract and significantly affects the patient's quality of life. In this presentation, we aimed to discuss the surgical management of a resistant cutaneous fistula developing after PAIR, in the light of the literature.

Material and Methods: An eighteen-year-old female patient presented with a persistent biliary discharge from the intervention site following a PAIR procedure performed on September 8, 2025, for a hydatid cyst in the left lobe of the liver. *Echinococcus* IgG antibody testing and radiological imaging were utilized during the diagnostic process. Liver MRI revealed a cystic lesion measuring 3.5×4 cm in segments 2-3, consistent with WHO-CE2/3. MRCP showed a communication between the intrahepatic bile ducts and the cyst wall. Due to the high-output fistula that did not close with conservative methods, a decision for surgical intervention was made.

Results: During exploration, a fistula tract extending between the PAIR entry site and the cyst cavity in the left lobe of the liver was identified. During the surgical procedure, the fistula tract was completely excised, the cyst content was cleared, and the identified micro-biliary communication points were sutured. Cystectomy and omentopexy were performed to obliterate the cyst cavity and prevent recurrence. The patient, whose skin discharge ceased and biliary drainage stopped during the postoperative period, was discharged without complications.

Conclusion: PAIR complications range from 5-25%, yet cutaneous fistulas remain rare. Etiopathogenesis involves high intracystic pressure, back-flow induced necrosis, and short needle tracks. Primarily, missed micro-biliary communications redirect bile toward the tract. MRCP is diagnostic. While percutaneous drainage suits low-output cases, radical surgery like cystectomy with omentopexy definitively treats high-output biliary fistulas. Despite PAIR's minimal invasiveness, high-morbidity complications require prompt surgical consideration.

Keywords: Cutaneous fistula, cystic echinococcosis, PAIR complications

Post-robotic Ivor Lewis esophagectomy nursing care: A case report

Hatice Tekin, Ayşegül Akar, Şahide Demir

Hacettepe University Faculty of Medicine, Ankara

Objective: Surgical resection is one of the fundamental steps in curative treatment for malignancies of the esophagus and gastric cardia region. Robotic surgical techniques offer advantages such as less tissue trauma, early mobilization, and shorter hospital stay. However, close nursing care, particularly during ward monitoring after robotic esophagectomy, is crucial for respiratory function, pain management, drainage management, nutrition, bleeding risk, and infection risk. The aim of this case presentation is to demonstrate the contribution of nursing care provided during ward monitoring to patient recovery in a patient who underwent robotic Ivor Lewis esophagectomy.

Material and Methods: A 63-year-old female patient presented with complaints of epigastric pain and dysphagia; endoscopic and pathological examinations resulted in a diagnosis of adenocarcinoma located in the gastric cardia. Following neoadjuvant chemotherapy, the patient underwent robotic Ivor Lewis esophagectomy, esophagogastrostomy, and retroperitoneal lymph node dissection. The patient was monitored in the intensive care unit for two days after the operation, and after achieving hemodynamic stability, was transferred to the surgical ward.

Results: Nursing care in the ward was planned with a focus on maintaining respiratory function, drain monitoring, pain management, reducing infection risk, and early mobilization. The patient had one chest tube, one Jackson-Pratt drain, and a peripheral venous catheter. The number, color, and characteristics of the drains were monitored and recorded at regular intervals. Due to the presence of a chest tube, breath sounds, oxygen saturation, and signs of dyspnea were closely evaluated, and the patient was taught deep breathing and coughing exercises. Pain level was monitored using a numerical pain scale, and analgesic treatment was administered as ordered by the physician. Drain and catheter care was performed using aseptic techniques, and the patient was regularly evaluated for signs of infection. The patient was observed during feeding, considering the risk of aspiration, and fluid and electrolyte balance was monitored. Early and gradual mobilization was supported, and the patient was encouraged to safely resume daily activities. The patient was discharged on the 6th postoperative day. In this case, the systematic and planned implementation of ward nursing care played a significant role in preventing complications in the postoperative period.

Conclusion: Planned, holistic, structured, and individualized nursing care applied in the ward period after robotic esophagectomy offers an effective approach in preventing surgical complications and supporting the patient's safe recovery process. Effective nursing care directly supports the success of surgical treatment.

Keywords: Robotic surgery, esophagectomy, nursing care

When axillary radiotherapy reaches the eye: The cause of acute central scotoma, macular hemorrhage, and radiation-induced macular degeneration in a 70-year-old female patient with stage IIIB breast cancer

Mehmet Eren Yüksel

Surgical Critical Care Unit, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Radiotherapy is widely used in the treatment of breast cancer, and its cardiac and pulmonary toxicities are well recognized. However, although the retina is an extremely radiosensitive organ, ocular injury is rarely considered during regional radiotherapy planning.

Material and Methods: A 70-year-old female patient with stage IIIB breast cancer received adjuvant radiotherapy to the axillary region. During treatment, the ipsilateral arm was positioned in full abduction and elevation. No ocular shielding was applied during radiotherapy. Written informed consent was obtained from the patient for publication of this case report.

Results: Two years after completion of radiotherapy, the patient developed sudden onset of central visual loss in the form of an acute central scotoma. Funduscopic examination revealed a fresh macular hemorrhage. Optical coherence tomography demonstrated subretinal fluid and disruption of the retinal pigment epithelium. Fluorescein fundus angiography showed active leakage from newly formed abnormal vessels, findings consistent with choroidal neovascularization and radiation-induced macular degeneration.

Conclusion: Excessive arm elevation may have altered beam geometry and increased scatter radiation toward the orbit. In the absence of ocular protection, secondary radiation may reach the macula, leading to endothelial injury, ischemia, pathological neovascularization, and hemorrhage. This mechanism explains the delayed yet sudden visual loss observed in this patient. The retina is at risk during axillary radiotherapy. Ocular protection should be considered during treatment planning, and the potential for radiation-induced visual loss should be clearly explained to patients before the initiation of therapy.

Keywords: Axillary radiotherapy, breast cancer, macular degeneration, radiation retinopathy

Adrenal metastasis of pleomorphic sarcoma: A rare case report

Büşra Küçükateş[1], Yiğit Türk[1], Murat Özdemir[1], Özer Makay[2]

[1]*Division of Endocrine Surgery, Department of General Surgery, Ege University Hospital, İzmir*

[2]*Centre for Endocrine Surgery, Özel Sağlık Hospital, İzmir*

[3]*Aristotle University School of Medicine, Thessaloniki, Greece*

[4]*Instituto Português De Oncologia De Coimbra Francisco Gentil, Coimbra, Portugal*

Objective: Pleomorphic sarcoma is one of the most common soft-tissue sarcoma subtypes, accounting for 10-15% of malignant soft-tissue tumors. The lungs, liver, and bones are the most frequent metastatic sites, while adrenal gland metastasis is extremely rare and reported only in a few case reports. Surgical resection of isolated adrenal metastasis may offer a survival benefit in selected patients.

Material and Methods: A 49-year-old male underwent surgery in 2018 for a posteriorly located left thigh mass, which was diagnosed as high-grade pleomorphic sarcoma. After adjuvant radiotherapy, a metastatic nodule in the left lower lung lobe was resected in 2020. During follow-up, metastasis developed in the right paraspinal region and left deltoid muscle; the patient received 20 cycles of chemotherapy and achieved a complete response. Local recurrence occurred in 2022 and was surgically resected.

Results: In the second quarter of 2025, a progressive solid lesion measuring 8×6.5 cm was detected in the right adrenal gland with high FDG uptake (SUV_{max}: 9.7) on PET-CT. The patient underwent right adrenalectomy. Intraoperatively, the mass was adherent to the retrohepatic vena cava; an iatrogenic injury occurred and was repaired primarily. Pathology confirmed metastatic pleomorphic sarcoma. Postoperative follow-up for 6 months after adrenalectomy is uneventful.

Conclusion: Adrenal metastasis of pleomorphic sarcoma is extremely rare. Surgical resection of isolated adrenal lesions can provide effective local control and disease-free survival. Even in cases with invasion of major vascular structures, adrenalectomy can be safely performed in experienced centers.

Keywords: Pleomorphic sarcoma, adrenal metastasis, adrenalectomy, soft tissue sarcoma, case report

Bleeding well-differentiated gastric neuroendocrine tumor managed with a NOTES-based minimally invasive endoscopic approach: A case report

Süleyman Çoşgun[1], Eyyüp Maral[2], Derya Ünal[1], Halil İbrahim Dündar[2], Sema Köse[3], Faik Yaylak[2]

[1]*Department of Internal Medicine, Kütahya Health Sciences University Faculty of Medicine, Kütahya City Hospital, Kütahya*

[2]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya City Hospital, Kütahya*

[3]*Department of Pathology, Kütahya Health Sciences University Faculty of Medicine, Kütahya City Hospital, Kütahya*

Objective: Gastric neuroendocrine tumors (gNETs) are rare gastric neoplasms with heterogeneous biological behavior and are usually detected incidentally. Presentation with upper gastrointestinal bleeding is uncommon. Advances in therapeutic endoscopy have expanded organ-preserving options for selected patients, and NOTES-based minimally invasive concepts support effective treatment without skin incisions. We report a bleeding well-differentiated gNET successfully managed using an advanced minimally invasive endoscopic approach and highlight the importance of close surveillance.

Material and Methods: A 38-year-old woman without comorbidities was referred for upper gastrointestinal bleeding. An external center had identified a bleeding pedunculated gastric mass and recommended surgery. After multidisciplinary evaluation, minimally invasive endoscopic management was planned. Endoscopy demonstrated a ~5 cm pedunculated polypoid lesion on the greater curvature of the gastric corpus and adjacent diminutive polyps. An endoloop was placed at the stalk for preemptive hemostasis, followed by snare polypectomy with transoral retrieval. Due to suspected tumor involvement at the resection margin, a second session was performed with endoscopic mucosal resection after submucosal injection; intraprocedural arterial bleeding was controlled using hemoclips. The patient was enrolled in close endoscopic follow-up.

Results: Initial histopathology was consistent with a well-differentiated neuroendocrine tumor (Grade 1; Ki-67 2%; low mitotic activity). Specimens from the second session showed focal higher proliferation (Ki-67 5-10%), suggesting a Grade 2 component. Follow-up endoscopy at two months revealed diminutive polyps near the scar that were removed; pathology again demonstrated Grade 1 NET. No perforation or major post-procedural complications occurred, and no recurrence was observed during follow-up.

Conclusion: In bleeding well-differentiated gNETs, advanced minimally invasive endoscopic management may be a safe and effective alternative to surgery in appropriately selected patients at experienced centers. Variable Ki-67 findings across specimens suggest intratumoral heterogeneity, supporting comprehensive histopathological assessment and structured endoscopic surveillance.

Keywords: Gastric neuroendocrine tumor, minimally invasive endoscopy, upper gastrointestinal bleeding

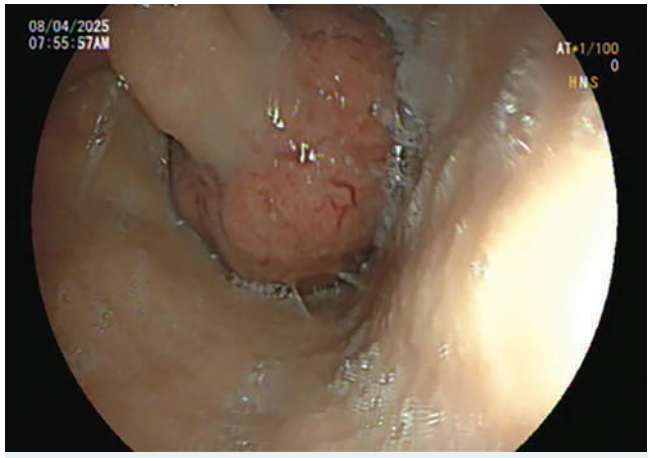

Figure 1. Endoscopic view of a giant polypoid lesion with an irregular stalk, about 5 cm in diameter, observed in the large curvature of the gastric corpus at the first gastroscopy.

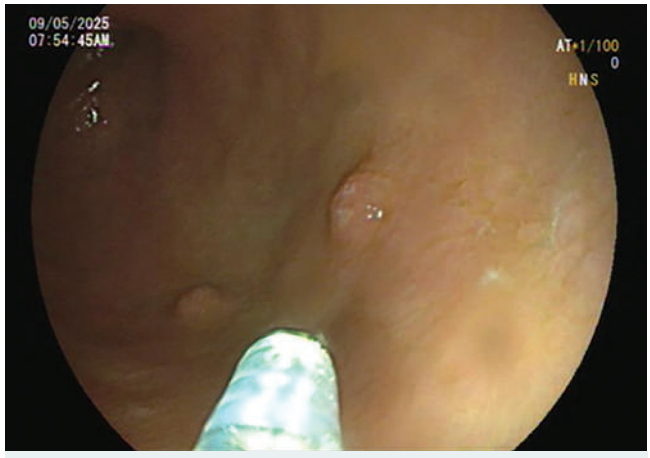

Figure 2. In the second session of gastroscopy, multiple diminutive polyps observed in and around the scar tissue showing battery convergence in the previous polypectomy area.

Unusual breast metastasis of gastrointestinal stromal tumor

Ahmed Kestir, Göksel Sarohan, Alper Parlakgümüş

University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Gastrointestinal stromal tumor (GIST) is the most common mesenchymal neoplasm of the gastrointestinal tract and is believed to originate from the interstitial cells of Cajal. Metastasis most frequently involves the liver and peritoneum. Breast metastasis is extremely rare, with only a few cases reported in the literature. We present a rare case of isolated breast metastasis from a primary gastric GIST without liver or peritoneal involvement.

Material and Methods: A 70-year-old female patient previously underwent wedge resection for a gastric GIST and received adjuvant imatinib therapy for three years. After five years of disease-free follow-up, a mass was detected in the left breast. The patient underwent breast magnetic resonance imaging (MRI), PET-CT, abdominal CT, endoscopy, and colonoscopy. A biopsy of the breast mass was performed, followed by segmental resection. Histopathological and immunohistochemical analyses were conducted.

Results: Histopathological examination of the breast mass revealed a mesenchymal neoplasm. Immunohistochemical staining demonstrated similar characteristics between the primary gastric tumor and the breast lesion, including positivity for CD117 and CD34. Systemic evaluation showed no evidence of liver or peritoneal metastasis. The findings were consistent with isolated distant breast metastasis from the primary gastric GIST.

Conclusion: Breast metastasis from GIST is an exceptionally rare clinical entity and should be considered in the differential diagnosis of spindle cell lesions of the breast, particularly in patients with a history of GIST. Immunohistochemical evaluation plays a crucial role in establishing the diagnosis. This case contributes to the literature by demonstrating isolated breast metastasis without hepatic involvement.

We made a literature review, breast metastasis from GIST have been previously described three cases (Table 1).

Thoracic wall extraskeletal Ewing sarcoma: A rare case report

Hanifi Furkan Yıldız[1], Muhammed Furkan Karadoğan[1], Hande Karabaş[1], Ayşe Daş Çerçi[2]

[1]*Viranşehir State Hospital, Şanlıurfa*

[2]*Çukurova University Faculty of Medicine, Adana*

Objective: Ewing sarcoma is predominantly a primary bone tumor; however, extraosseous involvement is rare and may clinically mimic benign soft-tissue lesions. In this report, we present the clinical, histopathological, and molecular characteristics of an extraskeletal Ewing sarcoma originating from the thoracic wall.

Material and Methods: A 21-year-old female patient presented with a rapidly enlarging subcutaneous mass in the right hypochondriac region that had progressed over a three-month period. Ultrasonographic evaluation revealed a 46×19 mm heterogeneous, hypervascular solid lesion, and surgical excision was subsequently performed. Intraoperatively, the mass was observed to extend between the intercostal muscle planes. Histopathological examination demonstrated a monomorphic population of small round cells, rosette-like structures, and areas of necrosis. Immunohistochemical analysis showed positivity for NKX2.2, while fluorescence *in situ* hybridization identified EWSR1 rearrangement with a t(22q12) translocation, supporting the diagnosis of Ewing sarcoma. The patient was referred for oncological follow-up and further treatment planning.

Results: Extraskeletal Ewing sarcomas may present as rapidly growing soft-tissue masses and encompass a broad differential diagnosis. Confirmation of the diagnosis relies on the integration of morphological findings with immunohistochemical markers and molecular analyses. Thoracic wall involvement poses additional challenges with regard to surgical planning and local disease control.

Conclusion: Ewing sarcoma should be considered in the differential diagnosis of rapidly enlarging thoracic wall masses in young patients. Early recognition and appropriate referral play a crucial role in establishing an effective and timely treatment strategy.

Keywords: EWSR1, extraskeletal Ewing sarcoma, soft tissue tumor

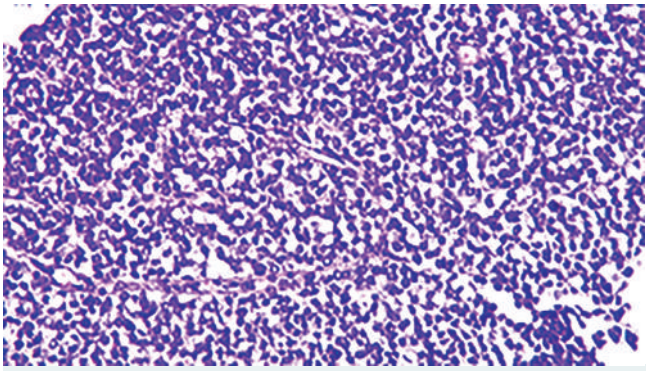

Figure 1. Histopathological features of extraskeletal Ewing sarcoma (H&E staining).

Hematoxylin and eosin–stained sections reveal a tumor composed of uniform small round cells with scant cytoplasm and round to oval nuclei. Occasional rosette-like structures and focal areas of necrosis are observed, consistent with the morphology of a small round blue cell tumor.

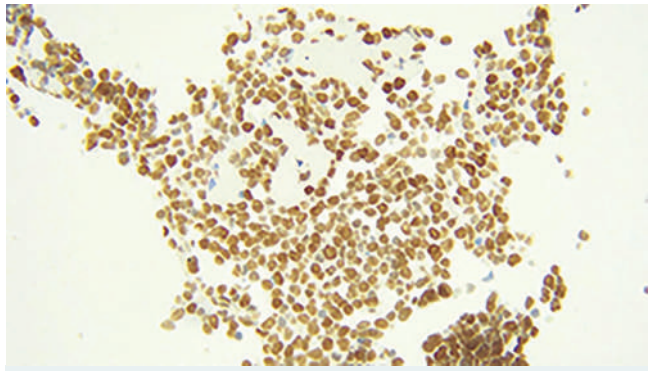

Figure 2. Immunohistochemical findings in extraskeletal Ewing sarcoma (NKX2.2 positivity).

Immunohistochemical analysis demonstrates diffuse nuclear positivity for NKX2.2 in tumor cells. The monomorphic population of small round cells is consistent with the diagnosis of Ewing sarcoma.

[P-106]

The effect of age on clinical and laboratory findings in patients with acute colonic diverticulitis: Comparison of patients over and under 70 years of age

Derya Alparslan[1], Hikmet Pehlevan Özel[2], Atahan Uzun[2], Erdinç Çetinkaya[3], Sadettin Er[2], Tezcan Akın[2], Özgür Akgül[2]

[1]*Clinic of General Surgery, Zonguldak Devrek State Hospital, Zonguldak*

[2]*Department of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[3]*Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara*

Objective: This study aims to evaluate the differences in clinical characteristics, complication rates, and laboratory parameters between patients over 70 years of age diagnosed with acute colonic diverticulitis and other age groups.

Material and Methods: Twenty-one patients over 18 years of age, of both sexes, diagnosed with acute colonic diverticulitis by clinical evaluation and computed tomography were included in the study. Patients were divided into two groups: those over 70 years of age and those under 70 years of age.

Results: The proportion of patients over 70 years of age was 19.9% (n=40), and the proportion of patients under 70 years of age was 80.1% (n=161). While female patients were in the majority in the over-70 age group, the proportion of male patients was higher in the under-70 age group (p=0.005). Right colon diverticulitis involving the cecum and ascending colon was not observed in patients over 70 years of age (p=0.022). Although the complication rate was higher in the under-70 age group, it was not statistically significant (p=0.060). In the multivariate regression analysis performed with variables that were significant with p<0.01 in univariate analyses of laboratory findings, only low GFR and high INR showed a significant difference between the two patient groups.

Conclusion: Right colon diverticulitis was not observed in patients over 70 years of age. It is known that symptomatic right colon diverticula are more common in younger patients, and the results of our study are consistent with the literature. Multivariate analysis showed a significant difference in GFR and INR in patients over 70 years of age. Low GFR and high INR are important indicators of organ failure, especially in the context of multiple organ dysfunction syndrome. Both parameters are of great importance in evaluating the severity and course of organ dysfunction in critically ill patients. The faster development of clinical deterioration in elderly patients may necessitate close monitoring and inpatient treatment. In our study, no significant difference was observed in complication rates between patient groups over and under 70 years of age. Although age is often considered a risk factor for complications, it is not a parameter that alone predicts negative outcomes. In addition, the presence of comorbidities, the type of surgical procedure performed, and the patient's overall health status are more critical in determining outcomes. This supports a more personalized patient care approach focusing on comprehensive preoperative assessments and individualized postoperative management strategies to ensure optimal outcomes in all patients.

The challenging stoma care process from debulking surgery to short bowel syndrome: A case report

Burcu Baş, Kadir Serkan Türel, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Complications following gynecological oncology surgeries can seriously affect both the physical health and quality of life of the patient. Conditions such as anastomotic leakage, stoma ischemia, and short bowel syndrome are significant problems that negatively impact the patient's quality of life and treatment process. Peristomal complications require a multidisciplinary approach and meticulous wound/stoma care. This presentation addresses the complex stoma management and care process following repeated surgeries.

Material and Methods: A 63-year-old female patient was diagnosed with Stage 4 Serous Ovarian Carcinoma and underwent total colectomy with debulking (TAH + BSO + omentectomy) at a university hospital, where an end-of-stomach ileostomy was created in the right quadrant and she was discharged. Three months after the surgery, she presented to our hospital with hyperemia and discharge in the peristomal area. She underwent surgery due to anastomotic leakage. Early ischemia in the newly created stoma was regularly monitored. Because the ischemia progressed towards the incision line and an abscess developed, a second surgery was performed 20 days later to debride the infective slag-filled areas and establish a vacuum system. The newly created stoma had to be moved back to the right quadrant. Following the second surgery, the patient, diagnosed with short bowel syndrome, was monitored with parenteral nutrition, gradually opened orally, and mobilization was supported. From the early postoperative period, efforts were made to improve and protect peristomal skin integrity using barrier spray, stoma powder, hydrocolloid dressing, hyaluronic acid-based silver spray, and a stoma belt. Due to the proximity of the peristomal area to the incision line and contact with bowel contents, cleaning was performed with a hypochlorous acid-based wound antiseptic.

Results: Initially, the patient experienced leakage and skin irritation requiring adapter changes four times a day. However, after the implementation of barrier methods and the transition to a convex system, the adapter change interval was extended to five days. Peristomal skin integrity was preserved, and drainage to the incision line was prevented. The patient's gradual transition from parenteral to oral feeding and mobilization improved proportionally with increased stoma security.

Conclusion: In high-output stoma situations such as short bowel syndrome, proper product selection and professional stoma care are vital. Maintaining stoma viability and ensuring peristomal skin integrity significantly improves the patient's quality of life and contributes positively to stoma adaptation. In challenging and multi-stage surgeries, individualized stoma care, conducted in collaboration with the patient, plays a crucial role in the successful completion of the treatment process.

Breast-localized Mondor disease: The importance of clinicopathological correlation in a rare case mimicking malignancy

Betül Alçelik, Sena Özgül, Gaye Ebru Şeker, Barkın Karmuş, Serkan Demir, Muhammed Salih Süer

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Mondor disease is a rare clinical entity characterized by thrombophlebitis of the superficial veins of the breast and anterior chest wall. Because it may clinically and radiologically mimic malignancy with findings such as a palpable cordlike induration and skin retractionlike appearance, it is important in the differential diagnosis. Conditions to be considered in the differential diagnosis of Mondor disease include cellulitis, erythema nodosum, lymphangiectasia, lymphangioma and metastatic skin cancers. In Mondor disease, the lateral thoracic vein, thoracoepigastric vein and superior epigastric vein may be involved with the thoracoepigastric vein being the most commonly affected. In this case report we present the diagnostic process of a patient with concern for breast cancer in whom malignancy was excluded and a diagnosis of Mondor disease was established through correlation of clinical and radiological findings with histopathology.

Material and Methods: A 36 year old female patient presented with sudden onset localized tenderness in the retroareolar region of the right breast, exacerbated by movement, along with a sensation of a cordlike, firm band under the skin. Her history revealed recent use of a tight bra and engagement in activities/exercises straining the upper extremity; she denied fever, nipple discharge or marked erythema. There was no family history of breast cancer. On physical examination, a localized firm area with associated tenderness was noted on palpation in the right retroareolar region. On inspection, a linearly oriented, cord-like band appearance conse immunohistochemical stent with the patient's description, along with mild skin retraction, was observed. Following clinical evaluation, breast ultrasonography was planned. Imaging demonstrated a solid lesion measuring approximately 17×10 mm in the retroareolar region of the right breast, with oval contours, well-defined margins, and focal areas of cystic degeneration. To exclude malignancy, a biopsy was obtained from the lesion, and histopathological examination with immunohistochemical evaluation, where appropriate, was performed.

Results: Histopathological examination revealed prominent inflammatory cell infiltration within the breast parenchyma, with lymphocyte-predominant inflammatory involvement of some venous walls, findings indicative of thrombophlebitis of superficial venous structures (Figures 1 and 2). On immunohistochemical analysis, no findings suggestive of malignancy or invasion were observed with pan-cytokeratin (Pan-CK) staining (Figure 3). When evaluated together with the clinical and imaging findings, the overall picture was considered consistent with Mondor disease.

Conclusion: Breast-localized Mondor disease may mimic mass lesions on physical examination and imaging, leading to suspicion of malignancy. Therefore, histopathological confirmation and clinicopathological correlation are of critical importance to avoid unnecessary surgical interventions. This case demonstrates that careful evaluation of venous wall inflammation and exclusion of malignancy through immunohistochemical methods are decisive in the diagnostic process. In most patients, a conservative approach is sufficient, and excessive interventions should be avoided in patient management.

A rare complication of calculous chronic cholecystitis: A case of cholecystocutaneous fistula

Serhat Gizlenci, Doğuhan Kaya, Özgür Yıldırım Yıldırım

University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Cholecystocutaneous fistula is a rare complication in contemporary practice, characterized by the spontaneous fistulization of the gallbladder to the skin. The most common cause is untreated calculous cholecystitis, and its incidence has markedly decreased due to early surgical interventions.

Material and Methods: The patient's clinical, radiological, intraoperative, and histopathological data were evaluated retrospectively. Preoperative assessment was performed using physical examination, laboratory tests, and contrast-enhanced abdominal computed tomography (CT). Surgical treatment was carried out via an open approach through a right subcostal incision. The resection specimen was submitted for standard histopathological examination.

Results: A 74-year-old female patient presented with a long-standing draining wound in the right upper quadrant. Her medical history revealed intermittent right upper quadrant pain. On physical examination, a cutaneous fistula opening with purulent drainage was observed in the right hypochondrium. Laboratory tests showed leukocytosis and elevated inflammatory markers. Contrast-enhanced abdominal CT demonstrated gallstones, marked thickening of the gallbladder wall, and a fistulous tract extending from the gallbladder to the skin surface. The findings were consistent with a cholecystocutaneous fistula. The patient was operated on under elective conditions. During exploration through a right subcostal incision, the gallbladder was found to be adherent to the anterior abdominal wall and opening to the skin surface via a fistulous tract. The gallbladder containing stones was dissected, and a cholecystectomy was performed. The fistulous tract was totally excised. After achieving hemostasis, a drain was placed and the operation was concluded. The postoperative course was uneventful. The patient was discharged without complications. Histopathological examination was consistent with chronic calculous cholecystitis.

Conclusion: Cholecystocutaneous fistula, although rare today, is a serious complication of chronic calculous cholecystitis. It should be considered in the differential diagnosis in the presence of a chronic draining lesion in the right upper quadrant. Contrast-enhanced CT plays an important role in diagnosis and surgical planning. The definitive treatment is cholecystectomy and total excision of the fistulous tract. Successful outcomes can be achieved with appropriate surgical intervention.

A rare case of SGLT-2–associated refractory metabolic acidosis following robotic left hemicolectomy

Yılmaz Özdemir1, Ezgi Güngördü2, Ömer Zühtü Yöndem2, Cihat Akyazı1, Gökhan Çağlar2, Tugay Çamlıbel1

[1]*Department of General Surgery, Lokman Hekim University Faculty of Medicine, Ankara, Türkiye*

[2]*Department of Anesthesiology and Reanimation, Lokman Hekim University Faculty of Medicine, Ankara, Türkiye*

Objective: Sodium-glucose cotransporter-2 (SGLT-2) inhibitors are oral antihyperglycemic agents widely used in the management of type 2 diabetes mellitus and are generally considered safe. However, euglycemic diabetic ketoacidosis (EDKA) is a rare but serious complication associated with this drug class. Unlike classical diabetic ketoacidosis, SGLT-2 inhibitor-associated DKA may present with severe metabolic acidosis despite normal or only mildly to moderately elevated serum glucose levels. In addition, cases of non-ketotic, normal anion gap metabolic acidosis have also been reported. During the perioperative period, surgical stress, acute illness, and reduced carbohydrate intake may increase the risk of EDKA. Near-normal glucose levels may delay diagnosis and treatment. Herein, we present a case of non-ketotic, euglycemic/mildly hyperglycemic metabolic acidosis that developed after reinitiation of empagliflozin following robotic left hemicolectomy.

Material and Methods: A 59-year-old male was diagnosed with adenocarcinoma on biopsy obtained from the sigmoid colon during screening colonoscopy performed due to family history. Robotic left hemicolectomy was planned. Sitagliptin, insulin glargine, and empagliflozin were discontinued two days prior to surgery. On postoperative day 6, oral intake was resumed and antidiabetic therapy was restarted.

Results: On postoperative day 7, the patient developed nausea, vomiting, tachycardia, and polyuria. Cardiac, pulmonary, and intra-abdominal complications were excluded. Arterial blood gas analysis revealed severe metabolic acidosis with pH 7.041, bicarbonate 9 mmol/L, sodium 147 mmol/L, chloride 121 mmol/L, and lactate 2.1 mmol/L. Plasma glucose was 249 mg/dL, creatinine 0.73 mg/dL, and albumin 4.3 g/dL. Urinalysis showed negative ketones and positive glucose. Normal lactate levels excluded lactic acidosis and sepsis. The patient was diagnosed with euglycemic/mildly hyperglycemic hyperchloremic metabolic acidosis. Oral antidiabetic agents were discontinued, and intensive intravenous fluid resuscitation along with insulin infusion therapy was initiated. The primary goals of treatment were correction of volume depletion, restoration of glucose–insulin balance, and suppression of keto/preketotic metabolism. Clinical and metabolic improvement was observed during follow-up. Repeat urinalysis demonstrated persistent glycosuria with negative ketones. The patient was discharged after adjustment of antidiabetic therapy.

Conclusion: SGLT-2 inhibitors increase urinary glucose excretion by inhibiting proximal tubular glucose reabsorption. Persistence of glycosuric effects beyond 48 hours after drug discontinuation, combined with postoperative stress hormone elevation and inadequate caloric intake, may reduce the insulin-to-glucagon ratio and precipitate resistant metabolic acidosis. Therefore, discontinuation of SGLT-2 inhibitors at least 48-72 hours prior to surgery is recommended. High clinical awareness is essential in atypical presentations to enable early diagnosis and prompt, effective management.

Colonic perforation due to ventriculoperitoneal shunt migration: A rare complication

Elif Elgiz Aktarı, Aytaç Selman, Meryem Günay Gürleyik

University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Ventriculoperitoneal (VP) shunting remains the most commonly performed surgical procedure for the management of hydrocephalus. Although VP shunts are generally considered safe, various complications may occur, including infection, obstruction, mechanical failure, and catheter migration. Gastrointestinal perforation caused by distal catheter erosion is an extremely rare but serious complication, potentially leading to peritonitis, sepsis, and mortality. In this report, we present an unusual case of asymptomatic sigmoid colon perforation with transanal protrusion of the VP shunt catheter.

Material and Methods: This report describes the clinical presentation, radiological findings, surgical management and postoperative course of a patient diagnosed with colonic perforation secondary to VP shunt migration. Clinical examination, laboratory evaluation, abdominal computed tomography and intraoperative findings were reviewed retrospectively.

Results: A 27-year-old male patient with a history of decompressive craniectomy developed post-hemorrhagic hydrocephalus and underwent VP shunt placement in 2021. He was admitted to the emergency department after noticing extrusion of the distal catheter through the anus. Remarkably, the patient did not report abdominal pain, fever, nausea, vomiting, or changes in bowel habits. On physical examination, the distal end of the shunt catheter was visibly protruding from the anal canal. Abdominal examination revealed no tenderness, guarding, or rebound, and laboratory findings were unremarkable, suggesting the absence of acute intra-abdominal infection. Abdominal computed tomography demonstrated that the peritoneal catheter had migrated into the pelvic cavity, perforated the sigmoid colon, and advanced intraluminally through the rectum, resulting in transanal extrusion. A diagnosis of asymptomatic colonic perforation secondary to VP shunt migration was established. The patient underwent urgent exploratory laparotomy. Intraoperative findings confirmed perforation of the sigmoid colon caused by the catheter. The shunt was identified in the subcutaneous tract, ligated at the abdominal entry site, and the distal segment was carefully removed transanally. The colonic defect was repaired primarily. Postoperatively, the patient was closely monitored in collaboration with the neurosurgery team. No complications such as peritonitis or sepsis developed, and the patient was discharged uneventfully on postoperative day five.

Conclusion: Colonic perforation due to VP shunt migration is a rare but potentially life-threatening complication. Clinical presentation may be subtle, and patients can remain asymptomatic until transanal protrusion occurs. Most reported cases in the literature present with abdominal symptoms or infectious complications, whereas our patient remained clinically asymptomatic. Early recognition, appropriate imaging, and timely surgical management are crucial for preventing severe infectious outcomes. Multidisciplinary follow-up is essential in the treatment of such complex cases.

Emergency laparoscopic appendectomy in a patient with a history of semaglutide use who developed appendiceal mesenteric infarction: A case report

Yılmaz Türk, Berkay Tuzcu, Hasan Faruk Hazar

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: The appendix mesentery contains the arteries, veins, and lymphatic vessels of the appendix. The appendix is usually supplied by a single terminal artery. Due to the single terminal artery nature of the Arteria appendicularis passing through the appendix mesentery, infarction inevitably leads to rapid ischemia of the appendix, and surgical appendectomy is the only treatment option. On the other hand, Semaglutide, an active ingredient whose use is rapidly increasing today for obesity/weight management indications, is a GLP-1 receptor agonist and was discovered in 2012. It was approved by the FDA in 2017. In 2018, its use for obesity/weight management indications began in the US. There are studies in the literature indicating that it does not increase the risk of infarction. This case presentation describes a patient with a history of Semaglutide use who developed appendiceal mesenteric infarction.

Material and Methods: The clinical and laboratory data of the patient included in the study were reviewed retrospectively.

Results: A 33-year-old male patient with no known comorbidities or history of surgery presented to the emergency department with complaints of nausea and vomiting accompanied by abdominal pain localized to the right lower quadrant, which had been progressively worsening for 5 days. It was learned that the patient had started semaglutide treatment at another center 29 days prior to presentation due to obesity. There is no history of coagulation disorders in the family. Physical examination revealed generalized abdominal tenderness, defense, and rebound tenderness in the right lower quadrant. Rectal examination was normal. Laboratory tests showed WBC: 12.2×10^9/L, total bilirubin: 1.7 mg/dL, direct bilirubin: 0.4 mg/dL, CRP: 14.9 mg/L; INR: 0.9 within normal limits. Contrast-enhanced abdominal CT showed a 16×12 mm hypodense area in the distal vermiform appendix with retrocecal placement and marked contamination in the surrounding mesenteric fat tissue. Based on the current clinical and radiological findings, emergency surgery was planned. During exploration, an approximately 2 cm area of infarction was detected in the appendix mesentery, and laparoscopic appendectomy was performed. The patient had an uneventful postoperative course and was discharged on postoperative day 2 with an ASA prescription.

Conclusion: The development of isolated mesenteric infarction of the appendix following semaglutide use in this patient without comorbidities or coagulation disorders suggests that further clinical and experimental studies are needed to elucidate the potential vascular or microcirculatory effects of semaglutide.

Keywords: Appendix, semaglutide, mesenteric infarction of the appendix

[P-113]

Ruptured cholangitic liver abscess presenting as acute abdomen in locally advanced pancreatic cancer: A case report

Enes Aksu, Özkan Akpınar, Gizem Aksu, Aydın Dalgıç

Gazi University Faculty of Medicine, Ankara

Objective: Pancreatic cancer is an aggressive malignancy associated with high mortality and morbidity. Gastrointestinal perforations are rare in locally advanced pancreatic cancer and are typically linked to direct tumor invasion or post-chemoradiotherapy necrosis. However, acute abdomen secondary to the rupture of a cholangitic abscess is highly atypical and infrequently documented in literature.

Material and Methods: We retrospectively evaluated the clinical course of a 65-year-old male patient with locally advanced pancreatic cancer and a metallic biliary stent. The diagnostic process, findings of emergency surgical exploration for acute abdomen, and postoperative biliary restoration via ERCP are analyzed and reported.

Results: We report the case of a 65-year-old man diagnosed two months prior with locally advanced pancreatic head adenocarcinoma, who had undergone metallic biliary stent placement. He initially presented to the emergency department with epigastric pain, nausea, and vomiting. His symptoms transiently improved with symptomatic treatment, and he was discharged against medical advice. He re-presented the following day with persistent complaints. Imaging revealed intraperitoneal free air, and a physical examination demonstrated signs of an acute abdomen, necessitating emergent surgical exploration. Intraoperative findings ruled out definite perforation in the duodenum, stomach, or small bowel. Instead, widespread peritonitis and a biliary leak were identified adjacent to the mass invading the hepatoduodenal ligament, originating from the rupture of a cholangitic abscess located in hepatic segment 2. The deformed Glisson's capsule overlying the abscess was incised, the cavity was debrided, and the intrahepatic bile ducts were repaired. Postoperatively, an endoscopic retrograde cholangiopancreatography (ERCP) was performed to replace the obstructed stent, and the patient achieved clinical improvement with targeted antibiotic therapy. Perforation in patients with pancreatic cancer is a marker of poor prognosis, most commonly resulting from tumor invasion into adjacent organs. In contrast, our case highlights a rare acute abdomen etiology caused by the rupture of a cholangitic liver abscess that developed secondary to a blocked biliary stent. This emphasizes the critical importance of biliary stent surveillance and aggressive cholangitis management in the multidisciplinary care of locally advanced pancreatic cancer patients.

Conclusion: In patients with locally advanced pancreatic cancer who develop an acute abdomen, atypical causes such as the rupture of a cholangitic abscess due to stent occlusion must be considered in the differential diagnosis, in addition to perforation related to tumor invasion. Early surgical intervention and prompt control of the infectious source are paramount for improving survival in these patients.

Persistent postoperative distension revealing an occult colorectal cancer after emergency inguinal hernia repair

Osman Akdoğan

Yalova University Faculty of Medicine, Yalova

Objective: Strangulated inguinal hernias are a frequent cause of emergency surgery. The presence of a colon segment within the hernia sac is rare, and the presence of a secondary mechanical obstruction due to distal colorectal malignancy is even more unusual. This poster aims to present a rare case of a patient operated on for a strangulated inguinal hernia, in whom persistent postoperative distension revealed underlying occult colorectal cancer.

Material and Methods: This study retrospectively evaluated the clinical course, imaging and endoscopic findings, and surgical treatment of a patient who underwent surgery for ileus. Informed consent was obtained from the patient.

Results: A 71-year-old male patient presented to the emergency department with complaints of inability to pass gas and stool, nausea, and vomiting for two days, along with an unreducible swelling in his left groin. Physical examination revealed a strangulated left inguinal hernia and abdominal distension. Plain abdominal X-ray showed colonic air-fluid levels. Abdominal CT showed incarceration of a segment of the sigmoid colon in the left inguinal canal and dilation throughout the entire colon proximally. Following nasogastric decompression, the patient underwent emergency surgery. Exploration under spinal anesthesia revealed a strangulated but viable sigmoid colon with good blood supply within the hernia sac. The bowel was reduced to the abdomen, and due to the absence of contamination, the hernia was repaired with prolene mesh. On the first postoperative day, persistent abdominal distension led to further nasogastric decompression and enema administration. On the second day, due to increased distension and the passage of approximately 2000 mL of fecal matter via nasogastric drainage, a contrast-enhanced whole-abdomen CT scan was performed. The CT scan revealed significant dilation throughout the colon and small intestine, starting from the rectosigmoid junction. Rectosigmoidoscopy revealed a mass lesion 16 cm from the anal verge, completely obstructing the lumen. The patient underwent reoperation 48 hours postoperatively, with low anterior resection of the rectosigmoid junction. Due to proximal colonic dilation and the patient's clinical condition, anastomosis was omitted, and the Hartmann procedure was chosen instead. Pathology reported the tumor as a T2N0 stage adenocarcinoma. The patient had an uneventful postoperative course and was discharged; no recurrence was detected during follow-up, and the colostomy was closed.

Conclusion: Persistent postoperative distension following strangulated inguinal hernia should not be dismissed with the assumption of paralytic ileus. Especially in elderly patients, the possibility of distal mechanical obstruction and occult colorectal malignancy should be kept in mind, and a secondary area of obstruction should be ruled out with early further investigation.

Keywords: Colonic obstruction, inguinal hernia, postoperative distension, strangulation

Figure 1. The initial pre-operative CT scan showed the sigmoid colon within a strangulated hernia. CT scan of sigmoid colon within strangulated hernia.

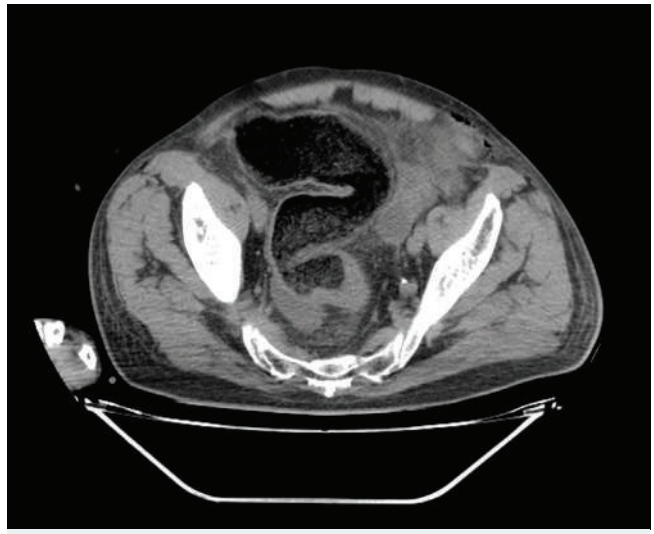

Figure 2. Contrast-enhanced CT scan on the second postoperative day revealed a scirrhous mass at the rectosigmoid junction and dilation proximal to it.

[P-115]

Pancreatic injury in major blunt trauma

Özgür Yıldırım, Görkem Müjde, Hikmet Kutlu Özkara

University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Blunt pancreatic injuries are relatively rare, accounting for only 0.25% of all trauma cases and 2.4% of abdominal traumas, and are associated with 4.3% of trauma-related mortality. Isolated pancreatic injuries are uncommon. In this study, we present two cases of AAST Grade 4 pancreatic injuries that were managed using non-operative approaches.

Material and Methods: The clinical courses of two patients with high-grade pancreatic injuries were retrospectively reviewed and compared with current literature.

Results: Two patients with AAST Grade IV pancreatic injuries were initially managed with non-operative follow-up. In one patient, distal pancreatectomy with splenectomy was performed due to deterioration of hemodynamic parameters and the development of generalized peritonitis at the 30th hour of follow-up. The second patient was successfully managed non-operatively and discharged. The operated patient was a 27-year-old male with pancreatic injury accompanied by multiple extremity traumas. Following the initial operation, he underwent three additional re-explorations for peritoneal lavage. At approximately one month of follow-up, he continues to be monitored with a pancreatic fistula producing a daily output of approximately 100 mL. The second patient was a 43-year-old male with an isolated pancreatic injury. CT-guided drainage catheters were placed for pseudocysts by the interventional radiology team. MRCP and ERCP demonstrated misalignment of the proximal and distal ends of the transected pancreatic duct, and stent placement was not feasible. During follow-up, the patient was discharged at the end of the first month with a daily drainage output of less than 50 mL.

Conclusion: In patients with grade IV pancreatic injuries, the treatment approach should be individualized according to the patient's hemodynamic status and clinical course. While surgical intervention may be unavoidable in certain cases, non-operative management can be considered a viable option in carefully selected patients when managed in appropriately equipped centers with multidisciplinary expertise. These cases highlight the importance of close monitoring and flexible treatment strategies in the management of high-grade pancreatic injuries.

Keywords: Blunt pancreatic injury, non-operative management

[P-116]

Management of postoperative nursing care in a patient who underwent pancreaticoduodenectomy (Whipple) due to periampullary tumor: A case presentation

Emine Özdemir, Sümeyye Karagöz, Damla Urcan

Hacettepe University Faculty of Medicine, Ankara

Objective: The aim of this study is to evaluate the nursing care provided during the diagnostic, treatment, and surgical processes of a patient diagnosed with a periampullary tumor who underwent pancreaticoduodenectomy (Whipple procedure).

Material and Methods: Patient: 61-year-old female.

Chief complaint: Fatigue, abdominal pain.

History: Three months ago, the patient presented to a different medical center with fatigue and abdominal pain. Investigations revealed choledocholithiasis. Further imaging with CT and endoscopic retrograde cholangiopancreatography detected a periampullary tumor. She was referred to our department after evaluation by the Gastrointestinal-Oncology Council. The patient was admitted to General Surgery (Ward 53) for surgical management.

Present condition: No active complaints. No jaundice. Normal stool and urine color. No abdominal pain.

Past surgery: None.

Allergies: None.

Medical history: Diabetes mellitus.

Medications: Novomix FlexPen, Forziga.

Surgical procedure: Pancreaticoduodenectomy on 15.01.2026. Postoperatively, the patient was monitored in the general surgery ICU for 2 days. After achieving hemodynamic stability, she was transferred to Ward 53 with an NG tube, feeding tube, one sump drain, Foley catheter, arterial line, and two peripheral IV lines.

Results: In the postoperative period, comprehensive nursing care was provided. To prevent atelectasis, breathing exercises were taught and early mobilization was encouraged. Drain output was monitored for amount and color, and the sump drain was changed as scheduled. Hourly urine output was measured via Foley catheter, and the patient was observed for signs of infection. Pain was assessed using a standardized scale, and prescribed analgesics were administered. As the patient was receiving anticoagulants, bleeding risk was closely monitored and laboratory values were recorded. Blood glucose levels, previously uncontrolled preoperatively, were carefully followed and regulated postoperatively. Due to leakage around the sump drain, it was removed and replaced with a wound pouch; the drainage characteristics were monitored and documented each shift. On postoperative day 6, oral feeding was commenced with a prescribed dumping diet. A multidisciplinary approach supported the patient's daily activities and self-care. Systematic nursing care played a key role in preventing potential postoperative complications.

Conclusion: Pancreaticoduodenectomy is an effective treatment option for periampullary tumors when performed with appropriate patient selection and a multidisciplinary approach. In this case, it was observed that teamwork and structured nursing care played a significant role in patient management from the diagnostic process through surgery and the postoperative care period. In surgical patients, early diagnosis, appropriate surgical intervention, and systematic care practices are critical in reducing complications and accelerating recovery.

Keywords: Nursing care, postoperative period, pancreaticoduodenectomy

Figure 1. Relationship of the pancreatic pseudocyst with the stomach and omentum during laparoscopic exploration. Contrast-enhanced abdominal computed tomography shows a recurrent pancreatic pseudocyst at the level of the pancreatic body–tail, accompanied by marked ductal dilatation and surrounding peripancreatic inflammatory changes.

Laparoscopic management of a recurrent pancreatic pseudocyst despite minimally invasive interventions: A case report

Kanan Ismayilzada, Babek Tabandeh

Medicana Ataşehir Hospital, İstanbul

Objective: Percutaneous and endoscopic interventions are considered first-line treatment options for pancreatic fluid collections following acute necrotizing pancreatitis. However, despite these minimally invasive approaches, recurrent pancreatic pseudocysts remain a clinical challenge, particularly in complex cases 3. This case report presents the laparoscopic surgical management of a recurrent pancreatic pseudocyst in a patient who previously underwent percutaneous and endoscopic interventions.

Material and Methods: A 41-year-old male patient with no known comorbidities or familial/genetic pancreatic disease presented with abdominal pain exacerbated by fatty meals and was diagnosed with acute biliary pancreatitis. Despite medical treatment, persistent pancreatitis findings and the development of a giant pancreatic pseudocyst were observed. The patient underwent percutaneous cholecystostomy and endoscopic cystogastrostomy at different centers. Following laparoscopic cholecystectomy, the patient remained clinically stable; however, approximately one year later, follow-up imaging revealed a recurrent pancreatic pseudocyst with marked ductal dilatation at the pancreatic body-tail junction (Figure 1). Due to persistent symptoms and recurrence despite conservative and endoscopic management, laparoscopic exploration was performed. Intraoperatively, the pseudocyst was found to be located posteriorly, closely associated with the stomach and omentum, causing anterior displacement of the stomach (Figure 2). A laparoscopic intragastric cystogastrostomy was performed. As shown in Figure 3, the cyst was drained transgastrically through the posterior gastric wall, and a wide cystogastrostomy anastomosis was created. The postoperative course was uneventful, oral intake was resumed early, and the patient was discharged. At one- and three-month follow-up visits, the patient remained asymptomatic, and no recurrence was detected on imaging.

Results: Current management of pancreatic fluid collections following acute necrotizing pancreatitis favors a step-up approach with minimally invasive techniques. While percutaneous and endoscopic interventions are effective in many cases, recurrence remains a concern, particularly in patients with necrotizing pancreatitis. Previous studies have reported that, in selected cases, surgical drainage may provide more durable long-term outcomes compared to endoscopic approaches. In patients with large, complex, or recurrent pancreatic pseudocysts—especially those who have undergone multiple prior interventions—laparoscopic surgical management represents an important treatment option. This case highlights that, despite advances in minimally invasive endoscopic techniques, surgery continues to play a critical role in the management of complex pancreatic fluid collections.

Conclusion: Pancreatic pseudocysts may recur despite percutaneous and endoscopic interventions. In recurrent and complex cases, laparoscopic surgery is a safe and effective treatment option. A step-up and multidisciplinary approach is essential to achieve optimal outcomes in the management of pancreatic pseudocysts.

Keywords: Pancreatic pseudocyst, recurrence, laparoscopic surgery, step-up approach, cystogastrostomy

Contrast-enhanced abdominal computed tomography demonstrates a recurrent pancreatic pseudocyst located at the body–tail region of the pancreas, accompanied by marked ductal dilatation and surrounding peripancreatic inflammatory changes.

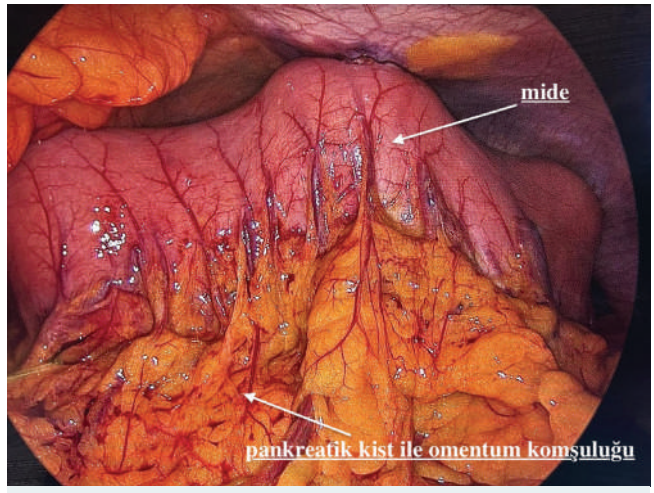

Figure 2. Laparoscopic view of the pancreatic pseudocyst and its relationship with the stomach and omentum. During laparoscopic exploration, the pancreatic pseudocyst is seen in close proximity to the posterior wall of the stomach and the omentum. The cyst is located posteriorly and causes anterior displacement of the stomach.

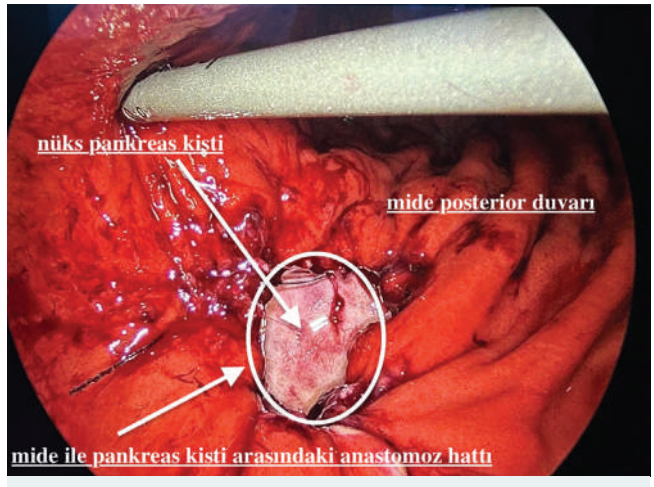

Figure 3. Laparoscopic intragastric cystogastrostomy and anastomosis site. The pancreatic pseudocyst was drained laparoscopically using a transgastric approach through the posterior gastric wall, and a wide cystogastrostomy anastomosis was created. The anastomosis site and cyst cavity are clearly visualized intraoperatively.

Temporary closure of anterior abdominal wall defect developing after recurrent liposarcoma excision with BTM on prolene mesh

Barış Tüzün, Murat Burç Yazıcıoğlu, Sumru Beril Çetintaş Atak, Sude Sezer, Murat Özdamar

Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli

Objective: Biodegradable temporary matrices (BTM) create granulation tissue suitable for skin grafting in deep lesions where the skin and subcutaneous tissue are completely absent. We wanted to present our application of skin grafting after BTM in a case of recurrent liposarcoma that underwent extensive abdominal wall excision.

Material and Methods: We retrospectively evaluated the surgical excision, BTM application, and grafting performed on a recurrent patient who had previously undergone liposarcoma excision twice in the abdominal wall, after no metastasis was detected following PET-CT.

Results: A 47-year-old male patient had previously undergone two surgical treatments for liposarcoma in the abdominal wall. He was evaluated for a recurrent mass larger than 40 cm in diameter extending into the peritoneum on the anterior abdominal wall. PET-CT showed no distant metastasis. The mass had extended into the peritoneum, incorporating the rectus fascia and the muscle itself on one side. During excision, surgical margins could not be evaluated with frozen-section biopsies. While awaiting pathological examination, prolene mesh was placed to induce granulation formation. Upon negative surgical margins, the wound was covered with BTM. The prolene mesh was fully integrated and largely preserved due to granulation. When the BTM delaminated and was removed, the skin was covered with split-thickness grafts taken from the thigh. In the follow-up, the patient developed localized prolene mesh exposure. The exposed meshes were removed, and wound care treatments were applied. After three months, the patient, who had no remaining wound problems, was transferred to the oncology clinic.

Conclusion: BTMs are commonly used in burn treatment. However, in recent years they have also found a place in chronic wound treatment. In this case, we prepared a wound of a size that could not be closed with flaps or wound care methods for grafting. We do not consider it correct to place BTMs without evaluating the surgical margin. Therefore, we triggered granulation by placing prolene mesh for a short period, but we saw high-quality granulation tissue on the prolene mesh before BTM, and therefore we did not remove it completely. Thanks to BTM, we applied grafts to the high-quality granulation tissue that developed on the exposed mesh without infection. We removed the exposed prolene mesh areas with wound care methods. Our unconventional approach developed specifically for this case. However, the application of BTM on prolene mesh has served as an example for us in the treatment of complex wounds such as hernia repairs that develop wound complications.

Keywords: BTM, wound, graft

Late-diagnosed coexistance of intraabdominal serouse carcinoma and B-cell lymphoma: Case report

Ezgi Altıntaş, Ahmet Erim Erdoğan, Mehmet Yıldırım

University of Health Sciences Türkiye, İzmir City Hospital, İzmir

Objective: Trauma, benign and malignant pathologies are important in the etiology of intraabdominal masses. Multidisciplinary approach is important in cases where a preliminary diagnosis of hematological disease is present. Patients often present late for surgical intervention, and this case report aims to highlight the importance of diagnosis in a patient with a preliminary diagnosis of B-cell non-Hodgkin lymphoma who had both intramesenteric serous carcinoma and B-cell lymphoma.

Results: A 77-year-old woman presented with palpable abdominal swelling and pain, was referred to the hematology department for further investigation due to lymphocytosis detected in her hemogram at an external center. Computed tomography scan revealed a septated mass lesion extending into the pelvis, approximately 30x23x22 cm, containing cystic components of varying density, and a similar lesion measuring 10x3 cm with a tendency to coalesce, located adjacent to the pelvis (Figure 1). Bone marrow biopsy showed involvement of B-cell non-Hodgkin lymphoma. Exploratory laparotomy revealed two masses in the abdomen; the larger mass projected into the abdominal cavity between the mesenteric layers, was of retroperitoneal origin, and showed loose adhesions to the uterus. A second mass, also retroperitoneally located, was found adjacent to it (Figure 2). Total extirpation of the masses revealed a total weight of 6.200 grams. The masses were found not to be of ovarian origin. The patient's postoperative period was without any complications and was referred to the hematology clinic. Histopathological examination of the mass revealed a diagnosis of "non-invasive low-grade serous carcinoma," and immunohistochemical examination showed neoplastic B lymphocytes with CD20(+), PAX5(+), Bcl-2(+), Bcl6(-), Cd10(-), CyclinD1(-), SOX11(-), TDT(-), Annexin-A1 (-), CD5 (-), CD23 (-), and IgD (-) immunophenotype, and a proliferation index of approximately 20% with Ki-67, thus confirming the diagnosis of marginal zone lymphoma. The patient was initiated on rituximab treatment in accordance with R-Bendamustine chemotherapy in the hematology clinic.

Conclusion: In surgical practice for the diagnosis of intraabdominal masses, the patient's medical and family history are important, early diagnosis should be achieved using laboratory and imaging methods. Since delayed diagnosis can lead to mass growth, it is essential to treat the mass before emergency situations such as compression symptoms, bleeding, perforation, obstruction occur. However, there is no immunohistochemical method to differentiate between primary and genital organ-derived serous carcinomas. Therefore, the mass in our patient contains a combination of primary serous carcinoma and B-cell lymphoma, and this possibility should be considered in the differential diagnosis in similar cases during the early stages of the disease.

Keywords: Intraabdominal mass, lymphoma, serous carcinom

Brachial artery-axillary vein arteriovenous fistula created using autologous saphenous vein in a hemodialysis patient with exhausted vascular access: An alternative solution

Mertcan Kayıkçı[1], Dilara Karakaya[1], Can Yahya Boztuğ[2]

[1]*Department of General Surgery, Ankara University Faculty of Medicine, Ankara*

[2]*Division of Peripheral Vascular Surgery, Department of General Surgery, Ankara University Faculty of Medicine, Ankara*

Objective: Establishing and maintaining reliable vascular access is essential for long-term survival and quality of life in patients undergoing hemodialysis. Repeated arteriovenous fistula (AVF) procedures, prolonged central venous catheterization, and progressive vascular deterioration may eventually lead to exhaustion of available access sites. This situation represents a major clinical challenge, particularly in patients receiving long-term hemodialysis. The use of autologous vessels is preferred over synthetic grafts due to lower rates of infection and thrombosis. However, alternative surgical approaches are required when superficial veins are inadequate. In this report, we present a case of brachial artery-axillary vein AVF created using an autologous saphenous vein graft in a patient with exhausted vascular access.

Material and Methods: A 64-year-old male patient undergoing hemodialysis for four years was evaluated. The patient had a medical history of hypertension. Previous vascular access procedures included right radiocephalic and brachiocephalic AVFs, central venous catheterization, and left radiocephalic and brachiocephalic AVFs. Due to failure of all previous access sites, an alternative vascular access strategy was planned. Preoperative Doppler ultrasonography demonstrated a brachial artery diameter of 4 mm and an axillary vein diameter of 7 mm. Based on these findings, the use of an autologous saphenous vein graft was considered appropriate. The saphenous vein was harvested from the left leg and reversed before implantation. An end-to-side anastomosis was created between the brachial artery and the axillary vein using the parachute technique with 5/0 polypropylene sutures. The total operative time was 124 minutes. All procedures were performed in accordance with standard surgical protocols. Written informed consent was obtained from the patient.

Results: No intraoperative or early postoperative complications, including bleeding, thrombosis, infection, or hematoma, were observed. Postoperative clinical examination revealed adequate thrill and bruit, indicating satisfactory blood flow through the fistula. At the sixth postoperative week, follow-up Doppler ultrasonography showed a fistula diameter of 6 mm and a flow volume of 650 mL/min, confirming successful maturation. The fistula was successfully cannulated for hemodialysis at the eighth postoperative week. During follow-up, the access remained patent and fully functional, allowing uninterrupted dialysis sessions.

Conclusion: Brachial artery-axillary vein AVF created using an autologous saphenous vein graft appears to be a safe and effective alternative for hemodialysis patients with exhausted vascular access. Favorable maturation parameters and sustained patency observed in this case support the potential role of this technique in selected patients. Careful patient selection and meticulous surgical technique are essential for achieving optimal outcomes.

A rare case report: An intra-abdominal mass caused by actinomyces infection

Burak Yavuz[1], Zülfi Zahidli[2], Burak Aydoğan[3], Gökberk Sevük[3], İshak Aydın[3], Serdar Gümüş[4], Uğur Topal[4], Ahmet Gökhan Sarıtaş[3], Gürhan Sakman[3]

[2]*Hilvan Şehit Halit Şiltak State Hospital, Şanlıurfa*

[3]*Department of General Surgery, Çukurova University Faculty of Medicine, Adana*

[4]*Department of Surgical Oncology, Çukurova University Faculty of Medicine, Adana*

Objective: Actinomycosis is a rare, subacute to chronic infection caused by Actinomyces species, which are Gram-positive, filamentous, non–acid-fast, anaerobic or microaerophilic bacteria. The infection is typically characterized by granulomatous and suppurative inflammation and, in its chronic form, progresses with multiple abscess formations and granulation tissue containing sulfur granules. Approximately 70% of cases are caused by *Actinomyces israelii* or *Actinomyces gerencseriae*.

Material and Methods: A 55-year-old male with no comorbidities or prior abdominal surgery presented with abdominal distension and a 15-kg weight loss over two months. Physical examination revealed a palpable abdominal mass, and he was referred for further evaluation. Laboratory findings showed elevated inflammatory markers (CRP 213 mg/L, WBC 12.86×10^9/L) with normal tumor markers. Colonoscopy demonstrated a suspicious lesion in the left colon; biopsies revealed chronic active inflammation with eosinophilic infiltration. Abdominal computed tomography (CT) identified a 57×74 mm mass in the right lower quadrant involving the terminal ileum and rectosigmoid junction, with associated bowel wall thickening and right ureteral invasion causing hydronephrosis. PET-CT showed intense FDG uptake (SUV_{max} 17.77) confined to the mass, with no distant involvement. The patient underwent elective surgery. Intraoperatively, a granulomatous mass invading the colon, distal small intestine, duodenum, ureters, and retroperitoneum was identified. Debulking surgery with colectomy was performed, leaving a rectal stump and creating a jejunostomy. Duodenal injury due to tumor invasion was repaired, and a feeding jejunostomy was placed. Histopathological examination revealed actinomycosis with xanthogranulomatous inflammation and abscess formation. The patient was treated with intravenous meropenem followed by oral amoxicillin and was discharged in good condition.

Conclusion: Actinomycosis is a disease that can occur in the presence of risk factors such as surgical or invasive procedures, trauma, or diabetes mellitus, and may present with a wide range of clinical manifestations depending on the affected region of the body. However, as demonstrated in our case, it is important to recognize that actinomycosis can also develop in the absence of any identifiable risk factors.

Metaplastic breast carcinoma: A rare case report of coexistence of invasive ductal carcinoma and mesenchymal sarcoma

Muhammed Özdemir[1], Zekeriya Pelen[1], Feyza Kaya[1], Sibel Bektaş[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul*
[2]*Department of Medical Pathology, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul*

Objective: Metaplastic breast cancer is a histologically and molecularly diverse cancer type. It is a rare and poorly prognostic malignancy, accounting for 0.2-5% of all breast cancers. Therefore, metaplastic cancer has the worst prognosis compared to other types of breast cancer and plays a significant role in global breast cancer mortality.

Results: This report presents a 70-year-old woman with metaplastic breast carcinoma. The patient was followed up at an external center with a cystic lesion in her right breast. During the follow-up period, it was observed that the cystic area grew rapidly and caused necrosis in the skin. Follow-up imaging revealed a solid component within the cyst, prompting frozen section examination followed by segmental mastectomy and sentinel lymph node sampling. Histopathological examination revealed an 11x8x4 cm lesion containing T2N0, nuclear grade III, ER (-), PR (-), cerbB2 (-), invasive ductal carcinoma, high-grade papillary carcinoma *in situ*, and high-grade mesenchymal sarcoma components. The patient received adjuvant radiotherapy and is being followed up 11 months postoperatively without recurrence.

Conclusion: In conclusion, metaplastic breast cancer has very different clinical and pathological characteristics from invasive ductal carcinoma. Its large size, high grade, and associated local recurrence and poor prognosis are negative features. Despite these negative characteristics, breast-conserving surgery can be performed in patients for whom it is possible, with adjuvant radiotherapy planned. The infrequent occurrence of nodal involvement should not rule out axillary surgery in these tumors, which can contain many components.

Approach to metaplastic squamous cell carcinoma of the breast: A rare case

Kerim Karslı[1], Serhan Akalın[2], Ogün Aydoğan[1], Erdem Barış Cartı[1]

[1]*Department of General Surgery, Aydın Adnan Menderes University Hospital, Aydın*
[2]*Clinic of General Surgery, Aydın State Hospital, Aydın*

Objective: Metaplastic breast carcinomas account for less than 1% of all breast malignancies. Metaplastic squamous cell carcinoma is a distinct subtype characterized by prominent squamous differentiation, keratinization, and absence of glandular structures. Most tumors demonstrate a triple-negative immunophenotype, lacking estrogen receptor, progesterone receptor, and HER2 expression. Due to the absence of specific clinical and radiological findings, definitive diagnosis is usually established by histopathological and immunohistochemical examination. Fine-needle aspiration and core needle biopsy may have limited diagnostic accuracy, and excisional biopsy is often required for definitive diagnosis.

Material and Methods: A 67-year-old female patient presented with a complaint of a palpable mass in the left breast. Mammography and ultrasonography revealed a 26x2 mm lesion in the upper outer quadrant of the left breast, described as a complex cyst containing internal echoes with layering, without pathological vascularization on Doppler sonography, and partially mobile internal echoes (BI-RADS 4A). Preoperative fine-needle aspiration biopsy performed prior to surgery reported atypical cells with large nuclei. To obtain a definitive diagnosis, a wire-localized excisional biopsy was planned. Histopathological examination of the excisional biopsy specimen revealed metaplastic squamous cell carcinoma. Immunohistochemical evaluation demonstrated that the tumor cells were ER 0%, PR 0%, HER2 0%, and the Ki-67 proliferation index was 40%; these findings were consistent with the triple-negative phenotype reported in the literature. Following the definitive diagnosis, the patient underwent PET-CT for oncological staging. No distant organ metastases were detected. A small, mildly hypermetabolic lymph node (SUV_{max}: 2.7) was observed in the right axilla, and a second operation for sentinel lymph node biopsy was planned. During this procedure, four sentinel lymph nodes were identified and removed using subcutaneous periareolar injection of methylene blue, and no metastases were detected. Axillary lymph node involvement in metaplastic breast carcinoma has been reported to be lower than in invasive ductal carcinoma.

Results: Metaplastic squamous cell carcinoma of the breast is a rare malignancy with aggressive biological behavior. Poor response to conventional systemic chemotherapy has been reported, contributing to an unfavorable prognosis compared with invasive ductal carcinoma. The frequent occurrence of inconclusive or suspicious cytological findings highlights the importance of excisional biopsy for accurate diagnosis. Although surgical resection remains the cornerstone of treatment, the role of adjuvant chemotherapy and radiotherapy remains controversial.

Conclusion: Metaplastic squamous cell carcinoma of the breast is rare; excisional biopsy confirms diagnosis, negative sentinel nodes may avoid axillary dissection, and it should be considered in differential diagnosis.

Keywords: Breast tumor, metaplastic breast carcinoma, squamous cell carcinoma

[P-158]

Migration of an intra-abdominal drainage catheter into the ileal lumen after surgery for perforated appendicitis: A case report

Omer Akay[1], Emre Erdoğan[2]

[1]*University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

[2]*Aktif International Kocaeli Hospital, Kocaeli*

Objective: Surgical drainage catheters are commonly used after intra-abdominal procedures to prevent fluid accumulation, control infection, and facilitate postoperative monitoring. Despite their prophylactic and therapeutic benefits, drainage catheters may rarely cause serious complications. Intraluminal migration of a surgical drain into the bowel is an extremely rare but potentially life-threatening event, with only a limited number of cases reported in the literature. Migration of a drainage catheter following appendectomy is particularly uncommon. In this report, we present a rare case of ileal intraluminal migration of a drainage catheter resulting in enterocutaneous fistula formation after surgery for perforated appendicitis.

Material and Methods: This study is a retrospective case report of a 26-year-old male patient who underwent emergency surgery for perforated appendicitis and subsequently developed intraluminal migration of an intra-abdominal drainage catheter. Clinical findings, laboratory parameters, radiological imaging, operative findings, and postoperative follow-up data were reviewed. Diagnosis and treatment decisions were guided by contrast-enhanced computed tomography and surgical exploration findings.

Results: The patient underwent emergency laparotomy for perforated appendicitis with fecal peritonitis. Appendectomy, intra-abdominal abscess drainage, and irrigation were performed, followed by placement of four Jackson-Pratt drainage catheters into the right and left paracolic gutters, pelvis, and appendectomy bed. On postoperative day 11, gastrointestinal content was observed draining from the catheter placed in the appendectomy bed. Oral contrast-enhanced computed tomography revealed that the drainage catheter had migrated intraluminally into the ileum. As the patient remained clinically stable, conservative management was initially preferred. After resolution of intra-abdominal inflammation, elective surgery was performed. Intraoperatively, the drainage catheter was found to have fistulized into an ileal loop approximately 50 cm proximal to the ileocecal valve and progressed intraluminally. Segmental ileal resection with primary anastomosis was performed. The postoperative course was uneventful, and the patient was discharged without complications.

Conclusion: Although intra-abdominal drainage catheters are valuable tools in postoperative management, they may rarely lead to serious complications such as intraluminal bowel migration and enterocutaneous fistula formation. Early recognition based on clinical findings and prompt radiological evaluation are essential to reduce morbidity. Careful patient selection, appropriate drain type, and early removal of drainage catheters may help prevent such complications. This rare case highlights the importance of vigilance regarding drain-related complications and contributes to the limited literature on this subject.

Fecal-related stercoral rectosigmoid perforation: A serious complication of fecal impaction

Güvenç Diner, Güven Erdoğrul, Boran Cihat Karakuş

University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: Chronic constipation is a common clinical problem in the elderly population and significantly reduces quality of life. Prolonged constipation can lead to hardening and accumulation of feces, a condition defined as fecaloma, which is frequently observed in elderly patients. Although fecaloma is usually benign, it can rarely lead to serious and life-threatening complications. Most important of these is stercoral colon perforation, which is associated with a high mortality rate. Stercoral perforation typically occurs in elderly individuals with multiple systemic comorbidities, limited mobility, and dependency in daily living activities.

Material and Methods: A 67-year-old male patient with a long-standing history of chronic constipation presented to the emergency department with progressively worsening abdominal pain for two days, accompanied by inability to pass gas and stool. Physical examination revealed significant abdominal distension and diffuse tenderness in all quadrants. Laboratory tests showed leukocytosis (WBC: 14,500/mm^3). Abdominal computed tomography demonstrated widespread fecalomas at the level of the left colon and rectum, accompanied by free air within the abdominal cavity. Based on these findings, the patient was taken for emergency surgical intervention. A large perforation area was identified at the rectosigmoid junction, with fecal contents spread into the abdominal cavity. A Hartmann procedure was performed. The distal rectum was closed with a stapler, the fecalomas in the left colon were evacuated, and an end colostomy was created. The postoperative course was uneventful, and the patient was discharged on postoperative day seven with appropriate recommendations.

Results: Constipation and fecal impaction are common clinical conditions, especially in elderly and bedridden patients. Prolonged fecal stasis leads to the formation of hardened fecal masses within the colonic lumen, known as fecalomas. Although the presence of fecaloma usually does not cause serious problems, in rare cases, increased intraluminal pressure may lead to ischemia of the colonic wall, which can subsequently result in stercoral perforation. Stercoral perforation is a severe and potentially fatal condition that occurs when hardened fecal masses exert continuous pressure on the intestinal wall, leading to loss of bowel integrity. Following perforation, intestinal contents can spread into the peritoneal cavity, resulting in severe peritonitis, rapid bacteremia, and multi-organ failure. The Sudeck point, located at the rectosigmoid junction where the marginal artery circulation is limited, is a watershed area prone to ischemia in the presence of increased intraluminal pressure and fecaloma.

Conclusion: Stercoral perforation is a rare but serious emergency surgical condition with a high mortality risk, particularly in elderly patients with chronic constipation and comorbidities.

Keywords: Chronic constipation, fecaloma, stercoral perforation

[P-160]

Combined preoperative botulinum toxin A injection and progressive pneumoperitoneum for the repair of a type II giant inguinoscrotal hernia: A case report

Burcu Çanakcı, Muhammed Selim Bodur, Şükrü Oğuz, Ceren Yolcu

Karadeniz Technical University Faculty of Medicine, Trabzon

Objective: Giant inguinoscrotal hernias are rare and challenging conditions. They are classified using two anatomical landmarks: The midpoint of the inner thigh and the superior border of the patella. Hernias extending above the midpoint are classified as type I, those below as type II, and those extending below the patella as type III. Hernioplasty alone is often insufficient in type II and III hernias due to loss of domain caused by long-standing herniation. Tensioned closure may result in respiratory compromise or abdominal compartment syndrome. This study presents a successful combined botulinum toxin A and progressive pneumoperitoneum approach in a type II case.

Material and Methods: In the preoperative evaluation, computed tomography (CT) was used as the primary imaging modality for abdominal assessment. The abdominal cavity and hernia sac were assumed to be ellipsoid in shape. Volumetric calculations were performed by selecting the maximum craniocaudal, transverse, and anteroposterior diameters from all CT slices. The day of the patient's initial presentation was designated as day 0. Abdominal cavity volume and hernia sac volume were calculated using CT images obtained on day 0 (Figure 1). On day 1 of follow-up, botulinum toxin was administered under ultrasound guidance by interventional radiology. A total dose of 200 IU (100 IU on the right and 100 IU on the left) was injected into the external oblique, internal oblique, and transversus abdominis muscles at three points on each side. Follow-up imaging was performed on day 10, and volumetric measurements and lateral abdominal wall muscle elongation were calculated. On day 20, an intraperitoneal catheter was placed. Insufflation was performed through this catheter with 500 mL of room air administered twice daily. This procedure was continued for five days. The patient was closely monitored with serial abdominal examinations, vital sign assessments, and urine output measurements. On day 26, the patient underwent elective surgical repair. Abdominal cavity volume and hernia sac volume calculations were performed using the ellipsoid volume formula, where a is the radius in the craniocaudal plane, b is the radius in the transverse plane, and c is the radius in the anteroposterior plane. Ellipsoid volume: $V=4/3\cdot\pi\cdot a\cdot b\cdot c$.

Results: Following botulinum toxin administration, the abdominal cavity volume increased to 4387 mL. Additionally, elongation of the lateral abdominal wall muscles by 4-5 cm was observed. CT performed on day 25 after progressive pneumoperitoneum demonstrated a further increase in abdominal cavity volume to 7084 mL. All procedures performed, along with changes in abdominal cavity volume, variations in lateral abdominal wall muscle length, and the ratio of hernia sac volume to abdominal cavity volume, are summarized in conclusion.

Conclusion: This case shows that botulinum toxin A and progressive pneumoperitoneum correct loss of domain and allow tension-free repair in type II inguinoscrotal hernia.

Keywords: Giant inguinoscrotal hernia, loss of domain, botulinum toxin A, progressive pneumoperitoneum

Local recurrence and leukemia twelve years after breast cancer treatment: A rare case report in a TP53-positive patient

Derya Selamoğlu, Baki Ekçi, Murat Demir, Işıl Aladağlı, Hüseyin Kılavuz

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Li-Fraumeni syndrome (LFS) is a hereditary cancer predisposition syndrome first described in 1969 by Frederick P. Li and Joseph F. Fraumeni Jr. It is caused by germline mutations in the *TP53* tumor suppressor gene, which regulates the cell cycle and induces apoptosis in response to DNA damage. *TP53* mutations are associated with a broad spectrum of malignancies, including breast cancer, sarcomas, brain tumors, and hematologic cancers. The tumor spectrum in LFS is age-dependent, with adrenocortical carcinoma, choroid plexus tumors, and rhabdomyosarcoma in childhood; osteosarcoma, leukemia, and gliomas in young adulthood; and breast and gastrointestinal cancers in early adulthood. This case highlights the development of a secondary hematologic malignancy in a *TP53*-positive breast cancer patient with long-term survival.

Material and Methods: A 54-year-old woman had been diagnosed with left breast invasive ductal carcinoma (ER+, PR+, HER2-) 12 years earlier and was treated with breast-conserving surgery, adjuvant AC-T chemotherapy, radiotherapy, and five years of hormonotherapy. Imaging performed for suspected ipsilateral recurrence revealed a 1.5×1 cm spindle cell malignant tumor with marked pleomorphism and 6-7 mitoses per 10 high-power fields on excisional biopsy.p53 positivity on immunohistochemistry prompted molecular analysis, which identified a heterozygous *TP53* c.844C>T (p.Arg282Trp) variant. Following genetic counseling, bilateral prophylactic mastectomy was performed. During follow-up, the patient developed bone pain, and PET/CT showed increased FDG uptake in the femur. Bone marrow biopsy confirmed acute myeloid leukemia. She underwent allogeneic bone marrow transplantation but died due to early post-transplant complications.

Results: This case is notable because it demonstrates both a solid tumor (breast cancer) and a hematologic malignancy (AML) developing years later in a *TP53*-positive patient. *TP53* mutations, particularly those associated with LFS, confer a lifetime cancer risk of up to 70-90%. Although hematologic malignancies typically occur in early childhood in this syndrome, they developed after age 50 in our patient. In addition, chemotherapeutic agents used in breast cancer treatment—especially alkylating agents and anthracyclines—may contribute to therapy-related AML; however, the presence of a germline mutation indicates an underlying genetic predisposition. The decision for prophylactic mastectomy may therefore be important not only for pathological risk but also for patients with genetic susceptibility. This case highlights the need for careful long-term surveillance for secondary hematologic malignancies in *TP53*-positive individuals.

Conclusion: Breast cancer patients harboring *TP53* mutations have an increased risk of developing secondary hematologic malignancies. Therefore, long-term genetic counseling, a personalized oncologic approach, and multidisciplinary follow-up are of great importance in this patient population.

Keywords: *TP53* mutations, breast cancer, Li-Fraumeni syndrome

Extended surgical approach for substernal goiter: Bilateral total thyroidectomy with sternotomy

Necati Adem Türker[1], Muhammed Alperen Taş[1], Yalçın Sönmez[1], Nebi Acar[1], Mehmet Fatih Ekici[1], Abdülkerim Özhan[2]

[1]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*
[2]*Department of Cardiovascular Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

Objective: Substernal goiter is defined as the presence of more than half of the enlarged thyroid mass below the sternal notch. Its incidence varies, but it is seen in approximately one in 5,000 people.While 20-40% of cases are detected incidentally during radiological examinations, the majority of cases present with symptoms such as dyspnea, dysphagia, and hoarseness secondary to mass compression.Approximately 81-99% of substernal goiter cases can be treated surgically with a cervical incision, while 2-19% require more invasive approaches such as sternotomy or thoracotomy. In this case, we present a bilateral total thyroidectomy with sternotomy in a patient with symptomatic substernal goiter.

Material and Methods: In this case, the diagnosis, treatment, and follow-up process of a patient who underwent bilateral total thyroidectomy with sternotomy due to substernal goiter at our clinic was evaluated.

Results: A 57-year-old male patient with a history of known diabetes, hypertension, and coronary artery disease, who is an ex-smoker, presented to the outpatient clinic with neck swelling and progressive dyspnea. On examination, a multinodular goiter was palpated in the substernal region. Blood tests showed euthyroid thyroid function. Due to its retrosternal location, a contrast-enhanced neck CT scan was planned. The CT scan showed hypodense nodules extending retrosternally, containing coarse calcifications in places. The patient was evaluated by a surgical endocrinology team consisting of general surgery, endocrinology, anesthesiology and resuscitation, ear nose and throat, and cardiovascular surgery teams. A decision was made to perform bilateral total thyroidectomy with sternotomy. The substernally located thyroid tissue was removed from the posterior mediastinum via sternotomy. The patient was intubated and monitored in the intensive care unit for two days postoperatively. Subsequently, the patient was transferred to the ward, and no pathology was observed in the postoperative vocal cord examination. The patient was discharged on the 6th postoperative day. No complications were observed during postoperative follow-up. The pathology results showed no malignancy.

Conclusion: Patients diagnosed with substernal goiter should undergo multidisciplinary evaluation during the preoperative period. Computed tomography is the primary imaging method used in the preoperative evaluation process to plan the surgical procedure and determine the necessity of sternotomy. During surgical treatment, the degree of extension into the mediastinum and the anatomical relationship with the surrounding tissue should be evaluated. Substernal goiter surgery has a higher morbidity rate compared to standard thyroid surgery. In these cases, not avoiding sternotomy increases surgical safety and reduces the risk of complications. The effective use of CT and a multidisciplinary approach play an effective role in determining the appropriate surgical approach.

Keywords: Goiter, sternotomy, thyroidectomy

Completecholedoc obstruction and choledocoduodenal fistula at 9 months after cholecystectomy

Yiğit Baydar, Barış Doğu Yıldız, Mustafa Dönmez, Mutlu Doğanay

University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: A 52-year-old female patient underwent cholecystectomy at an external center and presented to our hospital with jaundice and abdominal pain 9 months postoperatively. Imaging revealed complete obstruction of the common bile duct, and further investigation/endoscopic/interventional/surgical treatment options were planned for the patient.

Material and Methods: Initially, a percutaneous biliary tract (PTC) procedure was planned for the patient. A cholangiogram revealed a tract identified as a choledochoduodenal fistula, but without bile flow. External biliary drainage catheters were placed in the right and left hepatic ducts via PTC. Subsequently, an ERCP procedure was performed, locating and cannulating the fistula tract opening in the bulb, but bile drainage was not achieved. Therefore, a decision was made to proceed with surgical exploration. Surgical exploration revealed a severely dense and adherent hepatoduodenal ligament. The common bile duct was dissected, showing complete obstruction just distal to the level of the confluence, and severely dilated proximal to the stenosis, with an approximate diameter of 3 cm. The choledochoduodenal fistula tract was also located and excised. A Roux-N-Y hepaticojejunostomy was performed. The external biliary drainage catheters were preserved to ensure anastomotic safety. External biliary drainage catheters were discontinued one month after discharge.

Results: Nine months after cholecystectomy, a benign biliary stricture, potentially causing complete obstruction of the common bile duct, was considered the primary cause. Intraoperative exploration revealed no clips, staples, or sutures in the common bile duct. However, a choledochuodenal fistula allowed for continued bile drainage, enabling the patient to live with asymptomatic benign biliary stricture for nine months. Spontaneous obliteration of the fistula tract resulted in symptoms due to bile stasis.

Conclusion: Jaundice, abdominal pain, and intrahepatic bile duct dilation after cholecystectomy generally suggest the possibility of surgical complications/injury; however, it should be kept in mind that benign biliary strictures can also present with bile duct obstruction, proximal segment bile duct dilation, and jaundice. Nevertheless, in our patient, the presence of a choledochuodenal fistula prevented bile stasis even in the presence of complete obstruction, allowing for an asymptomatic course.

Keywords: Clodedoch cholecystectomy bile

[P-164]

Organ-preserving surgical experience in a young woman with solid pseudopapillary neoplasm of the pancreatic head

Doğuhan Kaya, Serhat Gizlenci, Sefa Özyazıcı

University of Health Sciences Türkiye, Adana City Hospital, Adana

Objective: Solid pseudopapillary neoplasm (SPN) is one of the rare epithelial tumors of the pancreas with low malignant potential. It accounts for approximately 1-3% of all pancreatic tumors and is observed predominantly in young women. Clinical findings are often non-specific; it most commonly presents with abdominal pain or as an incidentally detected mass. Although imaging modalities are helpful in guiding the diagnosis, definitive diagnosis is established through histopathological examination. In SPN, surgical resection is curative, and long-term survival rates are high. Particularly in young patients, parenchyma-sparing surgical approaches aimed at preserving pancreatic function have gained increasing importance.

Material and Methods: A 22-year-old female patient presented with recurrent epigastric abdominal pain. Laboratory investigations revealed mildly elevated serum amylase and CA 19-9 levels. Contrast-enhanced abdominal CT and magnetic resonance imaging demonstrated a well-circumscribed, solid mass measuring approximately 5×4 cm in the head of the pancreas. The lesion showed no invasion of the surrounding vascular structures, and no distant metastasis was detected. Although radiologically consistent with SPN, the possibility of malignancy could not be completely excluded. Considering the presence of a resectable mass and the patient's young age, surgical resection was planned by multidisciplinary board decision without performing a preoperative biopsy. The patient underwent central pancreatectomy with Roux-en-Y pancreaticojejunostomy. Preoperative CT imaging shows a 5 cm tumor located in the body and head of the pancreas.

Results: During the operation, a well-circumscribed solid mass was identified in the head of the pancreas, without invasion into the surrounding tissues. The resection was macroscopically complete. Histopathological examination reported the tumor size as 5 cm and established the diagnosis of solid pseudopapillary carcinoma. The surgical margins were negative for tumor involvement (R0 resection). No metastasis was detected in the resected lymph nodes. No major complications developed in the postoperative period. Serum amylase and CA 19-9 levels returned to normal ranges during follow-up. The patient was discharged without any problems, and no evidence of recurrence was observed during early follow-up visits.

Conclusion: Although SPN is rare in young female patients, its prognosis is generally favorable. This case demonstrates that R0 resection can be achieved without lymph node involvement despite the diagnosis of solid pseudopapillary carcinoma. In appropriately selected patients, central pancreatectomy may be a safe and effective organ-preserving surgical option that contributes to the preservation of pancreatic function.

Keywords: Solid pseudopapillary neoplasm, tumor of the head of the pancreas, organ preserving surgery

[P-165]

Use of stent and endo-SPONGE therapy in esophageal perforation

Sedef Poşul, İklil Eryılmaz, Selçuk Kaya

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Esophageal perforation and postoperative anastomotic dehiscence are challenging clinical conditions associated with high morbidity. Although surgical intervention has traditionally been the mainstay of treatment, minimally invasive endoscopic techniques such as esophageal stenting and endoscopic vacuum therapy (endo-SPONGE) have recently emerged as effective alternatives in selected patients.

Material and Methods: Forty-five-year-old female patient underwent upper gastrointestinal endoscopy for dyspepsia, nausea, and vomiting, which revealed a well-defined 2-cm submucosal lesion located 20 cm from the incisors. The patient was operated on via thoracotomy, and a posteromediastinal mass was excised. Intraoperatively, esophageal invasion was identified, resulting in a minimal esophageal defect that was primarily repaired with double-layer suturing. One month postoperatively, the patient presented with nausea and fever. Endoscopic evaluation demonstrated anastomotic dehiscence and fistula formation at the site of primary repair. A fully covered esophageal stent was placed. During follow-up, progressive esophageal wall thinning and tissue loss involving approximately one-third of the esophageal lumen were observed due to prolonged stent therapy. Consequently, treatment was converted to endoscopic vacuum therapy. Endo-SPONGE was applied twice monthly for a total of five sessions.

Results: Serial endoscopic evaluations during vacuum therapy showed a significant reduction in defect size. The diameter of the paraesophageal cavity decreased from 4 cm to 2 cm, and the depth regressed from 3.5 cm to 2 cm. Granulation tissue formation was observed, and complete closure of the fistula tract was achieved. Following successful healing, endo-SPONGE therapy was discontinued and a fully covered esophageal stent was reinserted. After three uneventful stent controls, the stent was removed one month later. The patient tolerated oral intake well and returned to normal daily activities.

Conclusion: This case demonstrates that esophageal perforations can be successfully managed without additional surgery using minimally invasive endoscopic techniques in appropriately selected patients.

Keywords: Esophageal stent, endo-SPONGE therapy

A rare case of Meckel's diverticulum perforation: A case report

Sude Sezer Özkul[1], Zekiye Çiler Aydın[1], Adem Yüksel[2], Savaş Fidan[1], Enis Onduk[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

[2]*Department of Gastrointestinal Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract and is usually asymptomatic. Complications of Meckel's diverticulum secondary to foreign bodies are extremely rare. Perforations caused particularly by sharp foreign bodies have been reported in only a limited number of cases in the literature. In this case report, we aimed to present a localized perforation of Meckel's diverticulum caused by ingestion of a sewing pin.

Material and Methods: A 20-year-old female patient presented to an external emergency department after accidentally swallowing a sewing pin that she had been holding in her mouth while fixing her headscarf. As there were no signs of acute abdomen, she was followed up with daily standing abdominal radiographs. Due to the lack of progression of the foreign body during a 10-day follow-up period, she was referred to our center for endoscopic evaluation. Endoscopic intervention was not considered because the pin was localized in the ileum. The patient reported right lower quadrant pain; however, abdominal examination findings were unremarkable. Since no progression was observed on radiographs despite oral contrast administration and enemas, surgical intervention was planned.

Results: During laparotomy, a Meckel's diverticulum was identified, and the sharp end of the sewing pin was found to have perforated the tip of the diverticulum and penetrated into the omentum. As there was no intra-abdominal contamination, diverticulectomy was performed using a linear stapler.

Conclusion: Meckel's diverticulum may serve as an anatomical trap for foreign bodies. In cases of sharp foreign body ingestion, Meckel's diverticulum should be kept in mind as a rare site of perforation.

Keywords: Meckel's diverticulum, perforation, sharp foreign body

[P-167]

Spontaneous spleen rupture secondary to infectious mononucleosis

Alim Akdağ[1], Sevda Yılmaz[2], Utku Özgen[2], Onur Birsen[2]

[1]*Denizli State Hospital, Denizli*

[2]*Pamukkale University Hospital, Denizli*

Objective: The etiology of spontaneous splenic rupture can be classified into six subgroups: infectious, neoplastic, inflammatory, congenital or structural, iatrogenic, idiopathic. In this classification, reviewed 632 relevant publications and examined a total of 845 patients. In this review, pathological rupture due to one or more etiological causes was observed in 93% of cases. In the remaining 7%, the spleen was normal (idiopathic rupture). Neoplastic diseases were the most frequent etiology (30.3%), followed by infectious causes (27.3%). The remaining 7% classified as idiopathic. Among neoplastic causes, hematological malignancies were reported as the most common. Among infectious causes, viral infections are the most common, followed by bacterial, protozoal infections. Among inflammatory etiologies, the most frequent causes include acute, chronic pancreatitis, pancreatic cancer, amyloidosis, Wegener's granulomatosis. Treatment options for SSR include total splenectomy (84.1%), organ-preserving surgery (1.2%), conservative treatment (14.7%).

Material and Methods: This is a poster presentation of a patient diagnosed with SSR due to EBV infection and who underwent surgery for this reason.

Results: A 21-year-old male patient presented with complaints of sore throat, fever, malaise, and left upper quadrant pain that started 3 days prior. He had no known underlying medical conditions. He had started treatment for an upper respiratory tract infection two days prior to admission; however, his symptoms had progressively worsened despite treatment. SPO_2: 100, BP: 125/72 mmHg, pulse: 105/min, temperature: 37.5 °C. Physical examination revealed marked tonsillar hypertrophy, cervical, submandibular lymphadenopathy, hepatosplenomegaly, and tenderness, guarding in the left upper quadrant. Laboratory tests showed leukocytosis (17.3 K/uL), significant elevation of liver transaminases (AST: 216 IU/L, ALT: 347 IU/L), increased LDH (489 U/L), thrombocytopenia (123 K/uL). Abdominal CT scan revealed hepatosplenomegaly, perisplenic, perihepatic free fluid, subcapsular hematoma. These findings were considered to be spontaneous splenic rupture. Due to the absence of a history of trauma and the sudden onset of splenic rupture, infectious causes were investigated. Serological tests showed positive results for EBV, VCA IgM, and IgG, leading to a diagnosis of spontaneous splenic rupture secondary to infectious mononucleosis. Emergency splenectomy was performed. During the operation, 1000 cc of free hemorrhagic fluid aspirated, and a ruptured hematoma observed in the lower pole of the spleen. The patient monitored in the intensive care unit for 48 hours after surgery and discharged after 7 days. An infection prevention protocol and necessary vaccination programs planned, and regular check-ups recommended. Pathology results showed no malignancy.

Conclusion: SSR although rare, is a life-threatening complication of IM. It should be considered in cases of left upper quadrant pain with hemodynamic instability. Early intervention with surgery when conservative treatment options fail is life-saving.

Diagnosis of Behçet's disease in a young male patient presenting with superior mesenteric vein thrombosis: Surgical approach and multidisciplinary management

Hasan Kumru[1], Zeynep Sena Kaya Kumru[2], Olgun Erdem[1], Süleyman Ümit Emanet[1], Aylin Acar[1], Tolga Canbak[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul*

[2]*Department of Internal Medicine, Marmara University, Pendik Training and Research Hospital, İstanbul*

Objective: Superior mesenteric vein (SMV) thrombosis is a rare but potentially life-threatening condition due to the risk of intestinal ischemia and high mortality. Its clinical presentation ranges from non-specific abdominal symptoms to bowel infarction and perforation. In young patients presenting with isolated venous thrombosis, underlying systemic inflammatory or vasculitic diseases should be carefully investigated. Behçet's disease is a multisystemic vasculitis that may involve the venous system and, in rare cases, present with mesenteric venous thrombosis. This report describes the diagnostic process and multidisciplinary management of a young male patient presenting with SMV thrombosis who was subsequently diagnosed with Behçet's disease.

Material and Methods: The clinical course, laboratory findings, and radiological imaging of a 20-year-old male patient presenting with abdominal pain and diarrhea were retrospectively reviewed. Surgical decision-making criteria and the multidisciplinary diagnostic approach were analyzed.

Results: The patient presented with a two-week history of epigastric abdominal pain and recent onset of watery diarrhea. Physical examination revealed abdominal distension with mild diffuse tenderness, without peritoneal signs. Laboratory evaluation showed marked leukocytosis (20,000/mm³) and elevated C-reactive protein levels (200-223 mg/L), while serial lactate measurements demonstrated a decreasing trend. Contrast-enhanced abdominal computed tomography revealed a filling defect in the proximal SMV. On the fourth day of hospitalization, CT angiography demonstrated a thrombus in the proximal SMV with loss of distal luminal flow. Despite these findings, no radiological evidence of intestinal ischemia, necrosis, or perforation was observed. Given the patient's clinical stability, normalization of lactate levels, and absence of peritoneal signs, surgical intervention was deferred, and conservative management with therapeutic-dose low-molecular-weight heparin was initiated. The patient's clinical condition gradually improved without surgical complications. Further evaluation for thrombotic etiology revealed negative results for JAK2 mutation and paroxysmal nocturnal hemoglobinuria. Dermatological findings, including recurrent oral aphthae, papulopustular lesions, a history of uveitis, and recurrent thromboembolic events, led to the diagnosis of Behçet's disease according to the International Criteria for Behçet's disease. Immunosuppressive therapy was initiated, and anticoagulation was continued with warfarin.

A thrombus consistent with a filling defect is observed in the proximal SMV; no accompanying findings of overt intestinal ischemia or free air are identified.

Conclusion: In young patients presenting with SMV thrombosis, underlying systemic vasculitides should be investigated after excluding acute surgical pathology. This case highlights that Behçet's disease may present with isolated venous occlusion and that conservative management can be safely applied under appropriate clinical conditions. Early diagnosis and multidisciplinary evaluation are essential to avoid unnecessary surgical intervention.

Keywords: Superior mesenteric vein thrombosis, Behçet's disease, acute abdomen, multidisciplinary approach, conservative management

Organoaxial gastric volvulus secondary to hiatal hernia: A case report

Ahmet Salhat, Caner Akgül, Yacob Habeş

Gebze Fatih State Hospital, Kocaeli

Objective: Gastric volvulus is a rare clinical condition that occurs when the stomach loses its normal anatomical position and rotates around its axis, carrying a high-risk of morbidity and mortality if diagnosis is delayed. The organoaxial type develops as a result of rotation along the stomach's longitudinal axis and is most commonly associated with hiatal hernia. Because clinical findings are often non-specific, diagnosis may be delayed, leading to serious complications. In this case report, we present the diagnostic process and successful treatment of organoaxial gastric volvulus secondary to hiatal hernia using a laparoscopic approach.

Material and Methods: A 56-year-old female patient presented to the emergency department with sudden-onset abdominal pain and recurrent vomiting. Her medical history was unremarkable except for hypertension. Physical examination revealed mild abdominal tenderness and distension, with no signs of guarding or rebound. Laboratory evaluation showed a leukocyte count of 13,160/mm³, while other parameters were within normal limits. Contrast-enhanced abdominal computed tomography demonstrated marked gastric distension, displacement of the greater and lesser curvatures, and abnormal positioning of the antropyloric region and part of the duodenum in the right upper quadrant. These findings were consistent with organoaxial gastric volvulus.

Results: Gastric decompression was achieved by insertion of a nasogastric tube, draining approximately 1600 cc of bilious gastric content. Subsequent upper gastrointestinal endoscopy revealed findings supporting gastric volvulus, along with diffuse mucosal edema and focal superficial ulcerations. Based on the clinical and radiological findings, emergency surgical intervention was planned. The patient underwent laparoscopic surgery. Intraoperative exploration revealed herniation of the proximal stomach into the thoracic cavity through the esophageal hiatus, resulting in organoaxial volvulus. The stomach was reduced from the thorax and restored to its anatomical position. No evidence of gastric wall ischemia or necrosis was observed. Crural repair and Nissen fundoplication were performed to address the hiatal hernia and prevent reflux. The postoperative course was uneventful, and the patient was discharged on postoperative day four.

Conclusion: Although rare, organoaxial gastric volvulus is an important surgical emergency requiring rapid diagnosis and intervention. In the presence of hiatal hernia, acute upper gastrointestinal symptoms should be carefully evaluated for gastric volvulus. In appropriately selected patients, laparoscopic management is a safe and effective option, offering both diagnostic and therapeutic benefits.

A rare cause of ileus: Small intestinal involvement in Behçet's disease and ileus secondary to hematoma

Atahan Uzun[1], Hikmet Özel[1], Fatih Kından[1], Derya Alparslan[2]

[1]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[2]*Devrek State Hospital, Zonguldak*

Objective: Behçet's disease is a chronic, relapsing multisystem vasculitis affecting both small and large vessels. Gastrointestinal involvement, reported in 3-25% of patients, represents one of the most serious complications and is associated with increased morbidity and mortality. The terminal ileum is the most commonly involved site, while isolated proximal small bowel involvement is rare. We report a case of a 49-year-old female with Behçet's disease who underwent segmental small bowel resection for ileus caused by an intramural hematoma.

Material and Methods: A 49-year-old female patient presented to the emergency department with complaints of abdominal pain, constipation, nausea, and vomiting persisting for approximately 10 days. The patient had a known diagnosis of Behçet's disease and a surgical history significant for total colectomy and cholecystectomy performed 10 years earlier. On physical examination, abdominal distension was noted, with tenderness on palpation in the right lower quadrant. Laboratory investigations revealed hemoglobin of 11.6 g/dL, leukocyte count of 18,180/µL, platelet count of 521,000/µL, and C-reactive protein level of 28.1 mg/L. Abdominal computed tomography demonstrated gastric and intestinal loop dilatation up to 42 mm, as well as millimetric air densities within the mesenteric fat tissue adjacent to small bowel loops in the right lower quadrant. Surgical exploration revealed a conglomerated small bowel segment with intramural hematoma and mass-like formation, starting approximately 110 cm distal to the ligament of Treitz and extending for nearly 40 cm. Segmental small bowel resection followed by side-to-side anastomosis was performed.

Results: Small bowel specimen: A resected small bowel segment measuring approximately 60 cm in length with a luminal diameter of 2.5 cm, collectively measuring 13×11.5×6 cm. Gross examination revealed multiple adhesions on the serosal surface, along with focal areas of hemorrhage. Histopathological evaluation demonstrated adhesions (macroscopic and microscopic), inflammatory granulation tissue, xanthomatous inflammation, and hemorrhage.

Conclusion: Gastrointestinal involvement in Behçet's disease is uncommon but may result in severe complications. Vasculitis-related intramural hematoma, although rare, can present with acute abdomen or mechanical ileus and lead to significant morbidity if not recognized early. In patients with Behçet's disease presenting with sudden-onset abdominal pain and obstructive symptoms, intestinal vasculitis–related complications should be considered. Early diagnosis and appropriate management are essential to reduce morbidity and prevent recurrence.

Keywords: Behçet's disease, hematoma, ileus

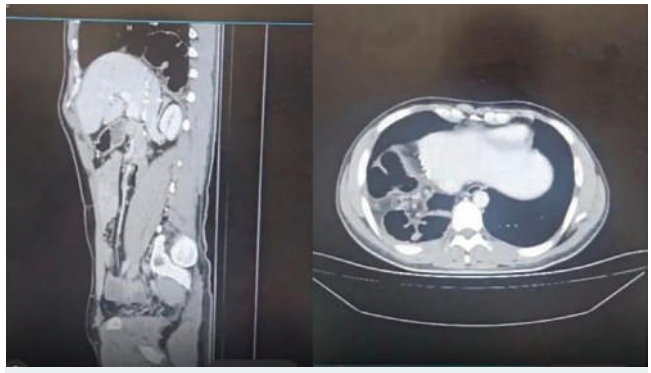
A rare cause of ileus; colon incarceration due to diaphragm rupture after right hepatectomy

Özde Baştar, Ali Cihat Yıldırım, Saim Taşpınar, Ayşe Tuğba Kurt

Clinic of General Surgery, Kütahya City Hospital, Kütahya



Objective: The diaphragm is a musculotendinous structure separating the thoracic and abdominal cavities and plays a key role in respiration. Diaphragmatic hernia is defined as herniation of intra-abdominal organs into the thoracic cavity through a congenital or acquired diaphragmatic defect. Most diaphragmatic ruptures are related to blunt or penetrating trauma and commonly occur on the left side, as the liver provides relative protection to the right hemidiaphragm. Delayed diaphragmatic rupture following trauma or upper abdominal surgery is uncommon and often presents with non-specific symptoms, leading to diagnostic delay and increased risk of complications such as organ incarceration, strangulation, and bowel obstruction. Diaphragmatic rupture after hepatectomy is rarely reported. This poster presents a case of delayed right-sided diaphragmatic rupture occurring two years after right hepatectomy and presenting with colonic obstruction.

Material and Methods: A 24-year-old male patient with a history of right hepatectomy for hepatocellular carcinoma two years earlier presented to the emergency department with a one-week history of abdominal pain and nausea. Physical examination revealed diffuse abdominal tenderness without signs of peritonitis. Contrast-enhanced computed tomography demonstrated a 4-cm defect in the right hemidiaphragm with herniation of colonic segments into the thoracic cavity and associated proximal bowel dilatation. Despite nasogastric decompression, the patient showed no clinical improvement during a 24-hour observation period. Based on radiological findings and persistent symptoms, emergency surgical intervention was planned.

Results: The patient underwent exploratory laparotomy under general anesthesia through a midline incision. Dense intra-abdominal adhesions related to the previous surgery were encountered. A diaphragmatic defect with surrounding deperitonized muscle tissue was identified on the right side, consistent with preoperative imaging. Incarcerated colonic segments were carefully reduced into the abdominal cavity. Due to an iatrogenic opening of the right parietal pleura during reduction, a closed underwater chest drainage system was placed. The diaphragmatic defect was repaired with a double-layer primary suture technique and reinforced with a composite mesh. The postoperative course was uneventful. Oral intake was initiated 24 hours after surgery, bowel function returned on postoperative day three, and the patient was discharged on postoperative day six without complications.

Conclusion: Delayed diaphragmatic rupture should be considered in the differential diagnosis of acute abdomen and intestinal obstruction, particularly in patients with a history of upper abdominal surgery. Following right hepatectomy, loss of the liver's protective effect and potential diaphragmatic weakening may predispose patients to late-onset rupture. Early recognition and prompt surgical repair are essential to prevent serious complications and ensure favorable outcomes.

Keywords: Colonic obstruction, diaphragmatic rupture, hepatectomy

Intra-abdominal hemorrhage due to ruptured HCC: A case report

Burcu Çanakcı[1], Arif Burak Çekiç[1], Mustafa Hilkat Bilaloğlu[2], Şükrü Oğuz[1], Muhammed Selim Bodur[1]

[1]*Karadeniz Technical University, Trabzon*

[2]*Bayburt State Hospital, Bayburt*

Objective: Hepatocellular carcinoma (HCC) is the most common primary malignant tumor of the liver and typically develops in the setting of cirrhosis or chronic hepatitis B infection. Spontaneous rupture of HCC is a rare but life-threatening complication associated with high mortality rates. In this case report, we present the diagnostic process and treatment of a hypotensive and tachycardic patient with no prior diagnosis of HCC who presented to the emergency department with syncope and abdominal pain, and whose management required a multidisciplinary approach across two centers.

Material and Methods: A 74-year-old male patient presented to an outside institution with complaints of syncope and epigastric pain. His medical history was significant for diabetes mellitus and chronic hepatitis B virus infection. On abdominal examination, tenderness was noted in the epigastric region and bilateral lower quadrants. No evidence of gastrointestinal bleeding was observed on nasogastric tube aspiration or digital rectal examination. Abdominal imaging performed due to decreased hemoglobin levels and the need for transfusion revealed a mass lesion in liver segment III and a large volume of free intraperitoneal fluid. Emergency laparotomy was performed, during which 1.700 cc of hemorrhagic fluid was aspirated. The source of bleeding was identified as the mass in liver segment III (Figure 1). As bleeding control was deemed unachievable at the referring center, intraoperative communication was established with our team. Perihepatic packing was applied, and following transfusion of six units of packed red blood cells, the patient was transferred to our center.

Results: The patient was admitted to the intensive care unit intubated and on low-dose inotropic support. A contrast-enhanced CT scan revealed a 48×40 mm heterogeneously enhancing hemorrhagic mass in liver segment III. Transarterial embolization of the hepatic artery branches via the celiac artery was performed (Figure 2), resulting in hemodynamic stability and no further hemoglobin decline. On postoperative day 1, the patient underwent removal of the packing and left lateral sectorectomy under low central venous pressure with a single 12-minute Pringle maneuver. The patient was extubated during follow-up and discharged on postoperative day 14.

Conclusion: Spontaneous rupture of HCC is a rare but potentially fatal clinical condition. Initial management must be systematic and rapidly implemented. In the present case, a favorable outcome was achieved through embolization at a tertiary referral center followed by elective surgical resection after initial surgical hemostasis.

Keywords: Hepatocellular carcinoma, spontaneous rupture, intraabdominal hemorrhage

[P-173]

A rare case of incidental colo-appendiceal fistula with appendiceal diverticulosis presenting as acute appendicitis: A case report

Ozan Erek, Atakan Erdoğan, Abdullah Kut

University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul

Objective: Acute appendicitis is the most common surgical cause of acute abdominal pain, Delayed diagnosis may lead to serious complications such as abscess, perforation, peritonitis, sepsis, and fistula formation.Appendiceal diverticulitis is a rare condition and may clinically mimic acute appendicitis. Appendiceal diverticula may be congenital or acquired. Due to mild or atypical symptoms, diagnosis may be delayed and the risk of perforation increases. Additionally, appendiceal diverticula are associated with a risk of neoplasia, particularly carcinoid tumors and mucinous adenomas. Colo-appendiceal fistula is a very rare complication. It is most commonly associated with Crohn's disease, colorectal malignancy, complicated appendicitis, or diverticular disease. Appendiceal diverticulitis is a rare but clinically significant condition that may lead to fistula formation.

Material and Methods: Patient: 51-year-old male History: Abdominal pain for 2 days Past medical history: Unremarkable Physical Examination:• Localized tenderness in the right lower quadrant Laboratory findings: • WBC: 7500 • CRP: 149 Imaging: Contrast-enhanced CT revealed findings consistent with acute appendicitis. Intraoperative Findings During diagnostic laparoscopy: • The appendix was found to be fistulized to the ascending colon • Multiple nodular structures consistent with diverticula were observed along the appendiceal wall • No macroscopic findings suggestive of malignancy or inflammatory bowel disease were detected • Terminal ileum and cecum appeared normalSurgical Procedure • The appendiceal base was closed and transected using an endo-stapler • Wedge resection of the involved colonic segment was performed with an endo-stapler for the distal fistulized segment • Laparoscopic appendectomy was completed.

Results: Pathological Findings Macroscopic examination: • Thickened and edematous appendiceal wall • Multiple diverticular structures • Thin fistula tract along the distal stapler line Histopathological examination: • Acute appendicitis • No malignancy or chronic inflammatory disease detected. The patient was discharged uneventfully on postoperative day 2.

Conclusion: Surgical approach surgical treatment should be individualized according to: • Etiology • Extent of colonic involvement • Intraoperative findings segmental colectomy may be required in cases with suspected malignancy or extensive inflammation. However, in selected cases without malignancy or widespread inflammation, simple appendectomy and separation of the fistula tract may be sufficient. The laparoscopic approach offers advantages including: • Less postoperative pain • Lower morbidity • Faster recovery • Shorter hospital stay technical evaluation if hem-o-lok clips or sutures are used instead of an endo-stapler, the procedure can be performed through a 5-10 mm port instead of a 15 mm port. This minimally invasive modification may reduce the risk of port-site incisional hernia and provide technical improvement for future cases. Colo-appendiceal fistula is a rare finding encountered during acute appendicitis surgery. Intraoperative awareness is important. In selected cases without malignancy or extensive inflammation, laparoscopic appendectomy and fistula separation is a safe and effective treatment option.

Keywords: Acute appendicitis, appendiceal diverticulosis, colo-appendiceal fistula

Giant Meckel's diverticulum causing adhesive small bowel obstruction with ischemia and inflamation: A case report

Elif Yılmaz

Ordu Umut Private Hospital, Ordu

Objective: Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, yet symptomatic disease in adults is uncommon. Most diverticula are <5 cm; truly giant diverticula are rare and can present as mechanical ileus—particularly in patients without prior abdominal surgery.

Material and Methods: A 67-year-old man presented with 3 days of nausea, vomiting, and obstipation. He had no history of abdominal surgery. Contrast-enhanced CT demonstrated markedly dilated small-bowel loops and a blind-ending, inflamed tubular structure (92×39 mm) in the right lower quadrant, separate from the cecum (Figure 1). Based on these findings, emergency laparotomy was performed.

Results: At exploration, the small bowel was diffusely dilated. A giant Meckel's diverticulum (approximately 14×4 cm) was identified about 50 cm proximal to the ileocecal valve on the antimesenteric border, with ischemic/necrotic changes and dense adhesions causing obstruction (Figure 2). Adhesiolysis and stapled diverticulectomy were carried out. Recovery was uneventful: Oral intake resumed on postoperative day 2, and the patient was discharged on day 4. Pathology confirmed transmural necrosis and intense neutrophilic inflammation, with no ectopic gastric or pancreatic mucosa.

Conclusion: Meckel's diverticulum is an uncommon but important cause of small bowel obstruction in adults. Keeping it in mind—especially when there is no surgical history—can speed up decision-making, and surgery remains definitive treatment.

Massive gastrointestinal hemorrhage due to splenic artery erosion in the setting of a pseudocyst: A rare vascular complication following necrotizing pancreatitis

Ayşe Abdukaya, Hüseyin Kılavuz, Murat Demir, Derya Selamoğlu, Birkan Bozkurt

Department of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam ve Sakura City Hospital, İstanbul

Objective: Acute pancreatitis is a heterogeneous disease whose clinical course can vary from a mild form to severe necrotizing pancreatitis, which carries a 20% mortality risk. Endoscopic and surgical drainage methods, such as cystogastrostomy or cystojejunostomy, are commonly used for the treatment of local complications, like pseudocysts and walled-off necrosis, in symptomatic patients following necrotizing pancreatitis. Complications such as infection, hemorrhage, and perforation may develop after these procedures. However, rare vascular complications following these interventions are of great clinical significance due to the difficulty in diagnosis and the high risk of mortality.

Material and Methods: This report presents a case of massive gastrointestinal hemorrhage due to vascular erosion at the junction of the splenic artery and celiac trunk, occurring late in a patient who underwent endoscopic cystogastrostomy and subsequent surgical cystojejunostomy for a pseudocyst that developed on the basis of necrotizing pancreatitis.

Results: A forty-nine-year-old male patient presented with a complaint of abdominal pain. His medical history included endoscopic cystogastrostomy and surgical cystojejunostomy for non-biliary necrotizing pancreatitis. The patient, who was being followed with medical treatment after an infected collection was detected in the pancreas body on imaging, developed hemodynamic instability with sudden syncope, hypotension, and massive hematochezia during follow-up. Active bleeding foci could not be demonstrated in upper and lower gastrointestinal endoscopies, CT angiography, or selective angiographies. Due to the continued clinical deterioration, the patient was taken for emergency laparotomy. During the exploration, it was found that the splenic artery was eroded in the setting of a pseudocyst at its junction with the celiac trunk, and the bleeding fistulized into the pseudocyst and from there into the stomach and small intestine, leading to massive gastrointestinal hemorrhage. Arterial repair was performed to control the bleeding, and the pseudocyst drainage tract was repaired.

Conclusion: In patients with a history of pancreatic drainage, vascular erosion and arterial rupture must be kept in mind as a possibility in the presence of unexplained massive gastrointestinal hemorrhage, even if endoscopic and radiological examinations are negative. Early surgical exploration and a multidisciplinary approach are of critical importance in reducing mortality.

Closed-loop obstruction from internal hernia caused by a peritoneal band: A case report

Ahmet Receb, Dilara Yılmaz Köse, Esmatullah Alizai, Muhammed Kerem Çolak, Berkan Acar, Ali Muhtaroğlu, Selahattin Vural, Tuğrul Kesicioğlu

Giresun University Faculty of Medicine, Giresun

Objective: Internal hernias are an uncommon but high-risk cause of acute bowel obstruction; once a closed-loop forms, ischemia can develop quickly. We present a case of closed-loop obstruction caused by an internal hernia related to a peritoneal band in a patient with no prior abdominal surgery.

Material and Methods: A 41-year-old man presented with sudden-onset abdominal pain, nausea, and vomiting. He had no comorbidities, no regular medications, and no history of abdominal surgery. Because the examination suggested an acute abdomen, contrast-enhanced abdominal CT was obtained and an emergency laparotomy was performed.

Results: CT showed dilated jejunal loops consistent with a closed-loop obstruction and two contiguous internal hernias extending from a defect toward both sides of the abdomen. Bowel wall enhancement in the obstructed segments was reduced (Figure 1). At surgery, a peritoneal band extending from the transverse colon mesentery to the descending colon mesentery was identified (Figure 2). Proximal small-bowel loops were herniated and trapped through the space between this band and the small-bowel mesentery. The band was divided and the bowel was reduced. The involved loops appeared edematous with only minimal ischemia, and peristalsis was preserved. After warming, perfusion improved, so no resection was needed. A pelvic drain was placed. The patient resumed oral intake on postoperative day 1 and was discharged uneventfully on day 6.

Conclusion: Even without a surgical history, internal hernias and peritoneal bands can cause mechanical obstruction. Closed-loop features and reduced enhancement on CT should prompt timely surgery. Early reduction may spare the bowel and avoid resection.

Keywords: Mechanical ileus, internal herniation, ischaemia, emergency surgery

A rare traumatic biliary complication after blunt abdominal trauma: Cystic duct stump rupture mimicking mesenteric hemorrhage

Banu Karapolat, Ahmet Yüğrük, Cennet Pınar Oymak, Selim Altındaş

Trabzon University Faculty of Medicine, Trabzon

Objective: Extrahepatic bile duct injuries following blunt abdominal trauma are exceedingly rare and are often diagnosed late. The main reason for this delay is the lack of specific early clinical findings and the fact that imaging studies frequently appear normal or provide misleading results. In patients with a history of cholecystectomy, decreased mobility of the short and fibrotic cystic duct stump renders this structure more vulnerable to traction forces. Consequently, rare but potentially serious biliary complications may occur. In this presentation, we report a rare case of traumatic cystic duct stump rupture that was initially operated on with a presumptive diagnosis of mesenteric hemorrhage but was identified intraoperatively.

Material and Methods: The clinical findings, radiologic images, and surgical intervention of a 22-year-old female patient with a history of laparoscopic cholecystectomy four years earlier who presented after a fall from approximately three meters were retrospectively reviewed. The trauma computed tomography (CT) images obtained at the initial presentation were compared with the contrast-enhanced CT findings from the second admission. Intraoperative findings during emergency laparotomy and the surgical management were analyzed.

Results: No pathological findings were detected on the initial trauma CT, and the patient was discharged (Figures 1 and 2). She returned the following day with worsening abdominal pain, vomiting, and loss of appetite. Physical examination revealed diffuse abdominal tenderness and rebound. Laboratory evaluation demonstrated a 2 g/dL decrease in hemoglobin level. Contrast-enhanced CT showed extensive intraperitoneal free fluid, and mesenteric hemorrhage was suspected (Figures 3 and 4). During emergency laparotomy, bile-stained fluid was identified in the subhepatic region. Following a wide Kocher maneuver, no injury to the duodenum, pancreatic head, or major bile ducts was detected. Careful dissection toward the hepatic hilum revealed detachment of the cystic duct stump clip with active bile leakage from the open end (Figure 5). The cystic duct stump was securely ligated using a double-ligation technique, the abdominal cavity was irrigated, and drains were placed. No postoperative bile leakage occurred, and the patient was discharged without complications.

Conclusion: This case demonstrates that isolated cystic duct stump rupture following blunt abdominal trauma in patients with prior cholecystectomy, although rare, can result in a life-threatening condition. Normal findings on early imaging do not exclude severe biliary injury. When clinical findings are discordant with radiologic results, surgical exploration should not be delayed. Such an approach facilitates timely diagnosis and may significantly reduce morbidity and mortality.

[P-178]

A jejunal diospyrobezoar causing complete small bowel obstruction in a patient with previous gastrojejunostomy: A case report and review of management

Enes Aksu, Ramazan Kozan, Mehmet Akif Türkoğlu

Gazi University Faculty of Medicine, Ankara

Objective: Phytobezoars are an uncommon yet clinically significant cause of mechanical small bowel obstruction, accounting for 0.4-4.8% of all cases. In this case report, we aimed to evaluate the diagnosis and surgical management of acute small bowel obstruction caused by a "diospyrobezoar" (persimmon bezoar) in a patient with a history of gastric surgery, in light of current literature.

Material and Methods: In this study, the diagnosis, treatment, and follow-up processes of a 35-year-old female patient who presented with acute mechanical small bowel obstruction and had a history of gastrojejunostomy were retrospectively reviewed. The patient's dietary intake, surgical history, and duration of clinical symptoms were evaluated; physical examination and laboratory findings were recorded. The diagnosis was based on contrast-enhanced abdominal computed tomography (CT) findings, which have high sensitivity in detecting bezoars. For the surgical approach, a laparotomic enterotomy and extraction technique was performed, determined by the degree of bowel dilatation and the consistency of the bezoar.

Results: A 35-year-old female with a history of gastrojejunostomy presented with a 5-day history of complete small bowel obstruction. Focused anamnesis revealed the consumption of two persimmons (Diospyros kaki) 3 days prior to symptoms. Laboratory tests showed leucocytosis and prerenal acute kidney injury. Abdominal CT demonstrated 6 cm proximal bowel dilatation and a pathognomonic "mottled gas sign" in the jejunum, consistent with a phytobezoar. At laparotomy, a firm, impacted diospyrobezoar was identified in the mid-jejunum, 40 cm distal to the Braun's anastomosis. Due to the high risk of mural injury with manual milking, a longitudinal enterotomy was performed for intact bezoar extraction. The enterotomy was closed transversely in two layers. The patient had an uneventful recovery and was discharged on postoperative day 5.

Conclusion: Previous gastric surgery, hypochlorhydria, and impaired motility are primary risk factors for phytobezoar formation. Persimmons, high in tannins, polymerize in acidic environments into hard "diospyrobezoar" masses. CT remains the diagnostic modality of choice for identifying pathognomonic features and obstruction levels. While chemical dissolution may suit partial obstructions, complete obstruction with significant dilatation mandates emergency surgery. In proximal, firm bezoars, enterotomy is preferred over manual milking to prevent perforation. Ultimately, clinicians must maintain a high index of suspicion in post-gastric surgery patients and provide essential dietary counseling regarding high-fiber foods.

Keywords: Diospyrobezoar, small bowel obstruction, gastrojejunostomy

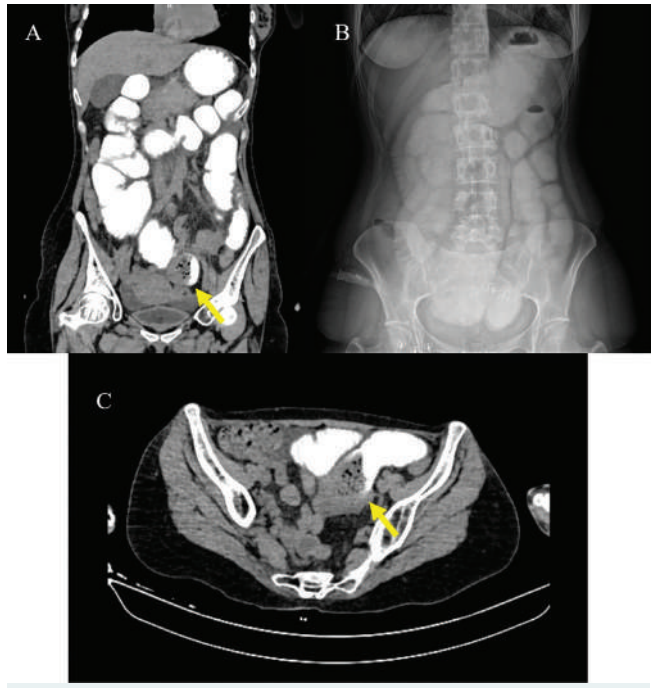

Figure 1. Preoperative imaging findings. (A) and (C) Coronal and axial CT images reveal a well-defined, mottled, gas-filled intraluminal mass within the small bowel (yellow arrows). Significant proximal bowel dilatation is present, consistent with a mechanical intestinal obstruction. (B) Upright abdominal X-ray reveals multiple dilated small bowel loops with a notable absence of distal gas, consistent with a mechanical obstruction.

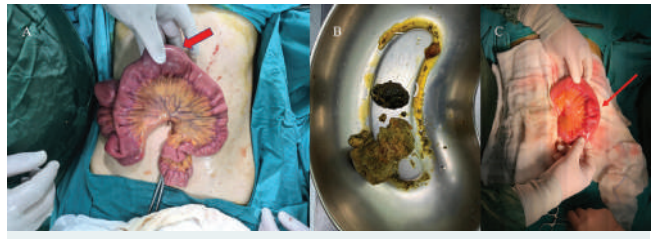

Figure 2. Intraoperative findings. (A) Intraoperative identification of the obstructive point (thick red arrow). (B) Subsequent delivery of the obstructing phytobezoar, a solid concretion composed of undigested persimmon fibers. (C) The longitudinal enterotomy was closed transversely in two layers to prevent luminal narrowing (thin red arrow).

Concurrent abdominal, upper extremity, and neck injuries associated with multiple stab-cut tool injuries: A case report

Ece Canpolat, Fatih Kından, Emin Yılmaz, Mustafa Ömer Yazıcıoğlu

University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Multiple stab-and-cut injuries are traumatic injuries that can lead to life-threatening bleeding and organ damage within a short period of time, requiring rapid decision-making and a multidisciplinary approach. This case presentation aims to present the diagnosis, treatment, and postoperative management of a patient who was hemodynamically unstable, underwent emergency surgery without preoperative imaging, and had simultaneous abdominal, upper extremity, and neck injuries.

Material and Methods: The literature has examined complex injuries resulting from multiple stab-and-cut injuries; in particular, the diagnostic and therapeutic role of emergency surgical exploration performed without preoperative imaging in hemodynamically unstable patients has been evaluated.

Results: A 57-year-old male patient presented to the emergency department with multiple stab and cut wounds following a suicide attempt. Physical examination revealed approximately 45 stab wounds on the body. Laboratory tests showed WBC: 26,000/µL and lactate: 3.72 mmol/L. Clinical evaluation revealed that the patient was hemodynamically unstable and therefore underwent emergency surgery without preoperative radiological imaging. During emergency surgical exploration; • Multiple tendon, nerve, and major vascular structure injuries in the left upper extremity, • Small intestine, stomach, liver, and colon injuries during abdominal exploration, • Penetrating-cutting instrument injury in the neck regionwere detected. Surgical procedures for abdominal and upper extremity injuries were performed simultaneously. The ear, nose, and throat team was involved in the operation due to a neck injury, and the Plastic Surgery team was involved due to a subtotal amputation of the left wrist. The surgical procedures were completed with the assistance of multidisciplinary teams. The patient was monitored in the intensive care unit during the postoperative period and hemodynamic stabilization was achieved. Further evaluation was performed when bile was observed in the surgical drains during follow-up. Magnetic resonance cholangiopancreatography revealed bile leakage, prompting the patient to undergo endoscopic retrograde cholangiopancreatography and biliary stent placement. Post-procedure drainage was observed to decrease. No other major surgical complications developed in the early postoperative period.

Conclusion: In cases of multiple stab and cut injuries with hemodynamically unstable course, emergency surgical exploration is life-saving even if preoperative imaging cannot be performed. Early diagnosis and management of complications that may develop in the postoperative period, such as bile leakage, using endoscopic methods reduces the need for additional surgery. This case highlights the importance of a multidisciplinary approach and close postoperative follow-up in cases of simultaneous abdominal, extremity, and neck injuries. After completing surgical treatment, the patient was transferred to the psychiatry department for further evaluation and treatment.

Strangulated giant umbilical hernia with limited fecal contamination to the hernia sac: A rare cause of transverse colon perforation

Mehmet Fatih Öztürk, Nurbolot Akmatov, Hande Köksal

Department of General Surgery, Selçuk University Faculty of Medicine, Konya

Objective: Adult umbilical hernias are associated with increased intra-abdominal pressure and impaired abdominal wall integrity, commonly seen in obesity, ascites, chronic cough, heavy and repeated physical strain, multiparity and chronic constipation.

Material and Methods: A 64-year-old male patient presented with abdominal swelling which increased in size since three days along with constipation for four days. Medical history included diabetes, hypertension, morbid obesity, and a sedentary lifestyle. He had been diagnosed with umbilical hernia four years ago, where surgical repair was recommended but declined by the patient. PE revealed a non-reducible giant hernia with tenderness in the supraumbilical region.The patient was hypotensive and tachycardic. Laboratory findings showed leukocytosis with elevated infective marker levels. CT demonstrated herniation of distal transverse colon segments through a 7-cm fascial defect at the umbilical level. Hernia sac reached approximately 22 cm in diameter and contained free fluid up to 14 cm in depth. Colonic loops proximal to hernia sac were dilated with air-fluid levels, and free air within the hernia sac was observed, consistent with perforation. The patient was underwent emergency surgery.

Results: On exploration, free colonic contents were found within the hernia sac, with a strangulation-related perforation of the transverse colon near the hepatic flexure. Severe edema, ischemia, and necrosis were present in the hernia sac, subcutaneous tissue, and anterior fascia. As contamination was limited to the hernia sac, temporary sutures were placed at the perforation site and irrigation was performed prior to entering the abdomen. No macroscopic intra-abdominal contamination was observed; only inflammatory fluid and dilation of the ascending colon were present. Right hemicolectomy and aggressive debridement of necrotic fascia and subcutaneous tissue were performed. Due to poor tissue quality and contamination risk, fascia was closed with interrupted non-absorbable sutures, and the skin was left for secondary healing. Patient developed respiratory failure, mixed acidosis, and oliguria peroperatively, and required mechanical ventilation for three days. Oral intake was resumed on postoperative day five. Secondary skin closure was performed on postoperative day eight. Combined broad-spectrum antibiotics were administered for 21 days. The patient was discharged on postoperative day 21 in stable condition. Histopathology revealed no malignancy.

Conclusion: Giant umbilical hernias can present with rare but life-threatening complications such as colonic perforation confined to the hernia sac. Early surgical intervention, meticulous contamination control, and careful abdominal wall management are crucial. This case highlights the importance of individualized surgical strategies in complex hernia emergencies, especially in patients with significant comorbidities.

Keywords: Hernia, strangulation, sepsis

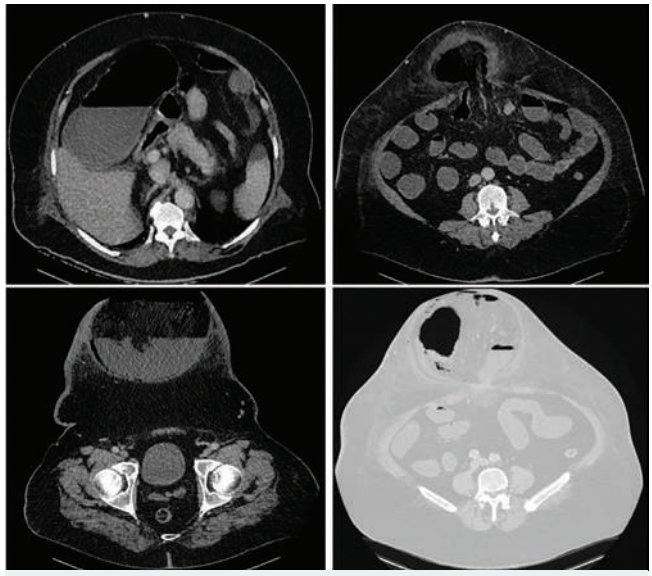

Figure 1. Computed Tomography (CT) images demonstrate herniation of the distal segments of the transverse colon through a defect at the level of the umbilicus, dilatation of the bowel loops proximal to the hernia sac with air–fluid levels, and the presence of free fluid and free air within the hernia sac.

Figure 2. Pre- and intraoperative images of the hernia sac, along with the resection specimen are shown.

Morel-Lavallée lesion following blunt abdominal trauma: A rare case report

Merve Gök

Tarsus State Hospital, Mersin

Objective: Although rare, Morel-Lavallée lesions (MLLs) typically occur following blunt trauma and result from the separation of the skin and subcutaneous tissue from the underlying fascial planes. This separation creates a potential space in which hematopoietic and lymphatic fluid accumulates, leading to clinical manifestations such as swelling, pain, fever, and tissue tension. Patients may receive a diagnosis within days of trauma; however, in some cases, symptoms may develop months or even years later, resulting in delayed diagnosis.

Material and Methods: The case was retrospectively evaluated, and management was determined based on the patient's clinical findings and the characteristics of the accumulated fluid.

Results: A 29-year-old male patient presented to the emergency department with fever, localized periumbilical swelling, and pain. Computed tomography revealed a cystic, hypodense fluid collection measuring 9 cm in diameter, located anterior to the rectus abdominis muscle in the anterior abdominal wall. The patient's medical history included a traffic accident (truck collision) one year prior, after which he had been observed in the emergency department for one day due to blunt trauma and subsequently discharged following non-operative management. During the post-traumatic period, it was noted that the patient had presented to the emergency department three times within one year with identical complaints. The MLL was first described in 1853 by the French physician Maurice Morel-Lavallée. This lesion represents a serous fluid collection that develops following closed degloving injuries and, in particular, after surgical procedures involving the pelvis and abdominal regions. Delays in diagnosis and treatment may lead to infection of the cystic cavity. Magnetic resonance imaging is considered the most reliable diagnostic modality. Treatment options include conservative management, percutaneous drainage, sclerosing agent injection, and open surgical debridement. The choice of treatment is guided by the patient's preference, clinical findings, and the characteristics of the accumulated fluid.

Conclusion: MLLs are rare entities that can develop following trauma, with potentially delayed diagnosis, and may present with symptoms even years after the initial injury. Awareness of MLLs is essential for emergency physicians and consulting surgeons to prevent delayed diagnosis and to avoid repeated surgical interventions.

Keywords: Morel-Lavallée, trauma, hematoma

(D) Focal areas of calcification within fibrotic tissue were identified (H&E X200).

[P-182]

Laparoscopic Meckel's diverticulum resection and hernia repair in an incarcerated Littre hernia: A case report

Mustafa Satman, Muhammet Ömer Çetinkaya, Kubilay Özgür Öztütüncü, Emre Bozdağ, Erkan Somuncu

Department of General Surgery, University of Health Sciences Türkiye, Kanuni Sultan Süleyman Training and Research Hospital, İstanbul

Objective: Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, occurring in approximately 2% of the population. Although most cases are asymptomatic, they may present with clinical findings such as bleeding, diverticulitis, and intestinal obstruction. The presence of Meckel's diverticulum within a hernial sac is called Littre's hernia and is a very rare clinical condition. Littre's hernia usually presents with incarcerated or strangulated hernia and is difficult to diagnose in the preoperative period. The diagnosis is usually made during surgical exploration. This study aims to present a case of Meckel's diverticulum detected within a strangulated inguinal hernia and treated with a laparoscopic approach.

Material and Methods: A case of Meckel's diverticulum detected and treated using laparoscopic methods was retrospectively evaluated.

Results: A 30-year-old male patient presented to the emergency department complaining of pain and swelling in his right groin that had persisted for two days. Physical examination revealed an irreducible right inguinal hernia. Ultrasound revealed a herniated bowel loop through a fascial defect, a non-peristaltic appearance, and free fluid within the hernia sac, leading to a preliminary diagnosis of strangulated hernia. The patient underwent surgery. Exploration using the TAPP approach revealed a strangulated Meckel's diverticulum within the indirect inguinal hernia sac. After the diverticulum was reduced into the abdomen, the hernia sac was dissected, and the preperitoneal space was prepared. Subsequently, a 10x15 cm polypropylene mesh was placed and fixed in the preperitoneal space, and the hernia repair was completed by suturing the peritoneal defect. Then, the diverticulum was resected using a laparoscopic linear stapler. Intestinal integrity was preserved during the operation, and no additional resection was required. The patient was discharged on the third day without complications in the postoperative period. Histopathological examination revealed findings consistent with a Meckel's diverticulum without ectopic tissue.

Conclusion: Littre's hernia is a clinical picture that should be kept in mind in the differential diagnosis of incarcerated or strangulated inguinal hernias, despite its rarity. Due to the difficulty of preoperative diagnosis, surgical exploration plays a decisive role in diagnosis and treatment. In the presented case, the strangulated Meckel's diverticulum was safely resected using the TAPP approach, and hernia repair with mesh was successfully performed simultaneously due to the absence of contamination findings. The laparoscopic approach should be considered an effective and safe treatment option in selected cases due to its ability to provide intraabdominal exploration, its minimally invasive nature, and its advantages of rapid postoperative recovery.

Keywords: Littre's hernia, Meckel's diverticulum, laparoscopic hernia repair

Superior mesenteric venous thrombosis and small intestine necrosis in a young patient with protein S deficiency: A rare case

Ömer Serhat Dağ, Hikmet Özesmer, Müslüm Çelik, Musa Yavuz

University of Health Sciences Türkiye, Diyarbakır Gazi Yaşargil Training and Research Hospital, Diyarbakır

Objective: This case study aims to highlight that protein sodium deficiency, a rare inherited thrombophilia, can lead to superior mesenteric vein (SMV) thrombosis and cause severe intestinal ischemia even under anticoagulation. Protein S deficiency is one of the inherited thrombophilias that disrupt the natural anticoagulant system and is quite rare in the general population. Although it poses a high risk for venous thromboembolic events, its association with mesenteric vein thrombosis has been reported in a limited number of cases in the literature. SMV thrombosis, while rare among the causes of mesenteric ischemia, can lead to serious morbidity and mortality if diagnosis and treatment are delayed. The non-specific nature of clinical findings can lead to delayed diagnosis, especially in young patients.

Material and Methods: A 28-year-old woman presented to the emergency department with abdominal pain. Her history included recurrent abortions, prior deep vein thrombosis, and known protein S deficiency, for which she was receiving regular low-molecular-weight heparin (LMWH). Physical examination revealed lower abdominal tenderness without signs of an acute abdomen. Laboratory tests showed normal lactate dehydrogenase, lactate, and creatine kinase levels. Contrast-enhanced abdominal CT angiography demonstrated normal opacification of the superior mesenteric artery; the main trunk of the SMV was patent, with filling defects consistent with thrombosis in the distal ileal branches.The patient was admitted for observation. Due to clinical progression despite anticoagulation, emergency surgery was performed. Laparoscopic evaluation revealed impaired bowel perfusion, necessitating conversion to laparotomy. A necrotic ileal segment approximately 40 cm in length was identified about 20 cm proximal to the terminal ileum. The affected segment was resected, and a primary ileoileal anastomosis was performed. Therapeutic-dose LMWH was continued postoperatively. Oral intake was initiated on postoperative day 2, and the patient was discharged uneventfully on postoperative day 5.

Results: A significant proportion of SMV thrombosis cases reveal underlying hypercoagulability. Although protein S deficiency is rare in the general population (0.03-0.13%), it poses a significant risk for venous thrombosis. This case is noteworthy because it demonstrates that SMV thrombosis and bowel necrosis can develop even with regular anticoagulation therapy. In young patients with a history of thromboembolic disorders, early imaging, close clinical monitoring, and timely surgical intervention significantly improve the prognosis.

Conclusion: Protein S deficiency is a rare cause of thrombophilia; however, it should be kept in mind that serious SMV thrombosis and intestinal necrosis can develop even under anticoagulation.

Keywords: Superior mesenteric vein thrombosis, protein S deficiency

Figure 1. Image of intraoperative bowel necrosis. A color difference is observed between the necrotic and healthy bowel loops.

[P-184]

Chest compressions as an inadvertent maneuver for gastric detorsion: A rare case of spontaneous reduction during CPR

Çağla Kaynak, Sarp Tunalı, Metehan Gök, Volkan Sayur, Taylan Özgür Sezer

Department of General Surgery, Ege University Faculty of Medicine, İzmir

Objective: Gastrik volvulus (GV) is a rare surgical emergency characterized by the rotation of the stomach more than 180 degrees around its own axis, posing a risk of vascular ischemia and perforation with high mortality. According to the anatomical axis of rotation, in the mesentero-axial type, the stomach rotates along its short axis (the perpendicular axis connecting the minor and major curvatures). This condition often results in the pylorus rising above the level of the esophagogastric junction and clinically mimics acute pyloric obstruction. The spontaneous resolution of this clinical picture—which usually requires emergency surgical or endoscopic intervention—during resuscitation (CPR) maneuvers is a mechanical phenomenon rarely encountered in the literature.

Material and Methods: A case of mesentero-axial gastric volvulus in an 84-year-old patient.

Results: An 84-year-old female presented with sudden severe epigastric pain, nausea, and inability to vomit for 24 hours. Medical history included hypertension and valvular heart disease. Physical exam showed epigastric tenderness, distention, and tympany. NG tube insertion failed due to resistance at the GE junction, confirming Borchardt's triad. Labs showed creatinine: 4.64 mg/dL and urea: 155 mg/dL, indicating secondary prerenal AKI. CT reported a massively dilated "upside-down stomach" with pylorus and duodenum herniated into the mediastinum, showing mesentero-axial rotation. Emergency endoscopy failed due to mucosal edema and anatomical distortion. During anesthesia induction for surgery, cardiac arrest occurred. After 2 minutes of CPR, spontaneous circulation returned. Upon laparotomy, the stomach—previously irreducible even by endoscopy—was found spontaneously reduced and detorsed due to intrathoracic positive pressure and mechanical maneuvers from chest compressions. Exploration confirmed preserved vascularity and no necrosis. The enlarged esophageal hiatus was repaired with primary sutures. Renal functions normalized rapidly, and the patient was discharged on day 8.

Conclusion: In the management of acute gastric volvulus, the primary goals are to restore the stomach to its anatomical position and prevent vascular damage. In cases where endoscopic interventions fail, surgical exploration is mandatory. The most unique aspect of this case is the unexpected mechanical effect of CPR maneuvers on herniated organs. High positive intrathoracic pressure generated during chest compressions acted as a "milking" maneuver, pushing the stomach trapped in the mediastinum back into the abdominal space and providing spontaneous reduction. Due to this phenomenon, it was observed peroperatively that the stomach was viable and the torsion had resolved. In conclusion, although perioperative mechanical events can instantaneously change the anatomical picture, surgical correction of the hiatal defect (crural repair) remains the mainstay of treatment to prevent recurrence.

Keywords: Gastric volvulus, borchardt triad, cardiopulmonary resuscitation

[P-185]

A rare cause of acute abdominal disease; transmesenteric internal hernia

Burak Telli, Bülent Öztürk, Hakan Buluş, Arif Uysal, Burak Kaşıkcı

Department of General Surgery, University of Health Sciences Türkiye, Atatürk Sanatorium Training and Research Hospital, Ankara

Objective: Internal herniation is a relatively rare cause of acute abdominal pain. Its incidence is reported in the literature as 0.2-0.9%. Internal herniation is a difficult pathology to diagnose due to the lack of specific physical examination and laboratory findings. Subtypes of internal herniation include paraduodenal, foramen of Winslow, perisigmoid, transmesenteric, and transomental. This study aims to discuss the diagnostic difficulties and clinical approach to internal herniation pathology, accompanied by a case of transmesenteric subtype internal herniation in a patient with no prior history of intra-abdominal surgery.

Material and Methods: The diagnosis and treatment process of a 69-year-old male patient who presented to our clinic with complaints of inability to pass gas or stool and generalized abdominal pain for three days was evaluated.

Results:s A 69-year-old male patient presented with complaints of inability to pass gas or stool and abdominal pain for 3 days. His medical history revealed no other illnesses or previous surgeries. Physical examination revealed guarding, rebound tenderness, and tenderness. Vital signs: Temperature 36.5 °C, blood pressure 120/70 mmHg, pulse 83/min, and blood oxygen saturation (SpO_2) measured at 96%. Laboratory findings were: WBC 12.5 x 10^3/µL, CRP 1 mg/L, HGB 14 g/dL. A plain abdominal X-ray showed four air-fluid levels. An oral+iv-enhanced contrast abdomen CT scan was performed. The imaging revealed that the orally administered contrast medium did not reach the cecum and that there was dilation in the small bowel loops reaching a diameter of 4 cm. An emergency laparotomy was decided upon. Exploration revealed a herniation of the jejunal bowel loop through a 4 cm defect in the ileal mesentery, 50 cm proximal to the ileocecal valve, disrupting the continuity of bowel passage. The herniated segment was removed through the defect. No ischemia, infarction, or perforation was detected in the bowel. The mesenteric defect causing the internal herniation was repaired with primary simple sutures. No other pathology was found during the operation. Oral intake was gradually opened 24 hours after the operation, and the patient was discharged on the 4th postoperative day.

Conclusion: Internal herniation is a rare but significant cause of acute abdomen in patients. The lack of specific physical examination and laboratory findings makes diagnosis difficult. Internal herniation should always be considered in cases of acute abdomen with inconsistent clinical and laboratory findings. Early surgical intervention is vital in reducing morbidity and mortality, and the decision for laparotomy should not be delayed.

Keywords: Acute abdomen, internal herniation, transmesenteric

Figure 1. Transmesenteric hernia defect. A segment of the jejunal bowel herniated through a 4 cm defect in the ileal mesentery, approximately 50 cm proximal to the ileocecal valve.

Metabolic crisis in glutaric aciduria type II initially suspected as gastrointestinal perforation

Kutay Demirkır, Süleyman Utku Çelik, Cihangir Akyol

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Glutaric aciduria type II (GAII), also known as multiple acyl-CoA dehydrogenase deficiency, is a rare inherited metabolic disorder characterized by impaired mitochondrial fatty acid and amino acid oxidation. Adult-onset or long-term asymptomatic cases may present with clinical manifestations mimicking surgical emergencies during periods of acute metabolic decompensation.

Material and Methods: A 25-year-old male with a childhood diagnosis of GAII had remained asymptomatic for approximately ten years without regular follow-up or pharmacological treatment. He presented with sudden-onset severe abdominal pain, nausea, and vomiting following a one-week history of dental infection treated with amoxicillin-clavulanate and non-steroidal anti-inflammatory drugs. Laboratory tests showed increased white blood cell count and eleveated C-reactive protein levels. Abdominal computed tomography performed at an outside institution revealed free air and fluid suggestive of gastric perforation. Consequently, the patient underwent emergency exploratory laparotomy.

Results: Intraoperative evaluation revealed no evidence of gastrointestinal perforation or other surgical pathology. During and after surgery, the patient developed profound metabolic disturbances, including severe high-anion-gap metabolic acidosis with arterial pH as low as 6.08, marked hyperlactatemia (maximum 11.8 mmol/L), hypoglycemia, hyperkalemia, and disseminated intravascular coagulation. Postoperatively, he required mechanical ventilation, vasopressor support, intensive bicarbonate infusion, and renal replacement therapy. The metabolic crisis was attributed to GAII, and treatment with high-dose riboflavin, carnitine supplementation, and continuous glucose infusion was initiated while lipid-containing solutions were avoided. Following targeted metabolic therapy, metabolic parameters gradually improved, and the patient achieved clinical stabilization. He was transferred to the ward and discharged on postoperative day 8.

Conclusion: This case demonstrates that GAII in adulthood may mimic an acute abdomen and that severe metabolic decompensation may be misinterpreted as surgical pathology. In patients presenting with acute abdomen accompanied by severe metabolic acidosis, hypoglycemia, and hyperlactatemia—particularly those with known or suspected metabolic disorders—metabolic crisis must be considered in the differential diagnosis. Early recognition and appropriate metabolic management are crucial to prevent unnecessary surgical interventions and serious morbidity.

Cyst of the canal of nuck treated with laparoscopic TEP: A case report

Batuhan Öğüt, Kemal Eyvaz, Gizem Nur Akay, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Although inguinal and femoral hernias are the most common causes of palpable groin masses in women, a cyst of the canal of nuck is often overlooked because of its rarity. This cyst develops due to incomplete obliteration of the processus vaginalis during fetal life and may extend along the inguinal canal into the labium majus. Clinical findings are usually non-specific, and physical examination or ultrasonography may not provide a definitive diagnosis. In suspected cases, computed tomography (CT) or magnetic resonance imaging (MRI) helps define the lesion's location and confirm its cystic nature. Surgical excision is the standard treatment, with laparoscopic approaches considered safe and effective.

Material and Methods: A 41-year-old woman presented with left groin swelling. She had no comorbidities or prior surgical history. Physical examination revealed a palpable, non-reducible mass in the left inguinal region without a cough impulse. Due to persistent suspicion, contrast-enhanced abdominal and pelvic CT demonstrated a 7×3 cm cystic lesion extending from the left inguinal canal toward the labium majus. Based on its location and imaging characteristics, the findings were consistent with a cyst of the canal of nuck. No additional intra-abdominal pathology was identified (Figure 1). Surgery was performed using a laparoscopic totally extraperitoneal (TEP) approach. After entering the preperitoneal space, a cystic lesion in the left inguinal canal was identified, dissected in the preperitoneal plane, and reduced. After evaluation of the inguinal anatomy, a synthetic mesh was placed in the preperitoneal space to cover the myopectineal orifice and secured in position. No intraoperative complications occurred (Figure 2).

Results: Surgical treatment is recommended to relieve symptoms and prevent potential complications. Although open surgical methods have long been used, laparoscopic approaches offer advantages such as better anatomical visualization, detection of concomitant hernias, less postoperative pain, and faster recovery. The totally extraperitoneal (TEP) approach, in particular, has been reported as a safe method due to preservation of peritoneal integrity and low complication rates. In the present case, the lesion was successfully treated using the laparoscopic TEP approach, with no early complications or recurrence observed.

Conclusion: Cyst of the canal of nuck is a rare but important entity in the differential diagnosis of groin masses in female patients. Advanced imaging modalities play a decisive role in diagnosis when clinical suspicion persists. The laparoscopic TEP approach may be considered a safe and effective surgical option in appropriately selected patients.

Delayed multidisciplinary reconstruction of cervical esophageal transection following thyroidectomy: A case report

Yusuf Emre Altundal, Süleyman Büyükaşık, Eyüp Demirci, Cansu Esen, Halil Alış

İstanbul Aydın University, Medical Park Florya Hospital, İstanbul

Objective: Esophageal perforation is a rare but life-threatening surgical emergency associated with high morbidity and mortality. Although iatrogenic perforations most commonly occur during endoscopic procedures, they may rarely develop during cervical surgical interventions. Complete cervical esophageal transection following thyroidectomy has been reported only in a limited number of cases in the literature and, when not recognized early, may lead to mediastinal sepsis and the need for complex reconstructive surgery. In this study, we present the delayed multidisciplinary reconstruction of a cervical esophageal transection that developed after thyroidectomy at an external center, where primary repair had failed.

Material and Methods: A 38-year-old female patient underwent total thyroidectomy and neck dissection at an external center due to thyroid carcinoma. A cervical esophageal injury that occurred intraoperatively was recognized in the early postoperative period, and the patient was reoperated for primary repair and drainage. However, clinical follow-up revealed failure of the repair. Surgical exploration demonstrated complete transection of the cervical esophagus at the level of the hypopharynx-pharyngoesophageal junction, along with left recurrent laryngeal nerve injury. A proximal esophagostomy and feeding jejunostomy were subsequently performed. The patient was referred to our center for definitive reconstruction. Following multidisciplinary evaluation, partial esophagectomy and delayed reconstruction were performed using combined thoracoscopic and laparoscopic approaches. The thoracic and abdominal esophagus were mobilized, the stomach was advanced into the mediastinum, and a tension-free pharyngoesophagostomy was constructed at the cervical level.

Results: Postoperatively, the patient was monitored briefly in the intensive care unit and then transferred to the surgical ward. Enteral nutrition was initiated via jejunostomy, and gradual transition to oral intake was achieved. No anastomotic leak, mediastinal infection, or reoperation-requiring complication was observed during follow-up. After discharge, partial dysphagia was noted during outpatient follow-up. Endoscopic evaluation revealed a partial anastomotic stricture. The patient underwent two sessions of endoscopic dilatation, after which no further complications were observed. Contrast-enhanced sagittal CT imaging of the neck and upper thorax demonstrates a proximal cervical esophagostomy. The distal cervical esophageal segment is closed using a linear stapler, with interruption of esophageal continuity. A clear separation between the proximal and distal segments is observed.

Conclusion: Cervical esophageal transection following thyroidectomy is a rare but life-threatening complication. In cases where primary repair fails, delayed reconstruction performed at experienced centers using a multidisciplinary approach can achieve favorable clinical and functional outcomes. Appropriate surgical timing, institutional expertise, and coordinated team management play critical roles in treatment success.

Keywords: Cervical esophageal transection, thyroidectomy complication, delayed reconstruction

Figure 1. Cervical esophageal transection following thyroidectomy: computed tomography imaging of proximal esophagostomy and stapled distal esophageal closure.

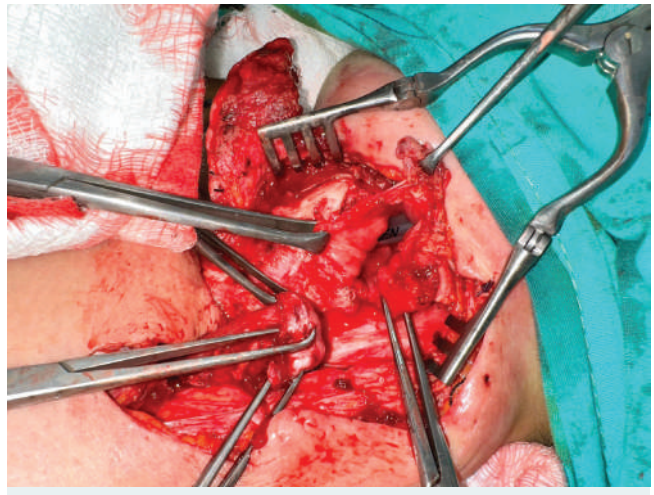

Figure 2. Intraoperative cervical exploration demonstrates loss of esophageal continuity, with the proximal esophageal segment remaining open. The distal cervical esophageal segment is noted to have been previously closed using a linear stapler. A clear gap is present between the proximal and distal segments.

Conservative management of a cecal perforation occurring during colonoscopic endoscopic submucosal dissection (ESD): A case report

Ozan Erek, Abdullah Kut

University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul

Objective: Endoscopic submucosal dissection (ESD) is an advanced endoscopic technique that enables en bloc resection of broad-based and superficial neoplastic lesions in the colorectal system. Perforation during colorectal ESD is a significant complication, particularly in the cecum, due to the thin structure of the colonic wall. Perforation rates in the literature have been reported to range between 4-10%. Perforations that are recognized early and closed during the procedure can often be successfully managed with conservative treatment. In this case, a cecal perforation that developed during the procedure was managed with endoscopic clipping and a conservative approach, resulting in recovery without the need for surgery.

Material and Methods: A 67-year-old female patient was evaluated with screening colonoscopy due to a positive fecal occult blood test. During colonoscopy, a 2.5×1 cm broad-based vegetative polyp was detected on a mucosal fold at the cecal base, located between the appendiceal internal orifice and the ileocecal valve. The polyp was removed en bloc by ESD. During the procedure, a cecal perforation occurred and the mucosal defect was closed using endoclips. Following the procedure, an oral and intravenous contrast-enhanced abdominal CT scan was performed. Widespread free intraperitoneal air was detected; however, no contrast extralumination was observed. On abdominal examination, distension and tenderness were present, but there were no signs of an acute abdomen, and vital signs were stable. Therefore, conservative management was planned: oral intake was discontinued and broad-spectrum intravenous antibiotics were initiated.

Results: During inpatient follow-up, the patient's abdominal tenderness decreased and she began to tolerate oral intake. As abdominal distension persisted, intraperitoneal air was evacuated using a 16 Fr intravenous catheter inserted at the level of the umbilicus, after which the distension regressed. Vital signs remained stable throughout follow-up and no complications developed. As the patient's general condition was good and oral intake was tolerated, she was discharged without any problems.

Conclusion: Cecal perforations that occur during colonoscopic ESD can be safely and effectively managed with conservative treatment when recognized during the procedure and closed with endoscopic clips. The presence of widespread pneumoperitoneum alone does not constitute an absolute indication for surgery. A conservative approach may be applied in patients without contrast extravasation, who are hemodynamically stable, and who do not exhibit signs of an acute abdomen. This case demonstrates that colon perforations can be managed without surgery through appropriate patient selection and close clinical follow-up.

Keywords: ESD, cecal perforation, conservative management

Surgical management of fibrosis-related gastric obstruction in gastric lymphoma with complete response to therapy

Yaşar Talha Temel[1], Orhan Üreyen[1], Emrehan İnci[1], Oktay Bilgir[2], Enver İlhan[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*
[2]*Department of Internal Medicine Hematology, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

Objective: Primary gastric lymphomas account for only 3-5% of all gastric malignancies, and chemotherapy constitutes the mainstay of treatment. Surgical management in gastric lymphomas is reserved for patients who develop complications. In this case, we aimed to present the surgical management of gastric outlet obstruction caused by fibrotic pyloric stenosis that developed despite achieving a complete hematologic response after systemic therapy.

Material and Methods: A 39-year-old male patient presented to the internal medicine outpatient clinic with complaints of night sweats, weight loss, and epigastric pain. Upper gastrointestinal endoscopy revealed a nearly circumferential ulcerated lesion involving the distal greater curvature of the corpus and extending into the antrum (Figure 1). Biopsy of the lesion was consistent with B-cell non-Hodgkin lymphoma. Systemic therapy with rituximab, R-bendamustine, and R-CHOP was initiated.The patient's nausea and vomiting progressively worsened. Post-chemotherapy upper gastrointestinal endoscopy demonstrated edema and irregularity around the pylorus, and the pylorus could not be traversed (Figure 2). Biopsy specimens obtained from this area were interpreted as fibrosis secondary to chemotherapy. The patient's nausea and vomiting continued to increase. A contrast study with water-soluble contrast material showed complete gastric obstruction (Figure 3). As the patient was not suitable for percutaneous endoscopic gastrostomy, distal gastrectomy with Roux-en-Y gastrojejunostomy was performed. Histopathological examination of the gastrectomy specimen revealed no residual lymphoma; however, extensive fibrosis was observed. The patient tolerated oral intake in the postoperative period and was discharged uneventfully on postoperative day six. At the third postoperative month follow-up, the patient maintained a complete response in terms of lymphoma and had no nutritional problems.

Results: The role of surgery in gastric lymphoma is limited. Surgical intervention may be required only in cases of perforation, bleeding, obstruction, or treatment-resistant disease. Fibrotic pyloric stenosis following chemotherapy is a rare complication. This case is noteworthy because surgical intervention was required due to obstruction despite a complete response to systemic therapy.

Conclusion: Even in cases of primary gastric lymphoma with a complete response to systemic therapy, fibrosis-related gastric outlet obstruction may rarely develop. Therefore, in patients presenting with vomiting and obstructive symptoms after chemotherapy, not only residual disease but also treatment-related fibrotic stenosis should be considered in the differential diagnosis. In appropriate cases, surgical management is a safe and effective treatment option.

Multivessel mesenteric artery involvement in a young age: A case report of chronic mesenteric ischemia

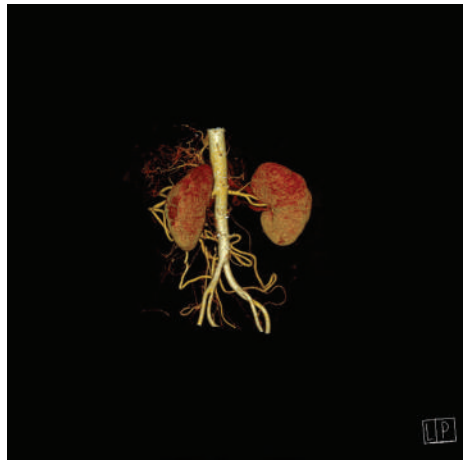
Ülkü Birnas Aşıroğlu, Hüsnü Alptekin, Sinan Şener, Fatih Türkoğlu

Selçuk University Faculty of Medicine Hospital, Konya

Objective: Chronic mesenteric ischemia is a rare but serious cause of abdominal pain. Advanced age, atherosclerotic disease, diabetes mellitus, hypercoagulable states, and smoking are recognized risk factors. We present a young male patient with no known risk factors other than a long-standing history of cigarette smoking.

Material and Methods: A 44-year-old male patient with a 30 pack-year smoking history presented with postprandial abdominal pain, vomiting, and decreased oral intake that had persisted for four years and led to recurrent hospital admissions. He had experienced an unintentional weight loss of 10 kg over the last five months.

Results: Physical examination revealed epigastric tenderness without signs of an acute abdomen. Contrast-enhanced abdominal CT angiography demonstrated significant stenosis of approximately 2 cm in length beginning at the origin of the celiac trunk, followed by distal occlusion. The common hepatic artery and splenic artery were not visualized; arterial perfusion of the liver and spleen was maintained via collateral circulation. The left gastric artery origin appeared stenotic with post-stenotic dilatation distally. The superior mesenteric artery was not visualized. The inferior mesenteric artery showed marked proximal stenosis extending approximately 3 cm from its origin, with post-stenotic dilatation. The small bowel loops were observed to be supplied through extensive collateral circulation via the inferior mesenteric artery. The patient was referred to interventional radiology for advanced endovascular treatment.



Conclusion: Chronic mesenteric ischemia involving all three major mesenteric vessels at a young age is rare. In young patients presenting with longstanding postprandial abdominal pain and weight loss, particularly those with a significant smoking history, mesenteric ischemia should be considered in the differential diagnosis. In our patient, the presence of well-developed collateral circulation masked the clinical figure and contributed to delayed diagnosis, while simultaneously preserving intestinal perfusion and preventing the need for bowel resection. Early diagnosis with appropriate imaging modalities is crucial to prevent irreversible intestinal damage.

Meckel's diverticulum perforation, laparoscopic diverticulectomy

Ramazan Onuş, Muhammed Hallaç, Engin Ölçücüoğlu

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract. Its incidence is approximately 2%. This diverticulum originates from a remnant of the omphalomesenteric duct. It may be asymptomatic, but it can also lead to clinical conditions such as bleeding, intussusception, volvulus, intestinal obstruction, and perforation. Surgical intervention is required for symptomatic diverticula. Open or laparoscopic surgical approaches can be used for treatment. There is an increasing number of studies in the literature demonstrating the success of laparoscopic treatment. In this case presentation, we aim to present the treatment of a patient who presented to the emergency department with acute symptoms and was diagnosed with Meckel's diverticulitis.

Material and Methods: The patient's clinical observation notes, laboratory parameters, and imaging findings were reviewed. Images from the video recordings of the surgery were used.

Results: A 38-year-old male patient presented to the emergency department with abdominal pain in the umbilical region that had been present for a 48-hour period. A physical examination was performed, which revealed tenderness in the right lower quadrant. The WBC count was 7600/μL, and the CRP was 58 mg/L. Abdominal computed tomography revealed the presence of a blind-ended intestinal loop of approximately 2.5 cm in length, associated with the ileal and located at the pelvic inlet level. Additionally, contamination was observed in the surrounding mesentery. Radiological analysis revealed that the appendix appeared to be normal. Laparoscopic exploration was planned. A 10 mm camera port was inserted infraumbilically. A 12 mm port in the lower left quadrant and a 5 mm port in the suprapubic region were used. During exploration, a segment consistent with Meckel's diverticulitis was observed in the distal ileum, and perforation was seen at the distal end. The specimen was isolated from the surrounding mesentery, and laparoscopic diverticulectomy was performed using stapler. A drain was inserted into the pelvis. The surgical procedure was successfully completed. On the first day postoperatively, oral fluid intake was initiated and gradually increased. On the fourth day, the drain was removed, and the patient was discharged. The pathology findings were consistent with Meckel's diverticulum, and no evidence of malignancy was detected.

Conclusion: With the increase in laparoscopic experience in surgery and the development of instruments, the use of laparoscopy in emergency cases is also increasing. There may be reservations about the use of laparoscopy, especially in emergency cases where small bowel-related pathology is suspected. Selecting the appropriate patient is important in making this decision.

Keywords: Laparoscopic emergency surgery, Meckel's diverticulum

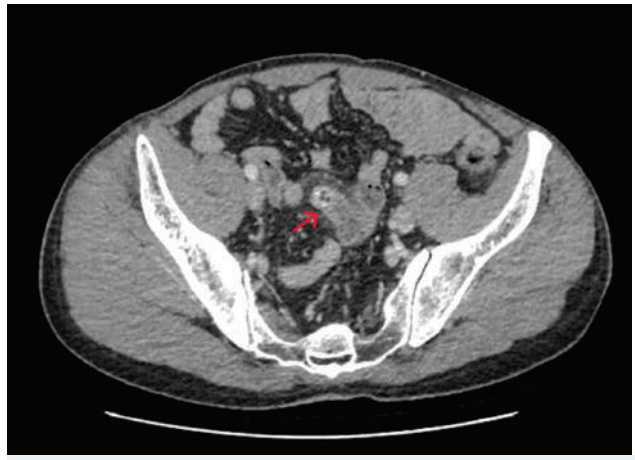

Figure 1. Abdominal CT scan. An intestinal loop with a blind end is observed, thought to originate from ileal loops. Inflammatory changes in the surrounding adipose tissue are also of note. Laparoscopic exploration images.

CT: Computed tomography.

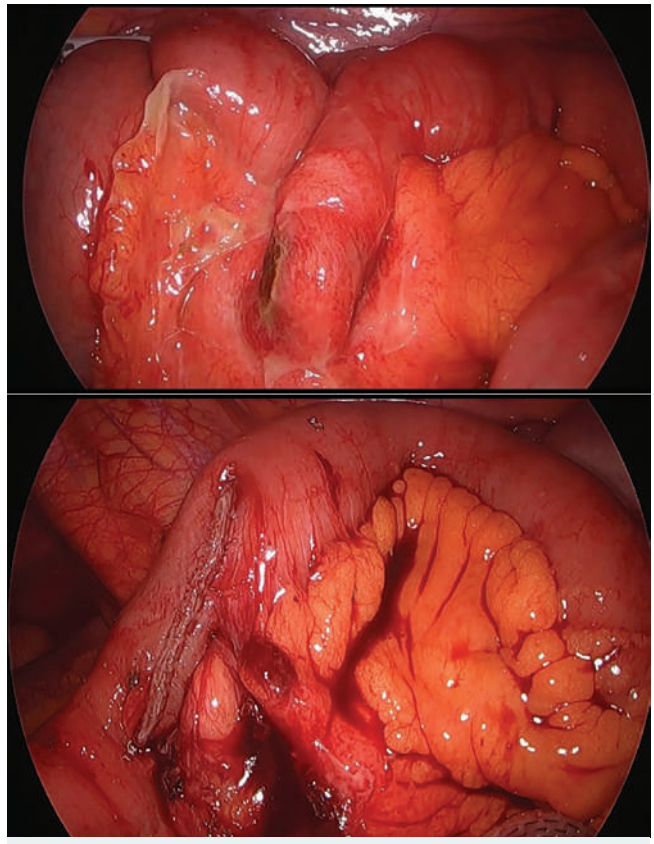

Figure 2. Meckel's diverticulum with necrosis and perforation observed at the distal end (above). It is seen that the diverticulum originates from the antimesenteric surface and that the inflammation is confined to the ileal mesentery. Ileal loop after diverticulectomy (below).

Enterobacter cloacae-associated necrotizing fasciitis following morsus insecti: Importance of early diagnosis and aggressive surgical debridement

Özcan Dere, Narmin Hajizada, Harun Ölmez

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Necrotizing fasciitis (NF) is a rapidly progressive soft tissue infection with high mortality that develops following disruption of the superficial skin barrier and spreads along fascial planes. Minor skin entry lesions, particularly insect bites (morsus insecti), may serve as a portal of entry for infection. NF following insect bites is rare in the literature and is most commonly associated with Gram-positive pathogens; however, Gram-negative organisms may also be implicated. This study aimed to present a case of *Enterobacter cloacae*-associated NF following morsus insecti and to emphasize the critical role of early diagnosis and aggressive surgical debridement.

Material and Methods: Clinical, laboratory, imaging, surgical, and microbiological data of a 55-year-old female patient presenting with soft tissue infection after an insect bite were retrospectively evaluated. The patient underwent emergency surgical exploration and debridement with a preliminary diagnosis of NF. Deep tissue samples were obtained for culture, and broad-spectrum antibiotic therapy was initiated. The clinical course, need for repeated debridements, and reconstructive management were analyzed.

Results: The patient reported an insect bite in a rural area two days before admission. The lesion initially appeared as a small erythematous papule but rapidly enlarged despite drainage at an outside center, and septic progression prompted referral. Physical examination revealed extensive edema, hyperemia, and ecchymotic areas extending from the anterior abdominal wall to the right lumbar region. Fever (38.5 °C) and tachycardia were present. Laboratory tests showed leukocytosis, elevated C-reactive protein, and hyponatremia; the LRINEC score was 8. Computed tomography demonstrated fascial thickening and fluid collections consistent with fasciitis. Surgical exploration revealed typical NF findings, and extensive debridement was performed. Deep tissue culture grew Enterobacter cloacae. During follow-up, seven additional debridements were required. After infection control, the defect was closed with a split-thickness skin graft. The patient was discharged in good condition with no recurrence during follow-up.

Conclusion: NF should be considered a potential diagnosis in patients presenting with pain and erythema following morsus insecti. Disproportionate pain and rapid progression are key early warning signs. Early diagnosis and aggressive surgical debridement remain the most important determinants of prognosis in NF. Awareness of this rare Gram-negative etiology may prevent diagnostic delay and reduce mortality.

Rives-stoppa repair with Madrid modification in the treatment of incarcerated incisional hernia: Case report

Ebubekir Korucuk, Volkan Sayur, Taylan Özgür Sezer

Department of General Surgery, Ege University Hospital, İzmir

Objective: Emergency abdominal wall hernia repair remains challenging due to the absence of adequate preoperative optimization and the frequent presence of bowel obstruction or ischemia. In contaminated or potentially contaminated fields, many surgeons avoid mesh placement or prefer onlay repair techniques because of concerns regarding infection. However, sublay (retromuscular) repair has demonstrated superior long-term outcomes in elective settings. In the Madrid modification of the Rives-Stoppa technique, subxiphoid dissection is performed in the preperitoneal plane rather than directly over the posterior rectus sheath, reducing the risk of injury to the neurovascular bundles or pleura. We present a case of incarcerated incisional hernia with multiple previous onlay repairs, treated with emergency laparotomy and retromuscular mesh repair using the Madrid modification of the Rives-Stoppa technique.

Material and Methods: A case of incarcerated incisional hernia treated with the Madrid Modification of Rives-Stoppa repair will be presented.

Results: A 43-year-old male (BMI 31.8 kg/m^2) with a history of umbilical and incisional hernia repairs performed with the onlay technique presented with a midline incarcerated incisional hernia (EHS classification M2-4 W2). Preoperative computed tomography demonstrated a 55 mm fascial defect. The patient had mechanical bowel obstruction secondary to incarceration. Emergency exploration revealed multiple "Swiss cheese-like" midline defects and incarcerated small bowel loops with ischemic changes. After adhesiolysis, a 20 cm ischemic ileal segment located 70 cm proximal to the ileocecal valve, unresponsive to tactile stimulation, was resected, followed by side-to-side anastomosis. For hernia repair, the posterior rectus sheath was incised lateral to the linea alba. From the xiphoid process extending 6-7 cm caudally, the sheath was opened longitudinally and the retrorectus space was dissected laterally until the neurovascular bundles were identified. At 6 cm caudal to the xiphoid, the posterior sheath was transected transversely and the preperitoneal plane was entered. Subxiphoid dissection continued until visualization of the diaphragm's central tendon, allowing complete development of the retrorectus plane. The posterior sheath was closed with USP 2/0 PDS sutures. A 10×30 cm mesh was placed in the retrorectus space, and the anterior fascia was closed primarily. Postoperatively, the patient developed transient paralytic ileus and superficial surgical site infection not requiring invasive treatment. He was discharged on postoperative day 11. At two months, no recurrence or wound complications were observed.

Conclusion: Retromuscular repair using the Madrid modification of the Rives-Stoppa technique can be safely performed in selected emergency cases. Subxiphoid preperitoneal dissection provides technical advantages by protecting midline neurovascular structures while enabling durable mesh reinforcement.

Intraoperative fascial traction after prehabilitation in giant incisional hernia treatment: A case report

Ebubekir Korucuk[1], Mehmet Avcı[1], Volkan Sayur[1], Egemen Öztürk[2], Taylan Özgür Sezer[1]

[1]*Department of General Surgery, Ege University Hospital, İzmir*

[2]*Department of Radiology, Ege University Hospital, İzmir*

Objective: In giant hernias primary repair is challenging because of loss of domain (LOD). While preoperative techniques like botulinum toxin A (BTA) and progressive pneumoperitoneum are used to reduce LOD, Intraoperative fascial traction (IFT) has recently gained popularity. We present a case managed with BTA followed by IFT and transversus abdominis release (TAR).

Material and Methods: A patient with a Carbonell index <2 and LOD >25% received preoperative BTA. A total of 300 U of BTA (Botox®, Allergan) diluted in 150 cc saline was injected into the lateral abdominal muscles at three points bilaterally under ultrasound guidance. IFT was performed using the Fasciotens® device.

Results: A 36-year-old male (BMI 30.8 kg/m^2) presented with a giant midline incisional hernia. Preoperative CT showed a defect width of 210 mm, an initial LOD of 45%, and a Carbonell index of 0.45. Thirty days post-BTA, the defect width was 190 mm, LOD 33%, and the Carbonell index 0.58. Surgery was performed 38 days after BTA. Following bilateral TAR, the anterior fascia could be approximated manually only to a gap of 8 cm. Consequently, IFT was applied for 30 minutes. Two 30x30 cm polypropylene meshes were placed in the retromuscular space, and the fascia was closed completely without tension. The patient was discharged on day 5 with no complications. On postoperative day 30, there was no complication and recurrence.

Conclusion: The combination of BTA & IFT eliminated the need for bridging or anterior component separation, enabling tension-free fascial closure. This multimodal approach is an effective strategy for managing complex abdominal wall hernias.

Videoscopic subcutaneous mastectomy with immediate implant reconstruction: A case report

Yunus Emre Aydoğdu, Jahad Jabıyev, Ufuk Karabacak, Ayfer Kamali Polat

Ondokuz Mayıs University Faculty of Medicine, Health Practice and Research Center, Samsun

Objective: Although breast-conserving surgery is the preferred approach in the surgical management of breast cancer, mastectomy remains necessary in a substantial number of patients. Advances in oncoplastic surgery have introduced reconstructive options and nipple-areola-skin-sparing techniques for patients requiring mastectomy. Compared with conventional mastectomy, these approaches provide improved cosmetic outcomes and better quality of life. To further optimize cosmetic results, minimally invasive surgical techniques—particularly endoscopy-assisted subcutaneous mastectomy—have recently been incorporated into breast surgery practice. In this report, we present a case of videoscopic subcutaneous mastectomy with immediate implant-based reconstruction performed in our clinic.

Material and Methods: A patient who had previously undergone two breast-conserving surgeries in 2016 and 2023 at an outside center for triple-negative invasive ductal carcinoma located in different quadrants of the right breast presented with a third recurrence. Subcutaneous mastectomy with implant-based reconstruction was planned. A 3-cm skin incision was made approximately 4 cm lateral to the areola. After adequate subcutaneous dissection, a GelPOINT Mini Advanced Access Platform was inserted. Three 5-mm trocars were introduced through the platform, and a 5 mm 30° endoscopic camera was used. The breast tissue was dissected from the subcutaneous plane and over the pectoral fascia and removed through the incision. Immediate reconstruction was performed in the same session using a 460 cc round implant and titanium mesh in a prepectoral plane. A Voyant Maryland energy device was utilized for dissection.

Results: The procedure was completed without intraoperative complications. The postoperative course was uneventful, and the patient was discharged in good condition on postoperative day three. No early postoperative complications were observed.

Conclusion: Videoscopic subcutaneous mastectomy offers several advantages, including its minimally invasive nature, the ability to prepare healthier skin flaps without excessive traction, favorable cosmetic outcomes, and reduced sensory loss. However, a longer operative time during the early phase of the learning curve may be considered a limitation. With appropriate patient selection and surgical expertise, this technique appears to be a safe and effective alternative in selected cases.

Keywords: Implant reconstruction, minimally invasive, videoscopic subcutaneous mastectomy

Management of iatrogenic appendiceal perforation in a patient with a history of antegrade continence enema (ACE) procedure: A case report

Murat Kesen, Mehmet Arda Yıldırım, Tarık Buğra Naralan, Nuri Emrah Göret, Eyüp Kebabçı

İzmir Bakırçay University, Çiğli Training and Research Hospital, İzmir

Objective: The antegrade continence enema (ACE) procedure is a surgical technique used for the management of bowel dysfunction associated with conditions such as Hirschsprung disease, myelomeningocele, spina bifida, quadriplegia, as well as idiopathic chronic constipation and fecal incontinence. It is primarily indicated in patients whose symptoms are refractory to conventional medical treatments. The main objective of the procedure is to achieve effective bowel evacuation by enabling antegrade colonic irrigation from the proximal to the distal colon. The ACE technique is based on mobilization of the appendix and its exteriorization as a stoma, referred to as an appendicostomy, usually positioned at the umbilicus or an appropriate abdominal quadrant. Lavage solutions administered through this channel create an antegrade flow within the colon, facilitating colonic cleansing. This method allows patients to control their defecation process, resulting in significant improvements in quality of life and social integration. Nevertheless, several complications have been reported, including stomal stenosis, leakage, channel obliteration, stomal prolapse, infection, bleeding, and perforation.

Material and Methods: A 27-year-old male patient who had undergone an ACE procedure at the age of seven due to Hirschsprung disease presented to the emergency department with severe abdominal pain following enema administration via the appendicostomy. Physical examination revealed diffuse abdominal tenderness and rebound tenderness in all four quadrants. Emergency imaging demonstrated diffuse intraperitoneal free fluid and free air, findings highly suggestive of intestinal perforation. Based on these findings, an urgent exploratory laparotomy was undertaken. During surgical exploration, approximately 200 mL of free intraperitoneal fluid was identified. All hollow visceral organs were systematically examined, yet no obvious perforation site was initially detected. Subsequently, methylene blue was administered through the umbilical ACE access. Extravasation of methylene blue was observed approximately two centimeters proximal to the appendicostomy, confirming the site of perforation. The appendicostomy was dismantled, and an appendectomy was performed.

Results: During the postoperative follow-up, the patient remained hemodynamically stable, exhibited no pathological drainage, and tolerated oral intake. Spontaneous passage of flatus and stool was observed. With normalization of clinical and laboratory parameters, the patient was discharged in good condition on postoperative day five, without complications observed.

Conclusion: The ACE procedure is relatively rare and is most often performed during childhood when suitable indications are present. Iatrogenic injuries occurring during lavage administration, as observed in the present case, represent one of the more common complications. In the majority of patients, these complications can be managed effectively with a simple appendectomy, leading to favorable clinical outcomes.

Keywords: ACE procedure, appendicostomy, perforation

Delayed breast reconstruction after mastectomy with lattisimus dorsi FLAP: Case report

Sümeyra Emine Bölük[1], Gülçin Ercan[1], Emre Hocaoğlu[2], İrem Basmaci[1], Zafer Ünsal Coşkun[1], Ali Türkoğlu[1], Elif Didem Terzi[1]

[1]*University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul*

[2]*İstanbul University, İstanbul Faculty of Medicine, İstanbul*

Objective: Breast cancer most commonly occurs between the ages of 50 and 69, but 5-7% of breast cancers are detected in women under 40. This highlights the importance of diagnosis and treatment management in younger breast cancer patients, given their longer life expectancy. Our case presentation aims to describe a 35-year-old patient who underwent mastectomy due to breast cancer and had late-stage reconstruction using a lattissimus dorsi flap.

Material and Methods: Case report.

Results: A 35-year-old female patient had a history of mastectomy and sentinel lymph node biopsy (SLNB) 3 years prior due to a 5 cm mucinous carcinoma in the right breast. She received adjuvant radiotherapy in the postoperative period. She presented at the 2nd postoperative year with no recurrence or metastasis detected and no additional adjuvant treatment planned. Since she had undergone mastectomy, a submuscular expander was initially placed. At 6 months postoperatively, due to insufficient skin width, reconstruction with a lattisimus dorsi flap and implant was planned. Because SLNB was performed during the first surgery, CT angiography was performed to evaluate the axillary region and the integrity of the lattisimus dorsi pedicle. No pathology was detected. Therefore, reconstruction with a lattisimus dorsi muscle-skin flap and implant was performed (Figures 1, 2). No pathology was detected during postoperative follow-up.

Conclusion: Oncoplastic surgery can currently be performed concurrently with mastectomy in suitable patients. However, late-stage reconstruction is also possible in patients for whom this is not feasible. In patients planned for this procedure, careful preoperative and multidisciplinary evaluation is crucial for the success of the surgery.

Papillary thyroid carcinoma associated with giant parathyroid adenoma: A case report introduction

İrem Basmacı, Nesibe Altay, Yavuz Poyrazoğlu, Elif Didem Terzi

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Primary hyperparathyroidism is a common endocrine disorder, most frequently caused by a parathyroid adenoma and characterized by hypercalcemia. Giant parathyroid adenomas are rare and are usually diagnosed with marked biochemical abnormalities. The coexistence of parathyroid adenoma and thyroid malignancy is a clinically important condition that requires careful evaluation. In this report, we present a case of a patient who underwent surgery for a giant parathyroid adenoma and was concomitantly diagnosed with papillary thyroid carcinoma.

Material and Methods: A fifty-year-old male patient was evaluated due to hypercalcemia and elevated parathyroid hormone (PTH) levels detected during routine examinations. Laboratory analysis revealed a serum calcium level of 12 mg/dL and a PTH level of 274 ng/L. Parathyroid scintigraphy demonstrated uptake consistent with a right inferior parathyroid adenoma. Neck ultrasonography showed a 1×1.2 cm solid nodule in the right thyroid lobe. Fine-needle aspiration biopsy was reported as benign. Neck and thoracic computed tomography revealed a 25×30 mm mass lesion in the right parathyroid region. The patient was scheduled for surgery.

Results: During surgery, a giant parathyroid adenoma weighing 13 grams and measuring 5.5×3×2 cm was excised. Right thyroid lobectomy was performed to allow complete removal of the parathyroid tissue. Histopathological examination confirmed the diagnosis of parathyroid adenoma. The thyroid lobectomy specimen revealed a 0.9 cm unifocal, classical-type papillary thyroid carcinoma. Surgical margins were negative, and no lymphovascular or perineural invasion was observed. Postoperatively, the patient was evaluated by general surgery and endocrinology departments, and completion thyroidectomy was not recommended.

Conclusion: Associated thyroid pathologies may be overlooked in cases of giant parathyroid adenoma. Therefore, careful evaluation of the thyroid gland is essential in patients undergoing surgery for primary hyperparathyroidism. Concomitantly detected papillary thyroid carcinomas may directly influence surgical strategy and follow-up planning. A multidisciplinary approach is crucial for optimal patient management.

Rare coexistence of papillary and medullary thyroid carcinomas in a patient with Graves' disease

Munther Shehada, Dilan Pehlivan, Adnan Çalik, Zeynep Türkmen Usta, Elif Aybala Sibal

Karadeniz Technical University, Trabzon

Objective: Graves' disease (GD) is a common cause of hyperthyroidism and is occasionally associated with thyroid malignancies, particularly papillary thyroid carcinoma (PTC). Medullary thyroid carcinoma (MTC) rarely coexists with GD. The synchronous occurrence of multiple distinct thyroid carcinoma subtypes in a single patient is extremely uncommon.

Material and Methods: In this study, the clinical, laboratory, and imaging findings of a patient who underwent total thyroidectomy for GD were retrospectively analyzed. The surgical specimen was subjected to detailed histopathological and immunohistochemical examination, and tumor subtypes were classified according to established pathological criteria. Postoperative follow-up included clinical assessment and measurement of serum calcitonin and carcinoembryonic antigen (CEA) levels.

Results: A 36-year-old female with GD underwent total thyroidectomy. Preoperative ultrasound revealed multiple benign-appearing nodules (TI-RADS 2). Histopathology unexpectedly revealed three distinct malignancies: Well-differentiated high-grade thyroid carcinoma (7 mm, right lobe), classic PTC (4.8×2×2 mm, left lobe), and bilateral MTC (2 mm right, 4 mm left). Immunohistochemistry confirmed the distinct tumor subtypes. Postoperative recovery was uneventful, and the patient was discharged on the first day. Levothyroxine therapy was initiated. At 2-year follow-up, the patient remains disease-free with negative CEA and calcitonin levels. This case underscores that GD may coexist with multiple, histologically distinct thyroid malignancies, even when imaging suggests benign disease. The incidental detection of PTC, well-differentiated carcinoma, and MTC highlights the importance of thorough histopathological examination and consideration of total thyroidectomy, particularly in endemic regions. Postoperative follow-up must include surveillance for MTC via calcitonin and CEA monitoring.

Conclusion: Clinicians should be aware that GD does not exclude the presence of multiple thyroid cancers. Comprehensive surgical and pathological evaluation ensures accurate diagnosis and guides appropriate postoperative management.

Intraperitoneal migration of hepatic hydatid cyst with intact daughter cysts: Case report and systematic review translate to Turkish

Ferdi Cambaztepe, Alphan Toyran, Begüm Irmak Çoban, Mahmut Hüdai Demir

Department of General Surgery, University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Intraperitoneal "delivery" of an intact hepatic hydatid endocyst—also termed spontaneous exovesiculation or hydatid delivery—is an exceptionally rare complication of cystic echinococcosis. Because the laminated (germinative) membrane remains unbroken, the presentation may be deceptively indolent and lacks the dramatic anaphylaxis and diffuse peritoneal seeding seen with frank rupture. We report a contemporary case and summarise the available evidence through a PRISMA 2020-compliant systematic review.

Material and Methods: PubMed, Embase, Web of Science and Google Scholar were searched from inception to December 2025. We included peer-reviewed reports of hepatic hydatid cysts in which the pericyst failed but the endocyst migrated intraperitoneally intact; cases with spillage/disseminated peritoneal hydatidosis or alveolar echinococcosis were excluded. Of 38 records screened, 11 published cases (1998-2023) met inclusion criteria; together with the present case, 12 cases were analysed. Most originated from the right lobe and gravitated to the pelvis (approximately 5-20 cm). Across reports, anaphylaxis and secondary peritoneal implantation were not observed, and surgical management was uniformly curative with no reported mortality or recurrence.

Results: A 67-year-old woman with hypertension and advanced chronic kidney disease was found to have multiple hepatic cysts. Initial indirect haemagglutination assay (IHA) was negative (31.01.2025), and the lesions were followed as presumed benign. A CT scan dated 25.09.2025 demonstrated hepatic cysts but no pelvic lesion. In December 2025, a new cystic pelvic mass was detected during gynaecological follow-up. Repeat serology became strongly positive (IHA 1:2560). MRI on 10.12.2025 demonstrated a cystic lesion in the pouch of Douglas with a classic "water-lily" sign, alongside a collapsed hepatic cyst cavity, consistent with intraperitoneal migration of an intact daughter cyst. Albendazole was initiated and surgery was performed on 26.12.2025. Laparoscopic exploration was converted to open laparotomy due to dense adhesions. An intact free hydatid cyst adherent to the ileum was removed en bloc with a short ileal segment followed by primary anastomosis. Concomitant hepatic cyst cavities were unroofed, evacuated, irrigated with scolicidal solution, and obliterated with omentoplasty. Recovery was uneventful, and no recurrence was observed at 2-month follow-up under antiparasitic therapy.

Conclusion: In endemic settings, the combination of a new pelvic cyst and a collapsing hepatic cyst cavity should prompt consideration of intact hydatid migration, even with previously negative serology. Early definitive surgery, meticulous anti-spillage technique, and adjunct albendazole appear to confer excellent outcomes.

Keywords: Cystic echinococcosis, hydatid cyst, intraperitoneal migration

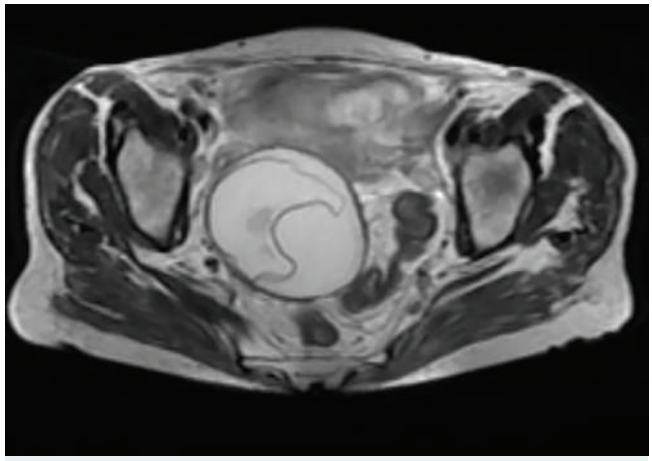

Figure 1. MRI image of hydatid cyst in the pouch of Douglas.

The cyst is seen as a rounded, well-defined fluid-filled structure situated between the uterus and the rectum in the cul-de-sac. It measures approximately 5 cm and has a multilayered appearance: note the detached parasitic membrane floating within the cyst (thin wavy hypointense line inside the cyst), a hallmark of hydatid cyst (sometimes referred to as the "water-lily sign"). The cyst exerts pressure on the uterus anteriorly and the rectosigmoid posteriorly. There is a mild rim of inflammatory reaction around the cyst, but no daughter cysts are obvious in the pelvis. This MRI conclusively demonstrates the secondary pelvic hydatid cyst that developed after the hepatic cyst rupture - a migration of hydatid elements leading to a new cyst implantation in the pelvic peritoneum peroperative view, *in situ*.

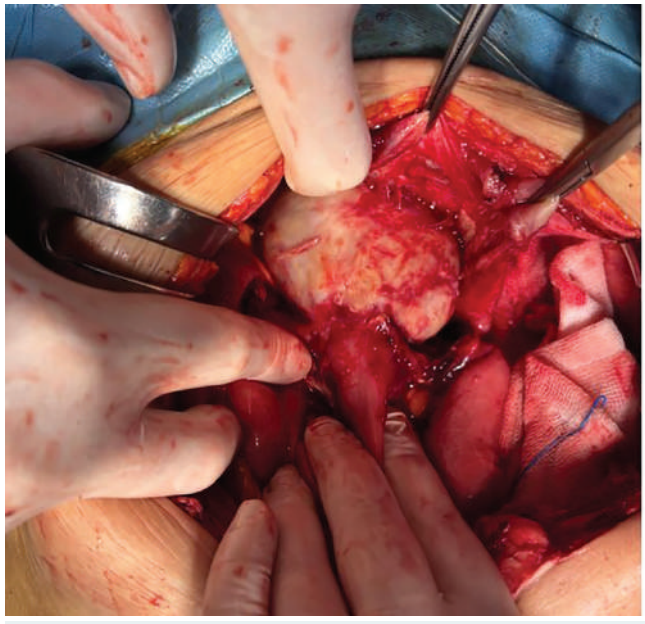

Figure 2. Intact pelvic hydatid cyst occupying the pouch of Douglas.

Table 1. Published cases of intraperitoneal migration of an intact hepatic hydatid cyst, with key features and outcomes

Case (year)	Age/sex	Liver cyst location	Cyst size	Migrated cyst location	Presentation	Management	Outcome
Arslan et al. (1998)	20 M	Left lobe (inferior surface)	~20 cm	Free in pelvis (causing bladder compression, ureteral obstruction)	Acute intestinal obstruction (bilateral hydronephrosis, uremia)	Laparotomy; intact cyst removal; hepatic pericyst left *in situ*	Recovered (no recurrence)
Sharma & Gupta (2000)	43 M	Left lobe	~20 cm	Free in peritoneum (pelvic)	Acute abdomen with peritoneal signs	Laparotomy; cyst excision; peritoneal washout	Recovered (no recurrence)
Karakaya et al. (2007)	35 F	Right lobe	~5 cm	Free in peritoneum (pelvis)	Mild abdominal pain only	Laparotomy; cyst removal	Recovered
Acer/Karnak et al. (2008)	10 F	Right lobe	~10 cm	Free in pelvis (POD)	Acute abdomen (sudden RUQ pain)	Laparotomy; cyst removal; liver repair	Recovered
Kahraman et al. (2016)	27 M	Right lobe	8 cm	Mobile in peritoneal cavity	Acute localized abdominal pain	Laparotomy; cystectomy; partial pericystectomy	Recovered
Idrissa et al. (2017)	6 M	Right lobe (segment VI)	7×5 cm	Free in pelvis (POD)	Acute pelvic pain & distension	Laparotomy; intact cyst removal; peritoneal lavage	Recovered
Ashebir et al. (2019)	25 F	Left lobe (with bile leak)	13×15 cm	Free in pelvis	Acute peritonitis (generalized pain, fever)	Laparotomy; cyst removal; lavage; omentoplasty	Recovered (albendazole given)
Markov et al. (2019)	30 M	Right lobe (+ small left lobe cysts)	10×13 cm	Free in lower abdomen (above bladder)	Subacute abdominal pain; mild hemoperitoneum	Laparotomy; cyst removal; plus aspiration of remaining liver cysts	Recovered (albendazole given)
Mehri et al. (2021)	85 M	Right & left lobes (multiple cysts)	10×13 cm	Free in pelvis (over bladder dome)	Dull generalized abdominal pain (chronic hydatidosis)	Laparotomy; intact cyst excision; drainage of liver cysts	Recovered (albendazole given)
Baccouch et al. (2021)	63 F	Left lobe (segment IV)	12×6 cm	Free in pelvis (POD)	2 months RUQ pain, acute exacerbation	Urgent laparotomy; hepatic pericyst resection; intact cyst removal	Recovered (no recurrence at 7 mo)
Ben Salem et al. (2023)	77 F	Left lobe	~10 cm	Free in peritoneum (bilobed cyst)	Acute RUQ pain (no trauma)	Laparotomy; intact cystectomy; partial pericystectomy	Recovered (albendazole 2 mo)
Present Case (2025)	67 F	Right lobe (segment VI; plus cysts in III, VII)	~7 cm (daughter cyst)	Free in pelvis (POD)	Chronic pelvic mass & pain (silent liver rupture)	Laparoscopy (converted to open); cyst resection with adherent ileal segment; liver cysts unroofed & omentoplasty	Recovered (albendazole given)

RUQ: Right upper quadrant, POD: Pouch of Douglas.

Mechanical ileus secondary to intestinal amyloidosis: A rare case report

Ahmet Ağların, Emil Hüseyinoğlu, Ayşegül Bekdemir, Tuba Göçmen

University of Health Siences Türkiye, Bursa City Hospital, Bursa

Objective: Amyloidosis is a heterogeneous disease characterized by extracellular deposition of misfolded protein fibrils in various organs. Although gastrointestinal involvement is rare, it may cause abdominal symptoms and motility disorders. Small bowel involvement due to submucosal and vascular amyloid deposition can lead to luminal narrowing and ileus. Only a few cases of mechanical obstruction secondary to intestinal amyloidosis have been reported.

Material and Methods: A 58-year-old woman presented with six days of abdominal pain, distension, nausea, vomiting, absence of flatus and stool, and syncope. Her history included hypertension. Physical examination showed a distended abdomen with diffuse tenderness and decreased bowel sounds, while laboratory tests revealed leukocytosis. Contrast-enhanced CT demonstrated marked jejunal distension with symmetrical wall thickening and partial asymmetry at the transition point. Wall thickening up to 1 cm was also observed in the ileal loops. The colon appeared collapsed, with mesenteric fat stranding and mild pelvic free fluid.Additionally, a suspicious 2.5 cm hypodense hepatic lesion and a 4 cm pathological right axillary lymphadenopathy were detected, suggesting metastatic malignancy. Emergency surgery revealed marked small bowel wall thickening and congestion. Approximately 100 cm of mechanically obstructed small intestine was resected starting 40 cm distal to the ligament of Treitz, followed by end-to-end anastomosis. Histopathology showed widespread amyloid deposits in the mesenteric tissue and intestinal wall, consistent with intestinal amyloidosis. The patient was followed for 20 days postoperatively and referred for systemic evaluation.

Results: Although gastrointestinal amyloidosis is rare, it can lead to serious complications. Amyloid deposition in the bowel wall causes rigidity, motility disturbances, and luminal narrowing, while vascular involvement may contribute to ischemia. Radiological findings are non-specific and often mimic malignant disease, as observed in our case.Treatment depends on clinical presentation. While supportive therapy may be sufficient in mild cases, surgical resection is required in patients who develop mechanical obstruction. Multidisciplinary evaluation is essential to assess systemic involvement.

Conclusion: Although intestinal amyloidosis is rare, it may present with serious surgical emergencies such as mechanical ileus. As it can radiologically mimic malignancy, it should be considered in the differential diagnosis. Definitive diagnosis is established by histopathological examination, and surgical resection is necessary in cases with obstruction.

Keywords: Amyloid accumulation, intestinal amiloidozis, mechanical obstruction

Approach to the patient with superior mesenteric artery syndrome

Abdülkadir Çamlı, Yalçın Sönmez, Nebi Acar, Ali Cihat Yıldırım, Mehmet Fatih Ekici, Faik Yaylak, Sezgin Zeren

Kütahya Health Sciences University, Kütahya City Hospital, Kütahya

Objective: Superior mesenteric artery syndrome (SMAS) is a rare cause of upper gastrointestinal obstruction resulting from compression of the third part of the duodenum between the abdominal aorta and the superior mesenteric artery. Clinical symptoms are often non-specific and require high index of suspicion for diagnosis. This case report shares the successful management of SMAS-related obstruction with surgical bypass in an elderly patient with a history of prolonged oral intake disorder and weight loss.

Material and Methods: A 71-year-old female patient presented with long-standing oral intake disorder, weight loss, nausea, and vomiting. She sought emergency care due to a marked increase in symptoms over the past week and the development of severe oral intake disorder. Physical examination revealed abdominal distension. Computed tomography (CT) of the abdomen showed severe gastric distension extending into the pelvis. A nasogastric tube was inserted, and approximately 4000 cc of bilious contents were drained during the initial decompression. Upper gastrointestinal endoscopy performed to clarify the etiology revealed no significant pathology. However, an average of 1500 cc of bilious drainage continued daily from the nasogastric tube. An abdominal CT scan performed with oral contrast alone showed that the oral contrast progressed to the third portion of the duodenum but did not pass distally. A decision was made to perform surgical exploration with the differential diagnoses of obstruction/mass at the SMAS and Treitz levels.

Results: Intraoperative observation revealed that the SMA was compressing the third portion of the duodenum, causing mechanical obstruction. During surgery, an antecolic Roux-en-Y gastrojejunostomy was performed to restore passage by altering the Treitz anatomy. No complications were observed in the postoperative period. A liquid diet was started on postoperative day 4, and solid food was introduced on postoperative day 6 after the patient tolerated it well. The patient was discharged on postoperative day 8 with recommendations following an uneventful clinical course.

Conclusion: The absence of significant pathology on endoscopy and the continued high-volume bilious nasogastric drainage, along with contrast retention at the D3 level on oral contrast-enhanced CT, supported the diagnostic approach for SMA. The literature indicates that CT, along with SMA-aorta angle and distance measurement, is considered the gold standard. Conservative treatment aims for weight gain through decompression, postural therapy, and nutritional support. However, in selected cases, the conservative approach may fail, and surgical treatment becomes necessary. At this point, current sources emphasize that conservative treatment may fail and that surgery should not be delayed.

Case report: Gastric cellular angiofibroma

Hasan Mert Kazancı[2], Zekai Serhan Derici[1], Özgül Sağol[3]

[1]*Department of General Surgery, Dokuz Eylül University Hospital Faculty of Medicine, İzmir*

[2]*Clinic of General Surgery, Bor State Hospital, Niğde*

[3]*Department of Pathology, Dokuz Eylül University Hospital Faculty of Medicine, İzmir*

Objective: Cellular angiofibroma (CAF) is a rare, generally considered to have a good prognosis, mesenchymal tumor. It is mostly found in the vulvo-vaginal region in women and in the inguino-scrotal region in men. Although extragenital localizations have been reported, there are no documented cases of CAF in the stomach in the literature. In this case presentation, we report a gastric CAF lesion detected in a patient who underwent laparoscopic gastric wedge resection with a preliminary diagnosis of gastrointestinal stromal tumor (GIST) originating from the stomach.

Material and Methods: A 75-year-old man with IgG kappa multiple myeloma was found to have a 2.5 cm submucosal gastric polyp during endoscopy for dyspepsia. Endoscopic ultrasonography showed a heterogeneous, hypoechoic lesion from the muscularis propria, measuring 23x20 mm. Biopsies revealed no diagnostic tissue. CT scan showed a 35x22x16 mm hypodense lesion in the stomach's small curvature, suggestive of GIST, with no metastasis. A type 3 hiatal hernia was also identified. The patient had laparoscopic wedge resection; a 2 cm polyp on the lesser curvature was excised. The hiatal defect was repaired with crurorrhaphy, mesh, and Toupet fundoplication.

Results: Pathology showed a 4x2.3x2.5 cm homogeneous, lobulated tumor 3 mm from the margin, consistent with CAF. Immunohistochemistry: Actin, desmin, h-Caldesmon, calponin negative; CD34, CD117 positive; DOG1, S100 negative; Ki-67 <10%; PR positive; SDH-B preserved.

Conclusion: CAF generally shows a good prognosis when excised with negative margins. To date, no studies reporting metastasis have been published in the literature. Nevertheless, cases of recurrence after excision with negative margins have been reported. Therefore, follow-up is important. In our case, the lesion was localized on the lesser curvature of the stomach and was identified as a subepithelial lesion, mimicking GIST on both CT and endoscopic imaging. In our case, DOG1 was negative, SDH-B was preserved, and CKIT was negative, but positive in mast cells. No signs of recurrence were observed during postoperative follow-up.

Keywords: Cellular angiofibroma, subepithelial lesion, gastric

Surgical management of superior mesenteric artery syndrome: A case series of 5 patients including a rare malignancy association

Deniz Elhakan[1], Hasan Mert Kazancı[2], Zekai Serhan Derici[1], Tarkan Ünek[1], Koray Atila[1], Işıl Başara Akın[1]

[1]*Department of General Surgery, Dokuz Eylül University Faculty of Medicine, İzmir*

[2]*Clinic of General Surgery, Bor State Hospital, Niğde*

Objective: Superior mesenteric artery syndrome (SMAS), also known as Wilkie's syndrome, is a rare cause of upper gastrointestinal obstruction characterized by the extrinsic compression of the third portion of the duodenum between the abdominal aorta and the superior mesenteric artery. Pathologically, defined by a significant reduction in the aortomesenteric angle (AMA) to below 25° (from a physiological mean of approximately 38°) and a decrease in the aortomesenteric distance (AMD) to less than 10 mm.

Material and Methods: This retrospective case series evaluated five patients surgically treated with a preliminary diagnosis of SMAS at a single center. Demographic characteristics, clinical presentation, radiological findings (AMA, AMD), surgical techniques, and postoperative outcomes were assessed.

Results: The study included five patients (3 females, 2 males) aged 19-45 years (mean age 29.6 years). All presented with gastrointestinal obstruction symptoms, including nausea, vomiting, abdominal pain, weight loss, and postprandial exacerbation. Postprandial nausea and vomiting were present in all cases; three also had preprandial nausea. Computed tomography (CT) confirmed SMAS, demonstrating an AMA of 14°-20.7° and a maximum AMD of 6 mm. Surgical management consisted of laparoscopic Strong's procedure (n=1), laparoscopic Roux-en-Y duodenojejunostomy (n=1), resection with duodenojejunostomy (n=1), laparoscopic side-to-side duodenojejunostomy (n=1), and combined laparoscopic Strong's procedure and duodenojejunostomy (n=1). One patient had concomitant Nutcracker syndrome. In another patient with a preoperative diagnosis of SMAS, an intraoperative malignant epithelial tumor was detected. Case 1: A 19-year-old female with a 5-year history of postprandial pain and vomiting, and recent hematuria, had a BMI of 15.22 kg/m². Imaging showed an AMA of 16° and AMD of 4 mm, with left renal vein compression consistent with Nutcracker syndrome. Laparoscopic duodenojejunostomy was performed. Case 2: a 38-year-old female with valvular heart disease presented with intermittent nausea and vomiting for one year and minimal weight loss (2.5 kg). CT demonstrated an AMA of 19° and AMD of 5.3 mm. Intraoperatively, a proximal jejunal mass not detected on preoperative imaging was identified; resection of the distal duodenum and proximal jejunum with side-to-side duodenojejunostomy was performed. Histopathology revealed adenocarcinoma with focal squamous differentiation, serosal invasion, and three metastatic lymph nodes (pT4N2).

Conclusion: SMAS should be considered in patients with rapid weight loss and upper gastrointestinal obstruction symptoms. Laparoscopic duodenojejunostomy remains the standard treatment, a single anastomosis is generally sufficient and Roux-en-Y diversion is usually unnecessary. Strong's procedure with Treitz ligament repositioning may be considered in selected cases. Even when radiologic criteria for SMAS are met, alternative causes, including malignancy, must be excluded.

Perforated jejunal adenocarcinoma arising in jejunal diverticulitis: A rare case report

Mehmet Selim Yağmur[1], Furkan Taş[1], Özgür İbiş[1], Cem Karaali[2], Orhan Üreyen[2]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Clinic of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir Faculty of Medicine, İzmir*

Objective: Jejunal diverticulosis is a rare pathology of the intestine, affecting elderly patients and usually remaining asymptomatic. However, it may lead to complications such as diverticulitis, perforation, bleeding, and obstruction. The diagnosis of acute jejunal diverticulitis is challenging due to non-specific onset and the limited sensitivity of imaging modalities, and it is often established during surgery. Small bowel adenocarcinomas account for only 1-3% of gastrointestinal malignancies, with jejunal localization being particularly rare. Adenocarcinoma arising from a jejunal diverticulum is exceedingly uncommon and presents with perforation or acute abdomen leading to delays in diagnosis and treatment. In this report, we present a rare case of jejunal adenocarcinoma presenting with diverticulitis and perforation, discussed in light of the current literature.

Material and Methods: This study is a case report of a patient presenting with acute abdomen and evaluated with a preliminary diagnosis of gastrointestinal perforation. Clinical findings, laboratory parameters, and radiological imaging (computed tomography) were reviewed. Intraoperative findings were recorded during surgery. Specimens were evaluated histopathologically and immunohistochemically.

Results: An 89-year-old male presented with a 10-day history of abdominal pain, worsening over the last two days, accompanied by oral intolerance and clinical deterioration. Associated symptoms included nausea, vomiting, and fever. Patient history included congestive heart failure, atrial fibrillation, hypertension, and type 2 diabetes mellitus. On admission, blood pressure was 90/50 mmHg, respiratory rate was 30/min, body temperature was 39 °C, and heart rate ranged 100-110 beats/min. Physical examination revealed generalized abdominal tenderness, rebound and signs of peritoneal irritation. Laboratory tests showed a CRP level of 350 mg/L and a leukocyte count of 23,000/mm^3. Computed tomography demonstrated diffuse free fluid and air throughout the abdomen (Figure 1). Emergency surgery was planned. Empirical intravenous piperacillin-tazobactam was administered. Exploration revealed generalized fecal peritonitis, a 7×7 cm tumoral mass in the cecum, and perforated jejunal diverticulum located 20 cm distal to the ligament of Treitz (Figure 2). Segmental small bowel resection with side-to-side anisoperistaltic stapled anastomosis was performed. Right hemicolectomy and end ileostomy were carried out for tumoral mass. The patient was under high-dose inotropic support postoperatively. Patient died on postoperative day 3 due to septic shock-related multiple organ dysfunction syndrome. Histopathology revealed moderately differentiated adenocarcinoma in both the cecum and the jejunal diverticulum.

Conclusion: Jejunal diverticulosis should be considered in cases of unexplained small bowel obstruction or perforation. In the presence of diverticulosis-associated masses detected intraoperatively, the possibility of malignancy should not be overlooked, and surgical resection should be performed with oncological principles.

Spontaneous adrenal hematoma presenting with abdominal pain in an elderly patient and complicated by delayed adrenal insufficiency: A case report

Nebi Acar, Abdülkadir Çamlı

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya City Hospital, Kütahya

Objective: Spontaneous adrenal hemorrhage (adrenal hematoma) is a rare but potentially life-threatening condition associated with significant morbidity and mortality. It often presents with non-specific symptoms such as abdominal or flank pain, nausea, and fatigue, leading to delayed diagnosis. Reported etiologies include trauma, sepsis, coagulopathies, anticoagulant use, and underlying adrenal lesions, with increased risk in elderly patients due to comorbidities. Despite its rich arterial supply, the adrenal gland has limited venous drainage, predisposing it to hemorrhage under stress conditions. Computed tomography (CT) is the primary diagnostic modality. Conservative management is generally sufficient in hemodynamically stable patients without evidence of active bleeding. Recent reports have highlighted an association between spontaneous adrenal hemorrhage and direct oral anticoagulant (DOAC) therapy.

Material and Methods: An 80-year-old woman presented with a two-day history of diffuse abdominal pain. Her medical history included hypertension, diabetes mellitus, chronic kidney disease, and a prior ischemic cerebrovascular event. She was receiving rivaroxaban therapy. Physical examination revealed stable vital signs and a benign abdominal examination. Non-contrast CT performed at an outside facility demonstrated a large hematoma involving the left adrenal gland and perirenal region. The patient was admitted with a diagnosis of spontaneous adrenal hematoma and managed conservatively.

Results: Hemoglobin level decreased from 12 g/dL at initial presentation to 9 g/dL on admission but remained stable on serial measurements. Contrast-enhanced CT showed no evidence of active contrast extravasation, and the hematoma measured up to 8×15 cm. On hospital day eight, the patient developed acute mental status changes, hypotension, and tachycardia. Hemoglobin levels remained stable, and follow-up imaging showed no progression of hemorrhage. Endocrinology consultation raised suspicion for adrenal insufficiency secondary to adrenal hematoma. Intravenous hydrocortisone therapy was initiated, resulting in rapid clinical improvement. The patient was transferred from the intensive care unit back to the ward and subsequently discharged in good condition.

Conclusion: Spontaneous adrenal hematoma is a rare and diagnostically challenging cause of abdominal pain, particularly in elderly patients receiving anticoagulant therapy. Conservative management is safe and effective in hemodynamically stable patients, even in cases of large hematomas. However, clinicians should remain vigilant for delayed adrenal insufficiency. Prompt recognition and early corticosteroid replacement therapy are critical and may be life-saving.

Superficial abdominal venous thrombophlebitis: A rare clinical case

Banu Karapolat, Yunus Emre Topkaya, Faruk Aksoy

Department of General Surgery, Trabzon University Faculty of Medicine, Trabzon

Objective: Superficial thrombophlebitis most commonly affects the veins of the lower extremities, particularly the great saphenous vein. However, superficial abdominal veins—such as the thoracoepigastric and superior epigastric veins—are rarely involved. This condition is also described in the literature as abdominal Mondor disease. First reported by Mondor in 1939, it was most frequently described in the veins of the chest wall, whereas involvement of the abdominal wall is exceedingly rare. Risk factors include local trauma, surgical interventions, infection, malignancy, and hypercoagulable states. Clinically, it may present as a painful, cord-like lesion and can be misdiagnosed as an abdominal abscess, hernia, or intra-abdominal pathology. In this report, we present a case of superficial abdominal vein thrombophlebitis that developed following minor trauma.

Material and Methods: The clinical evaluation, laboratory tests, and imaging findings of a patient presenting with pain and swelling in the left upper quadrant were retrospectively reviewed. Superficial soft tissue and Doppler ultrasonography were used for diagnostic purposes. The treatment approach and short-term clinical course were also evaluated.

Results: A 51-year-old female patient presented to our outpatient clinic with complaints of pain and swelling in the left upper quadrant that developed after minor trauma caused by a branch strike approximately one week earlier. Her medical history was significant for hypertension and chronic hepatitis B infection, and she was receiving antiviral therapy (Viratt®). Physical examination: A linear, cord-like subcutaneous lesion with tenderness on palpation was detected in the left upper quadrant. No erythema or fluctuation was observed. Laboratory findings: hematological and biochemical parameters were within normal limits. Ultrasonography: Superficial soft tissue ultrasonography revealed a non-compressible millimetric superficial venous structure with increased surrounding echogenicity in the left upper quadrant, consistent with thrombophlebitis. No extension into the deep venous system was observed. Treatment and follow-up: Conservative treatment including non-steroidal anti-inflammatory drugs, local warm application, and rest was initiated. Anticoagulation therapy was not considered necessary. At the one-week follow-up, clinical findings had markedly regressed.

Conclusion: Superficial abdominal vein thrombophlebitis is a rare condition that can easily be misdiagnosed. It should be considered in the differential diagnosis, particularly in patients presenting with a cord-like lesion and a history of trauma. Doppler ultrasonography is indispensable for diagnosis. Most cases resolve uneventfully with conservative treatment.

Giant infected thyroid mass complicated by vascular injury: A surgical challenge

Furkan Dağkaya, Emre Zengin, Hande Köksal

Department of General Surgery, Selçuk University Faculty of Medicine, Konya

Objective: Thyroid gland pathologies are common diseases, but giant thyroid masses complicated by infection, skin penetration, and major vascular involvement are rare today. Large goiters or malignant thyroid lesions can lead to complications such as airway obstruction, vascular injury, and life-threatening postoperative neck hematoma. Here, we present a complex case of a patient who presented to the emergency department with necrosis and bleeding in a neck mass, underwent surgery for a giant thyroid mass.

Material and Methods: An 85-year-old female patient presented with a progressively growing and bleeding mass in the anterior neck region. Her medical history included hypothyroidism. A computed tomography scan of the neck revealed a mass lesion approximately 83×107 mm, extending anteriorly into the subcutaneous tissue and skin. The lesion contained scattered air densities and calcified foci. These findings were considered consistent with an abscess collection associated with malignancy.

Results: The patient underwent surgery for total thyroidectomy. The cystic components of the thyroid gland had penetrated the skin and showed significant inflammatory adhesions to surrounding tissues. During dissection of the right lobe of the thyroid, the internal jugular vein was injured due to the fragility of the tissues. The injury was primarily repaired. The parathyroid glands were preserved. Recurrent laryngeal nerve monitoring was performed intraoperatively. Total thyroidectomy was completed. In early postoperative period, the patient developed acute cervical swelling. Due to the patient's tracheotomy, airway security was ensured, and neck exploration was decided. Approximately 100 cc hematoma was drained. There was no active arterial or venous bleeding focus. Minimal leakage between tissue planes was controlled with electrocautery. The tracheotomy opening was repaired, and the patient was admitted to the intensive care unit.

Conclusion: In this case, despite successful vascular repair, the development of a postoperative hematoma without the detection of an active bleeding focus highlights the importance of diffuse capillary leakage in inflamed surgical areas. This case emphasizes the importance of careful dissection in infected and malignant thyroid diseases, being alert to the risk of tracheomalacia due to compression of giant thyroid masses, being prepared for vascular repair, close postoperative monitoring in high-risk patients, and the decision for early surgical re-exploration. Successful management was achieved through timely vascular repair, careful postoperative monitoring, and early re-exploration. Awareness of potential complications in such complex thyroid surgeries will improve surgical outcomes.

Keywords: Giant thyroid lesion, emergancy surgery, bleeding

Figure 1. An 85-year-old female patient presented with a progressively growing mass and bleeding in the anterior neck region.

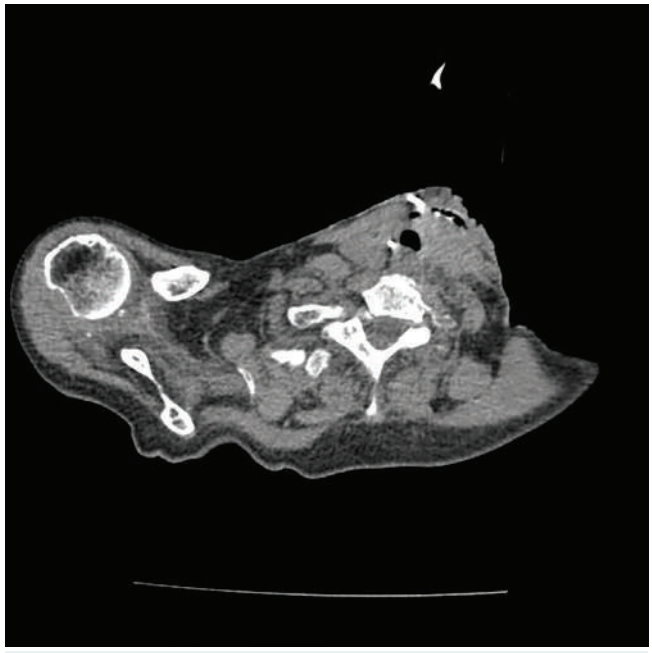

Figure 2. A contrast-enhanced neck computed tomography scan revealed a mass lesion approximately 83×107 mm in size, filling the thyroid gland lodge and extending anteriorly to the subcutaneous tissue and skin. The lesion contained scattered air densities and calcified foci. These findings were onsidered consistent with an abscess collection accompanying malignancy.

[P-248]

A rare cause of necrotizing fasciitis: Vaginal perforation

Fatih Kocalar, Hande Köksal

Department of General Surgery, Selçuk University Faculty of Medicine, Konya

Objective: Necrotizing fasciitis (NF) is a rare but life-threatening soft tissue infection affecting the skin, subcutaneous tissues, and fascia, characterized by rapid progression and high mortality. Early diagnosis and aggressive surgical treatment are critical for prognosis. This poster presents a case of extensive NF extending from the vagina to the subcostal space of the anterior abdominal wall, requiring repeated debridement.

Material and Methods: A 46-year-old female patient presented to our emergency department with pain and tenderness in the suprapubic area. Initial assessment revealed a moderate to good general condition and stable vital signs. Redness and foul-smelling discharge were present in the suprapubic area. History indicated that an abscess had been drained from this area a few days prior. Physical examination revealed tenderness in the suprapubic region and an opening approximately 4 cm in size. Digital examination showed that this opening extended from the anterior vaginal wall to the urethra. The urethra was assessed as intact. The patient showed elevated infectious markers and decreased albumin (WBC: 18.5 K/uL, Hgb: 13 g/dL, alb: 2.4 g/dL, CRP: 580 mg/L, proc: 2.03 ug/L). Computed tomography revealed subcutaneous emphysema starting in the suprapubic region, continuing under the skin along the muscle planes of the left lateral abdominal wall, and extending posteriorly into the lumbar region, along with accompanying increased density in the subcutaneous fatty planes. This appearance did not extend into the intra-abdominal area but did extend into the left inguinal region.

Results: The patient was found to have a fasciitis area extending from the left femoral head to the left subcostal space. After obtaining culture and pathology samples, the necrotic areas were debrided.In the postoperative period, the patient was empirically started on vancomycin/meropenem/metronidazole and frequent daily debridement and dressing changes were performed. Coryneform bacilli were cultured from the patient's blood. No growth was detected in cultures taken from the debrided areas. During this time, electrolyte imbalances and low albumin levels were treated with appropriate replacements. After the progression of necrosis was halted with frequent debridement and dressing changes, the patient was referred to plastic reconstructive and aesthetic surgery for appropriate flap surgery due to the very large area debrided. During follow-up with our team, a reduction in the size of the wound was observed.

Conclusion: This case highlights the rare but aggressive course of necrotizing fasciitis and the critical importance of early, repeated surgical debridement in treatment. A multidisciplinary approach and close follow-up improve patient survival.

Keywords: Necrotizing fasciitis, abdominal wall, repeated debridement

Figure 1. The patient, who underwent surgery with a diagnosis of necrotizing fasciitis, was found to have a fasciitis area extending from the level of the left femoral head to the left subcostal space.

Figure 2. After the progression of necrosis was halted with frequent debridement and dressing changes, the patient was referred to plastic reconstructive and aesthetic surgery for appropriate flap surgery due to the very large area of debridement performed.

[P-249]

A rare cause of acute mechanical intestinal obstruction: A case of ileocecal endometriosis

Elif Elgiz Aktarı, Damla Beyazadam, Meryem Günay Gürleyik

Department of General Surgery, University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Mechanical intestinal obstruction is a common cause of acute abdomen. However, intestinal endometriosis represents a rare etiological factor, particularly in women of reproductive age. Although endometriosis is predominantly confined to the pelvic organs, gastrointestinal involvement is less frequent, and terminal ileal or cecal localization may rarely present with obstructive symptoms. Herein, we report a case of cecal endometriosis presenting with acute mechanical intestinal obstruction, in which a scirrhous cecal mass was detected intraoperatively.

Material and Methods: A 40-year-old woman was admitted to the emergency department with nausea, vomiting, and abdominal pain, accompanied by the absence of flatus and stool passage. She was hospitalized with a preliminary diagnosis of mechanical bowel obstruction. Her past surgical history was remarkable only for a previous cesarean section. Due to the lack of clinical improvement under conservative management, diagnostic laparotomy was performed.

Results: Abdominal computed tomography demonstrated dilated bowel loops, diffuse air-fluid levels, and an image suggestive of nested bowel segments at the medial aspect of the cecum, raising suspicion of a cecal mass. Intraoperative exploration revealed endometriotic implants on the left ovary and peritoneal surfaces. Multiple lymphadenopathies were observed in the colonic mesentery. A well-demarcated polypoid mass causing obstruction was identified in the cecum, with marked dilatation of the proximal small bowel loops. In addition, a 15-cm segment of the terminal ileum exhibited cobblestone-like suspicious areas and luminal narrowing. The patient was also noted to have previously undergone appendectomy. An ileocecal valve resection was performed, and the specimen was sent for frozen section analysis, which reported the lesion as an endometrioma. Final histopathological evaluation revealed no evidence of inflammatory bowel disease; instead, the ulcerated areas were interpreted as subacute ischemic changes secondary to intussusception caused by endometriotic foci. The postoperative course was uneventful, and the patient was discharged on postoperative day 7.

Conclusion: Endometriosis is a common condition with a challenging diagnosis. Intestinal endometriosis should be considered a rare yet clinically significant cause of mechanical bowel obstruction in young female patients. When presenting as a scirrhous cecal mass, it may mimic malignancy or inflammatory bowel disease, making intraoperative pathological assessment essential for guiding surgical decision-making. In this case, endometriotic implantation in the ileocecal region, possibly related to the patient's previous cesarean section accompanied by appendectomy, was considered to have contributed to the pathogenesis of obstruction. Early recognition and timely surgical resection are crucial for achieving favorable clinical outcomes.

Keywords: Endometriosis, mechanical bowel obstruction, ileocecal resection

Figure 1. Macroscopic appearance of the ileocecal resection specimen; marked mural thickening and luminal narrowing are observed in the ileocecal region.

Figure 2. Macroscopic appearance of the ileocecal segment during intraoperative frozen-section evaluation; after sectioning of the bowel wall, a nodular lesion causing mural thickening is observed.

Gastrointestinal perforation due to foreign body

Barış Özkan[1], Oğuzhan Alp Öztürk[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul*

[2]*Department of General Surgery, Trakya University Faculty of Medicine, Edirne*

Objective: Foreign body ingestion is more commonly encountered in the pediatric population; however, it also represents an important cause of emergency department admissions in adults. Ingestion may occur intentionally, such as in cases of self-harm or suicide attempts, although the majority of cases are accidental. In most instances, ingested foreign bodies pass through the gastrointestinal tract spontaneously. Nevertheless, perforation, bleeding, mechanical obstruction, impaction within the gastrointestinal tract, and chemical toxicity are among the most frequent complications. The size, shape, and material composition are considered the primary determinants of complication risk. To date, there is no clear evidence in the literature supporting patient-specific characteristics as independent risk factors.

Results: A 64-year-old female patient presented to the emergency department with abdominal pain and fever. Physical examination revealed abdominal guarding and rebound tenderness. A midline surgical scar and an incisional hernia were also noted. The patient had a history of endoscopic retrograde cholangiopancreatography (ERCP) and cholecystectomy. Review of the most recent ERCP report indicated distal migration of a biliary stent. Abdominal computed tomography performed in the emergency setting demonstrated small bowel loops within the hernia sac, along with free fluid and free air. The patient underwent emergency surgery with a preliminary diagnosis of acute abdomen. Intraoperative exploration revealed that the biliary stent had perforated the bowel wall within the herniated small bowel segment and had migrated extraluminally. A 44-year-old male patient presented with pain and swelling in the inguinal region. Physical examination demonstrated an incarcerated inguinal hernia, and ultrasonography raised suspicion for strangulation, prompting emergency surgical intervention. During exploration, a wooden toothpick was identified within the small bowel loop contained in the hernia sac, perforating the bowel wall from the mesenteric side and extending beyond the lumen. The patient reported no history suggestive of foreign body ingestion.

Conclusion: Although foreign body ingestion is relatively uncommon in adults, it may present with atypical clinical manifestations and lead to severe complications. Sharp, pointed, foreign bodies carry a substantial risk of gastrointestinal perforation. A notable challenge in such cases is the frequent absence of a clear history of ingestion, which may delay diagnosis and treatment. The presence of gastrointestinal segments within a hernia sac may represent a potential facilitating factor for perforation and other complications related to foreign bodies. While imaging modalities play a critical role in diagnosis, definitive diagnosis may often require surgical exploration. Further studies are needed to better explain the underlying pathophysiology and associated risk factors.

De Garengeot hernia: An uncommon presentation of acute appendicitis

Barış Rafet Karakaş, Mert Türlü, Metin Yalçın, Osman Zekai Öner, Arif Aslaner

Department of General Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: De Garengeot hernia occurs in 0.5-1% of femoral hernia cases and is defined by the presence of the vermiform appendix within the femoral hernia sac. This emergency condition is typically diagnosed intraoperatively.

Material and Methods: This is a case presentation of De Garengeot hernia.

Results: A 76-year-old woman presented with a three-day history of pain and swelling in the right groin. Physical examination revealed an erythematous, edematous, and tender femoral mass. Laboratory investigations demonstrated leukocytosis and elevated C-reactive protein levels. Abdominal computed tomography confirmed the presence of the appendix within the right femoral hernia sac, accompanied by loculated fluid and inflammatory changes. Open femoral exploration identified the distal appendix incarcerated in the femoral ring, without evidence of perforation or abscess (Figure 1). Due to limited inflammation, mesh hernia repair and appendectomy were performed.

Conclusion: De Garengeot hernia remains challenging to diagnose. Preoperative computed tomography is essential for accurate identification and effective surgical planning. Early recognition and prompt surgical intervention are critical to achieving optimal patient outcomes.

Keywords: Femoral hernia, appendicitis

Migrated gastric balloon causing small bowel obstruction: Surgical milking and endoscopic extraction

Ali Şahin, İsmail Ege Subaşı, Muhammed Osman Çolak

Clinic of General Surgery, University of Health Sciences Türkiye, Sancaktepe Şehit Prof. Dr. İlhan Varank Training and Research Hospital, İstanbul

Objective: Obesity has become one of the most prevalent global health issues today. The quest to reduce morbidity in treatment has highlighted minimally invasive methods, which are more frequently preferred by patients. Among these methods, intragastric balloon (IGB) application holds a significant place. Although it has a safe profile, like every medical procedure, IGB application carries certain risks of complications. Spontaneous deflation of the balloon or migration to the small intestine due to volume loss is a serious condition that can lead to acute mechanical intestinal obstruction. In this study, we present our combined surgical and endoscopic management technique aimed at minimizing morbidity by avoiding enterotomy in a case of ileus caused by a migrated gastric balloon.

Material and Methods: A supraumbilical median laparotomy was performed under general anesthesia on a patient diagnosed with mechanical ileus. During surgical exploration, a mobile foreign body causing complete lumen obstruction was palpated approximately 60 cm distal to the ligament of Treitz. No ischemia or perforation was observed in the relevant bowel segments. Through a "Retrograde Milking" maneuver performed by the surgical team, the foreign body was manually pushed back proximally from the jejunum. Simultaneously, the duodenal lumen was visualized via gastroscopy; the balloon was grasped at the level of the bulb using endoscopic tripod forceps and extracted, thus terminating the procedure.

Results: A 43-year-old female, who had undergone IGB placement for weight loss 3 months prior, presented with abdominal pain, nausea, and vomiting lasting 8 days. Although she had visited emergency services previously, no diagnosis was made. Physical examination revealed abdominal distension and tenderness. Computed tomography confirmed mechanical ileus caused by a foreign body obstructing the small bowel lumen.

Conclusion: In patients with a history of gastric balloon, the risk of migration should be considered in the presence of abdominal pain and vomiting, even if the balloon appears to be in place. It is not essential for the balloon to rupture; loss of turgor and volume can also cause passage through the pylorus and subsequent small bowel obstruction. Preserving bowel integrity is essential in surgical treatment. The surgical retrograde milking and endoscopic extraction method we applied, as opposed to traditional enterotomy (bowel incision), is a safe and effective hybrid option that eliminates the risk of anastomotic leak and infection while shortening the length of hospital stay.

Spontaneous rectus sheath hematoma: A case report

Uğur Arda, Ercan Önder, Süleyman Atalay, Adem Akçakaya

Department of General Surgery, Bezmialem Vakıf University Hospital, İstanbul

Objective: Rectus sheath hematoma is a rare but clinically significant condition characterized by the accumulation of blood within the rectus sheath due to injury of the epigastric vessels or rectus muscle fibers, and it may mimic an acute abdomen. The most commonly associated factors include anticoagulation therapy, trauma, iatrogenic causes, and conditions that increase sudden abdominal muscle contraction; however, it may also develop spontaneously in patients without medication use. Contrast-enhanced CT provides high diagnostic accuracy by demonstrating the exact localization of the hematoma, its extent, and signs of active bleeding.

Material and Methods: Following is a case ropert regarding spontaneous rectus sheath hematoma.

Results: A 76-year-old male patient with no known comorbidities and no history of anticoagulant use presented to the emergency department with abdominal pain that had started the same day. Physical examination revealed tenderness and a palpable firm mass in the right upper quadrant of the abdomen. Ecchymosis was observed on the abdominal wall (Figure 1). Contrast-enhanced abdominal CT revealed a collection measuring approximately 90×48×92 mm within the right rectus abdominis muscle, consistent with a hematoma, and hyperdense areas within the collection suggestive of active extravasation (Figure 2). The patient was hospitalized for observation and treatment. During follow-up, his general condition remained stable, and he had adequate oral intake. Serial monitoring showed no decrease in hemoglobin levels. Control ultrasonography demonstrated no increase in the size of the hematoma. The patient was discharged on hospital day 5 with a stable clinical course.

Conclusion: Rectus sheath hematoma is an important differential diagnosis of acute abdominal pain in elderly patients, even in the absence of anticoagulant use. Contrast-enhanced CT plays a critical role in diagnosis. In hemodynamically stable patients without hemoglobin decline and without radiological progression, conservative management with close follow-up may be successful; in cases of instability or ongoing bleeding, endovascular embolization is an effective option. Conservative follow-up is often sufficient in stable cases, whereas embolization is prioritized in ongoing bleeding.

Keywords: Rectus sheath hematoma, spontaneous, acute abdomen, elderly

Aortoenteric fistula secondary to endovascular graft infection: Surgical management of a rare complication

Emine Sena Cünük[1], Burhan Özyavuz[1], Emrah Akın[2], Fatih Altıntoprak[2]

[1]*Sakarya Training and Research Hospital, Sakarya*

[2]*Sakarya University Faculty of Medicine, Sakarya*

Objective: Fistulas between the aorta and surrounding organs are extremely rare; however, they can be fatal if not promptly recognized and treated. Primary aortoenteric fistula is a rare cause of gastrointestinal hemorrhage. Without treatment, the survival rate is 70% within the first 6 hours, dropping to 50% after 24 hours. Its classic triad consists of abdominal pain, gastrointestinal hemorrhage, and a pulsatile abdominal mass. This triad is observed in only 10-23% of cases. Secondary aortoenteric fistula (SAEF) is a rare but potentially fatal complication of aortic reconstructive surgery. The incidence of SAEF has increased as a result of advances in vascular surgery and aggressive surgical treatments.

Material and Methods: Surgical management and follow-up: Operation: The patient underwent surgery with a diagnosis of aortobiiliac graft infection. Erosion of the duodenum wall by the graft was observed. Procedure: Excision of the infected graft, new graft anastomosis (*in situ* reconstruction), duodenal resection, and gastrojejunostomy were performed. Outcome: After postoperative intensive care follow-up, the patient was transferred to the ward on day 5. During an endoscopy planned due to vomiting that developed on day 14, cardiac arrest occurred following sedation, and the patient died.

Results: Patient: 68-year-old male. Chief complaint: Fever of 38.6 °C and hematochezia. Medical history: Emergency EVAR due to ruptured abdominal aortic aneurysm 7 years ago. Embolectomy 3 years ago. Under follow-up for suspected graft infection due to recurrent febrile episodes. Diagnostic findings: Laboratory: Leukocytosis (17,000/mm³) and elevated CRP. Computed tomography: Diffuse thickening of the graft wall, air densities, and obliteration of the fat planes between the duodenum and the graft. Endoscopy: Migration of the graft into the duodenum was observed.

Conclusion: The operative and postoperative mortality rates of SAEF are extremely high, averaging around 50-60%. Various surgical strategies have been reported for the management of SAEF. Typical treatment consists of graft excision, debridement of infected tissues, revascularization, and repair of the intestinal fistula. In recent years, endovascular treatment has also gained prominence. In conclusion, SAEF should be the primary suspicion in any patient with a history of aortic reconstructive surgery presenting with gastrointestinal hemorrhage, abdominal pain, and sepsis; the diagnosis must be confirmed as soon as possible. Even in the absence of abdominal pain and sepsis, it is crucial to promptly determine whether the bleeding is caused by SAEF in patients with a history of aortic grafting. Contrast-enhanced abdominal CT and upper gastrointestinal endoscopy can provide a rapid and effective diagnosis. Early diagnosis and timely surgical intervention are life-saving for this patient group.

Keywords: Aortoenteric fistula, complication, surgery

Recurrent psoas abscess

Nedim Akgül, Batuhan Öğüt, Erdem Bedur

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Psoas abscess's a rare clinical condition, can lead to serious morbidity and mortality if not diagnosed and treated promptly. It's formed by collection of purulent fluid in the iliopsoas muscle. The infection may originate primarily from distant focus via the hematogenous route or develop secondarily as a result of direct spread from adjacent anatomical structures. The incidence has increased with development of imaging techniques, CT and MRI playing important role in this process. Our article aims to discuss diagnostic process, etiological causes, treatment approaches and mechanisms of recurrence based on a case of recurrent psoas abscess.

Material and Methods: Case report.

Results: 62-year-old woman developed recurrent right retroperitoneal abscess first detected in 2019, measuring 113×116 mm and initially treated with percutaneous drainage and antibiotics. After 15-day hospitalization, she was followed as an outpatient. One month later, 5 cm abscess recurred at same site, enlarged to 8 cm within six months, and required repeat drainage. Despite negative cultures and improvement in infection markers, abscesses continued to recur over subsequent years. Two years later, she presented with right-sided pain and 8.5 cm abscess, treated with drainage and antibiotics. One year later, MRI showed 10 cm abscess. Multiple additional drainages and antibiotic courses within a year failed to achieve durable resolution. In 2025, she presented to the ER with similar symptoms and underwent laparotomy. Exploration revealed a retrocecal appendix tip within the psoas muscle beneath migrated omental adhesions. Appendectomy, abscess drainage, and debridement were performed. The postoperative course was uneventful. She was discharged.

Conclusion: Psoas abscess is a rare clinical condition, can lead to serious complications if not diagnosed and treated promptly. Determining the etiology in recurrent cases is important for treatment success. In this case, despite repeated percutaneous drainage and antibiotherapy, the abscesses couldn't be controlled; surgical exploration revealed that the infection was associated with retrocecal appendicitis. Retrocecal appendicitis can be overlooked due to the absence of classic symptoms and difficulty in diagnosis by imaging. Due to its proximity to the psoas muscle, it can cause recurrent abscesses. This case emphasizes the need to investigate secondary causes with atypical anatomical localizations in cases of recurrent psoas abscesses with negative cultures and lack of response to treatment. It also demonstrates that surgery can be both diagnostic and therapeutic when conservative approaches fail. Treating patients who absolutely require surgery with non-surgical methods and delaying necessary surgical intervention leads to repeated patient visits, increased treatment costs and patient suffering.

Gastric perforastion secondary to strangulated hiatal hernia: A rare case report

Ozan Erek, Abdullah Kut

University of Health Sciences Türkiye, İstanbul Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul

Objective: Hiatal hernias are commonly encountered in clinical practice; however, strangulation and subsequent gastric ischemia with perforation are rare but life-threatening conditions associated with high morbidity and mortality. Clinical presentation is often nons-pecific, typically including epigastric pain, nausea, and vomiting, which may delay diagnosis. In some cases, patients may present with signs of an acute abdomen. The presence of mediastinal free air on imaging is usually suggestive of esophageal perforation, yet in rare instances it may also indicate gastric perforation secondary to a strangulated hiatal hernia. Therefore, careful correlation of clinical and radiological findings is crucial for timely surgical intervention.

Material and Methods: A patient presenting to the emergency department on the 24th with sudden-onset epigastric pain, nausea, and vomiting was evaluated. Physical examination findings were consistent with an acute abdomen, demonstrating diffuse abdominal tenderness, guarding, and rebound tenderness. Laboratory investigations revealed leukocytosis. Contrast-enhanced thoracic and abdominal computed tomography (CT) was performed. Based on clinical and radiological findings, the patient was taken to emergency surgery. Intraoperative exploration guided the decision for resection and gastrointestinal reconstruction.

Results: Contrast-enhanced thoracoabdominal CT demonstrated prominent mediastinal free air along with intra-abdominal free air and free fluid. Herniation of the gastric fundus into the thoracic cavity and thickening of the gastric wall were also observed. During surgery, severe ischemic changes were noted in the herniated gastric segment. A 6×3 cm perforation with extensive necrosis on the anterior wall of the gastric fundus was identified. Due to the wide necrotic area and the unsuitability of primary repair, a total gastrectomy with Roux-en-Y esophagojejunostomy reconstruction was performed. No major postoperative complications occurred.

Conclusion: Although rare, strangulated hiatal hernias may lead to life-threatening complications such as gastric ischemia and perforation. The coexistence of mediastinal free air with intra-abdominal free air and fluid should strongly raise suspicion for gastric perforation. Early diagnosis, prompt surgical decision-making, and appropriate resection with reconstruction significantly improve patient outcomes. In this case, the postoperative course was uneventful, and the patient was discharged on postoperative day seven. This report highlights the importance of considering gastric perforation secondary to strangulated hiatal hernia in the differential diagnosis when mediastinal free air is detected.

Keywords: Strangulated hiatal hernia, gastric perforation, mediastinal free air

Abdominal evisceration and multiple organ injuries secondary to shotgun trauma: A damage control surgery approach

Bülent Toksöz, Önder Karahallı, Anıl Çağlar Emir, Ali İmran Küçük, Mehmet Aziret

University of Health Sciences Türkiye, Balıkesir Atatürk City Hospital, Health Practice and Research Hospital, Balıkesir

Objective: Firearm injuries, particularly shotgun-related trauma, represent severe clinical entities due to the wide dispersion of pellets and the extensive tissue destruction they may cause. Such injuries frequently result in multiple organ damage. In penetrating abdominal trauma, hemodynamic status is the primary determinant of surgical strategy. In the presence of hemodynamic instability or ongoing hemorrhage, damage control surgery (DCS) is widely accepted as an effective staged approach aimed at reducing mortality. This study presents the management of abdominal evisceration and multiple organ injuries secondary to shotgun trauma using a DCS strategy.

Material and Methods: A 22-year-old male was admitted to the emergency department following a shotgun injury. On initial evaluation, he was conscious, cooperative, and oriented, with a Glasgow Coma scale score of 15. His arterial blood pressure was 100/53 mmHg. Physical examination revealed a midline abdominal wall defect above the umbilicus with evisceration of the stomach and intestinal segments. Contrast-enhanced abdominal computed tomography demonstrated multiple metallic pellet fragments in the vicinity of the liver, spleen, and stomach, along with diffuse hemoperitoneum and free intraperitoneal air. The patient was diagnosed with penetrating abdominal trauma and was taken emergently to the operating room.

Results: Exploratory laparotomy revealed approximately 1000 mL of hemorrhagic fluid within the abdominal cavity. A 10 cm actively bleeding laceration was identified in segment IV of the liver, and a pellet fragment was removed. A 0.5 cm perforation on the anterior wall of the gastric corpus was repaired primarily in two layers. No additional intra-abdominal organ injuries were detected. Due to persistent oozing from the hepatic laceration, perihepatic packing and temporary abdominal closure were performed as part of a damage control strategy. A planned second-look operation 48 hours later demonstrated no active bleeding or bile leakage. Definitive repair was completed with topical hemostatic application, omentopexy, and suturing of the liver laceration. The patient was monitored in the intensive care unit postoperatively and was discharged uneventfully on postoperative day 19.

Conclusion: In shotgun-related penetrating abdominal trauma, rapid surgical intervention and appropriate patient selection are crucial. In patients at risk of ongoing hemorrhage and physiological deterioration, DCS represents a safe and effective treatment strategy. This case highlights the importance of a staged surgical approach in achieving favorable clinical outcomes in complex multi-organ injuries.

Keywords: Firearm injury, penetrating abdominal trauma, damage control surgery

Perforation secondary to incarceration of an umbilical Littre's hernia: A rare case

Gamzegül Kirit, Yasir Keçelioğlu

Department of General Surgery, Pamukkale University Faculty of Medicine Hospital, Denizli

Objective: Meckel diverticulum is a congenital anomaly resulting from the persistence of the vitelline duct and is usually asymptomatic. The most common complications include mechanical intestinal obstruction, bleeding, perforation, and diverticulitis. The presence of a Meckel diverticulum within any hernia sac is defined as a Littre's hernia. Littre's hernia is most frequently observed in the inguinal region, whereas umbilical localization with perforation secondary to incarceration is extremely rare. In this report, we present a case of perforation caused by incarceration of an umbilical Littre's hernia.

Material and Methods: An 18-year-old male patient was admitted to the emergency department with a one-day history of abdominal pain. Physical examination revealed tenderness in the umbilical region without guarding or rebound tenderness. Computed tomography demonstrated a 28×12 mm blind-ending tubular structure adjacent to the ileal loops at the level of the umbilicus. A 9 mm peripherally enhancing collection consistent with an abscess was observed in the surrounding area. Heterogeneity in the adjacent fatty tissue and millimetric air densities were also noted. These findings were suggestive of a perforated Meckel diverticulum. The patient was taken to emergency surgery.

Results: The procedure was initially started laparoscopically; however, conversion to laparotomy was required after identifying a Meckel diverticulum adherent to the umbilical hernia sac. A perforated Meckel diverticulum secondary to incarceration within the umbilical hernia sac was detected. A localized abscess formation was present around the perforation site. Diverticulectomy was performed using a surgical stapler, and simultaneous mesh-free umbilical hernia repair was carried out. Following appropriate medical management, the patient was discharged uneventfully on postoperative day six. Histopathological examination confirmed the diagnosis of Meckel diverticulum.

Conclusion: In patients presenting with acute abdominal pain accompanied by umbilical tenderness, an umbilical Littre's hernia, although rare, should be considered as a clinically significant differential diagnosis. In the present case, the perforation was noteworthy in that it resulted from incarceration within the umbilical hernia sac rather than from inflammation secondary to ectopic mucosa, which may be associated with Meckel diverticulum. It should be kept in mind that incarceration in umbilically located Littre's hernias may predispose to perforation.

Keywords: Incarceration, Littre's hernia, Meckel's diverticulum

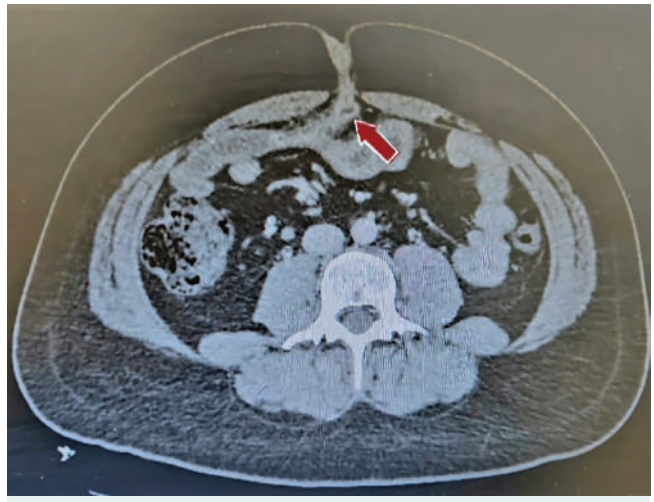

Figure 1. Preoperative abdominal CT. On abdominal CT, a blind-ending tubular structure at the level of the umbilicus with surrounding abscess is observed, consistent with a perforated Meckel's diverticulum.

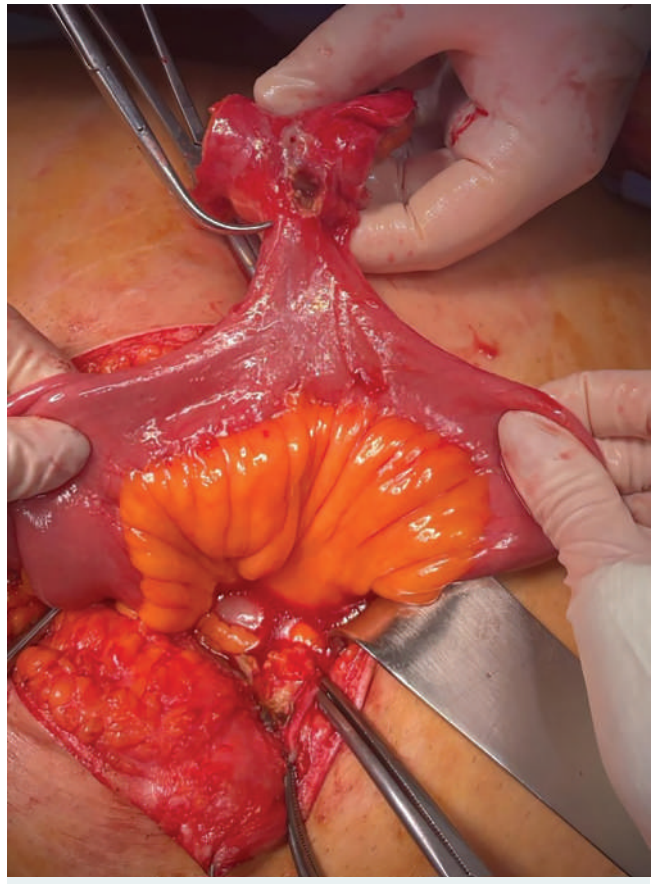

Figure 2. Perforated Meckel's diverticulum-intraoperative view. A perforated Meckel's diverticulum was identified within the umbilical hernia sac during intraoperative evaluation.

Recurrent inguinal hernia with bladder herniation: Laparoscopic TAPP experience

Ferdi Alkan, Yasir Keçelioğlu, Onur Birsen

Department of General Surgery, Pamukkale University Faculty of Medicine Hospital, Denizli

Objective: Although inguinal hernias are a common pathology in general surgical practice, the presence of the urinary bladder within the hernia sac is a rare clinical condition. In the literature, bladder herniation has been associated with advanced age, male sex, obesity, and a history of recurrent inguinal hernia. A significant proportion of cases may be asymptomatic or may mimic lower urinary tract symptoms, leading to delays in diagnosis. Bladder herniations that are not recognized preoperatively may result in serious complications during surgery, such as bladder injury, urinary leakage, and infection. This risk is further increased in long-standing and recurrent hernias due to disruption of anatomical planes caused by previous surgeries. Although the widespread use of imaging modalities has increased preoperative diagnostic rates, clinical awareness remains crucial. In this case report, we present the diagnostic process and surgical management of bladder herniation in a patient with a long-standing recurrent direct inguinal hernia, treated with a laparoscopic TAPP approach, in light of the literature.

Material and Methods: A 77-year-old male presented with persistent left groin pain and swelling. He had a history of open, non-mesh, tension-free repair performed abroad 40 years ago, with recurrence about 10 years later. The patient reported manually reducing the hernia during urinary urgency. Physical examination revealed a reducible direct hernia and a previous incision scar. Abdominal CT showed herniation of the left anterior bladder into the left inguinal canal, with a stone-density image in the bladder lumen, likely due to residual urine. Laparoscopic TAPP herniorrhaphy was planned.

Results: Intraoperative evaluation confirmed the presence of the bladder within the hernia sac. Following careful dissection, the bladder was safely reduced, and an anatomical mesh was placed in the left inguinal region. Laparoscopic TAPP herniorrhaphy was successfully completed. No intraoperative or postoperative complications occurred. The patient was discharged uneventfully on the second postoperative day.

Conclusion: Bladder herniation should always be considered in the differential diagnosis of long-standing and recurrent inguinal hernias. Preoperative computed tomography is of critical importance for establishing the diagnosis and determining the surgical strategy. The laparoscopic TAPP approach is an effective and safe surgical option in recurrent inguinal hernias, as it provides a wide field of view, allows better evaluation of anatomical structures, and enables safe reduction of the bladder. This case demonstrates that recurrent inguinal hernias with bladder herniation can be successfully managed with appropriate preoperative assessment and meticulous laparoscopic dissection.

Localized Boerhaave syndrome with spontaneous drainage via fistula to the gastric: A rare case

Mehmet Kocaoğlu, Mehmet Nuri Yıldız

Şanlıurfa Training and Research Hospital, Şanlıurfa

Objective: Boerhaave syndrome is a rare clinical entity with high mortality, characterized by a full-thickness rupture of the esophagus, most commonly occurring after severe vomiting. In most cases, free perforation leads to mediastinitis and sepsis, whereas in some cases, a more subtle and atypical clinical course may occur due to localized perforation. The development of a mediastinal abscess following localized perforation and its spontaneous drainage into the stomach through fistulization is an extremely rare condition reported in the literature. In this study, we present a case that was initially evaluated with a preliminary diagnosis of subileus but was ultimately diagnosed as localized Boerhaave syndrome, demonstrating spontaneous drainage into the stomach via fistulization on endoscopic examination

Material and Methods: The clinical evaluation, laboratory findings, radiological imaging, and upper gastrointestinal endoscopy performed under emergency conditions of the patient who presented with epigastric pain, nausea, vomiting, and rapid weight loss were retrospectively reviewed. The clinical course, administered treatment, and referral process were analyzed in detail.

Results: A 33-year-old female patient with no known comorbidities presented with nausea, intermittent vomiting, epigastric pain, and approximately 10 kg of unintentional weight loss over the preceding week. Her medical history revealed a single episode of sudden-onset, painful vomiting 3-4 months earlier. Physical examination showed mild diffuse abdominal tenderness without guarding, rebound tenderness, or fever. Laboratory tests demonstrated a CRP level of 84 mg/L and a WBC count of 8.5×10^9/L, which decreased to 73 mg/L and 8×10^9/L, respectively, after seven hours. Contrast-enhanced abdominal CT revealed findings consistent with subileus. Due to significant weight loss and persistent symptoms, emergency upper gastrointestinal endoscopy was performed, demonstrating a pouch-like appearance in the distal esophagus, a fistulous opening into the stomach, and purulent material spontaneously draining through the fistula. These findings were consistent with localized distal esophageal perforation (contained Boerhaave syndrome) with fistulization into the stomach. Oral intake was discontinued, intravenous antibiotics and proton pump inhibitor therapy were initiated, and the patient was referred to a tertiary care center for further evaluation.

Conclusion: This case demonstrates that early gastroscopy can be diagnostic in patients initially evaluated with a preliminary diagnosis of subileus but presenting with significant weight loss and persistent vomiting. Since atypical and localized esophageal perforations may lead to serious morbidity and mortality when diagnosis is delayed, esophageal perforation should always be considered in the differential diagnosis, particularly in the presence of clinical-radiological discordance.

[P-265]

Acute small bowel obstruction caused by left paraduodenal hernia: A case report

Eda Nural[1], Hakan Ataş[2], Selma Nil Ayan Uğurcan[2], Nazmiye Sena Arıkan[2]

[1]*Clinic of General Surgery, Kahramanmaraş State Hospital, Kahramanmaraş*

[2]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

Objective: Paraduodenal hernias are the most common type of congenital internal hernias resulting from anomalies in midgut rotation and fixation. Left paraduodenal hernias account for approximately 70-75% of cases and often present with non-specific symptoms or remain asymptomatic for long periods. However, they may initially manifest with acute small bowel obstruction or other serious complications. In patients without prior abdominal surgery and unexplained small bowel obstruction, left paraduodenal hernia should be considered in the differential diagnosis. Contrast-enhanced computed tomography is the gold standard for diagnosis, and early surgical intervention is crucial to prevent complications. This report presents a rare case of left paraduodenal hernia presenting with acute small bowel obstruction.

Material and Methods: Case a 27-year-old male patient presented to the emergency department with intermittent abdominal pain lasting for two weeks. He had no significant past medical history and no previous history of abdominal surgery. Physical examination revealed diffuse abdominal tenderness without guarding or rebound tenderness. Digital rectal examination showed stool contamination and diarrheal discharge. Biochemical parameters were within normal limits, and complete blood count revealed leukocytosis with a white blood cell count of 11,000/mm³.

Results: A contrast-enhanced abdominal computed tomography scan performed in the emergency department demonstrated clustered small bowel loops with mesenteric edema in the left quadrant, suggestive of internal herniation, along with free pelvic fluid (Figure 1). Based on the clinical and laboratory findings, the patient underwent emergency surgery. Intraoperatively, the entire small bowel up to the terminal ileum was found herniated into a sac adjacent to the duodenum (Figure 2). The bowel loops were reduced, and the defect was closed without causing luminal narrowing (Figure 3). Oral intake was initiated on postoperative day 1 and advanced as tolerated. The patient was discharged in good condition on postoperative day 4 after the return of bowel function.

Conclusion: The literature indicates that left paraduodenal hernia is the most common form of internal hernia and that diagnosis is often delayed due to non-specific clinical findings. In young adults without a history of abdominal surgery presenting with unexplained abdominal pain or small bowel obstruction, left paraduodenal hernia should be considered in the differential diagnosis. Contrast-enhanced computed tomography is the gold standard for diagnosis, and early surgical intervention can prevent serious complications such as strangulation and bowel ischemia. In the present case, early surgical management resulted in a favorable outcome without postoperative complications.

Superficial abdominal vein thrombophlebitis – a rare clinical case

Banu Karapolat, Yunus Emre Topkaya, Faruk Aksoy

University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon

Objective: Superficial thrombophlebitis most commonly affects the veins of the lower extremities, particularly the great saphenous vein. However, superficial abdominal veins—such as the thoracoepigastric and superior epigastric veins—are rarely involved. This condition is also described in the literature as abdominal Mondor disease. First reported by Mondor in 1939, it was most frequently described in the veins of the chest wall, whereas involvement of the abdominal wall is exceedingly rare. Risk factors include local trauma, surgical interventions, infection, malignancy, and hypercoagulable states. Clinically, it may present as a painful, cord-like lesion and can be misdiagnosed as an abdominal abscess, hernia, or intra-abdominal pathology. In this report, we present a case of superficial abdominal vein thrombophlebitis that developed following minor trauma.

Material and Methods: Case presentation.

Results: A 51-year-old female patient presented to our outpatient clinic with complaints of pain and swelling in the left upper quadrant that developed after minor trauma caused by a branch strike approximately one week earlier. Her medical history was significant for hypertension and chronic hepatitis B infection, and she was receiving antiviral therapy (Viratt®). Physical examination: A linear, cord-like subcutaneous lesion with tenderness on palpation was detected in the left upper quadrant. No erythema or fluctuation was observed. Laboratory findings: Hematological and biochemical parameters were within normal limits. Ultrasonography: Superficial soft tissue ultrasonography revealed a non-compressible millimetric superficial venous structure with increased surrounding echogenicity in the left upper quadrant, consistent with thrombophlebitis. No extension into the deep venous system was observed. Treatment and follow-up: Conservative treatment including nonsteroidal anti-inflammatory drugs, local warm application, and rest was initiated. Anticoagulation therapy was not considered necessary. At the one-week follow-up, clinical findings had markedly regressed.

Conclusion: Superficial abdominal vein thrombophlebitis is a rare condition that can easily be misdiagnosed. It should be considered in the differential diagnosis, particularly in patients presenting with a cord-like lesion and a history of trauma. Doppler ultrasonography is indispensable for diagnosis. Most cases resolve uneventfully with conservative treatment.

Keywords: Superficial thrombophlebitis, abdominal wall, Mondor disease, minor trauma, Doppler ultrasonography

Giant inguinal hernia containing stomach, small and large bowel: A rare case report

Onur Can Yenen, Serkan Karaıslı, İbrahim Kokulu, Fevzi Cengiz

İzmir Katip Çelebi University, Atatürk Education and Research Hospital, İzmir

Objective: Inguinal hernias are among the common causes of emergency department admissions. Today, many different surgical approaches have been defined for inguinal hernia repair. The most commonly herniated abdominal structures are the omentum and small intestine. In long-standing and large indirect hernias, herniation of organs such as the colon, bladder, ovary, spleen, and rarely the stomach has been reported.

Material and Methods: A 75-year-old male patient with a history of inguinal hernia for approximately 30 years presented to the emergency department with complaints of nausea and vomiting lasting for three days. Computed tomography (CT) performed in the emergency department revealed herniation of a portion of the stomach together with small and large bowel loops within the hernia sac. The patient was taken to emergency surgery with a diagnosis of incarcerated hernia.

Results: Exploration revealed that the gastric antrum, all small bowel loops starting from the mid-jejunum, the cecum, and the sigmoid colon had herniated through an approximately 6 cm defect in the inguinal region. After adhesions within the hernia sac were dissected, the contents were reduced into the abdominal cavity. A serosal injury of the stomach secondary to herniation was detected and repaired primarily. The hernia defect was repaired using mesh with a preperitoneal approach.

Conclusion: The number of reported cases in the literature describing the presence of the stomach within the inguinal hernia sac is quite limited, and gastric injury related to herniation has been reported in only 10 of these cases. To date, only one case has been reported from Türkiye. In long-standing and incarcerated inguinal hernias, CT imaging is an important diagnostic tool for evaluating herniated organs and possible complications. Although conservative management may be possible in selected cases, surgical treatment is required in most patients.

Keywords: Inguinal hernia, gastric herniation, incarcerated hernia, computed tomography

Recurrent severe foul-smelling diarrhea after Roux-en-Y gastric bypass with reproducible response to an antiparasitic herbal combination a case report

Ala Elcircevi[1], Ali Önder Devay[2]

[1]*Atakent Cihan Hospital, Kocaeli*

[2]*Medicana Hospital, Bursa*

Objective: Foul-smelling diarrhea after Roux-en-Y gastric bypass (RYGB) is frequently attributed to fat malabsorption, bile acid–related diarrhea, or postoperative microbiota changes. However, early-onset, socially disabling malodor with nocturnal symptoms may suggest additional etiologies. This case highlights a reproducible dechallenge–rechallenge response to an over-the-counter herbal combination with traditionally antiparasitic components, raising the possibility of an infectious or parasitic contribution in selected post-RYGB patients.

Material and Methods: Clinical data were obtained from structured patient interview focused on bariatric timeline, stool characteristics, associated gastrointestinal symptoms, exposure risks, and patient-reported outcomes. The temporal relationship between symptom onset and interventions was documented. The patient had undergone sleeve gastrectomy in February 2010, followed by weight regain after four years. RYGB was performed in September 2025. No stool microscopy, antigen testing, or polymerase chain reaction panel had been performed at the time of symptom onset. The patient self-initiated a short course of three products used concurrently. Clove capsules (*Eugenia caryophyllata*). Green black walnut hull tincture (*Juglans nigra*). A wormwood-containing blend (*Artemisia absinthium*).

Results: Two weeks after RYGB, the 56 years old patient developed constant, highly distressing stool malodor described as a mixture of rotten and sulfuric smell, particularly worse after meals. She reported watery, pale stools with marked oiliness, 7 to 9 bowel movements daily, relief after defecation, abdominal bloating, and nocturnal diarrhea. Dysphagia was also reported. The symptom had never occurred after sleeve gastrectomy despite prior weight loss and subsequent weight regain. Dietary measures provided minimal benefit. The patient had household exposure to three cats for five years and traveled to Saudi Arabia for Umrah one week after the bypass operation. After starting the herbal combination, she reported complete resolution of malodor and diarrhea within days. Symptoms recurred after discontinuation with lower intensity and resolved again promptly after re-challenge, reproducing the initial effect. The condition had caused severe stress, avoidance behavior, and significant impairment of social and working life, all of which improved after symptom resolution.

Conclusion: This case suggests that, beyond malabsorption, infectious or parasitic contributors should be considered in severe, early-onset, persistent malodorous diarrhea after RYGB, especially when a reproducible response to antiparasitic exposure is observed. Systematic stool testing and targeted evaluation may prevent prolonged morbidity and guide appropriate therapy.

Brachial artery aneurysm secondary to a hemodialysis arteriovenous fistula: A case report

Kutay Demirkır, Dilara Karakaya, Can Yahya Boztuğ, Ömer Arda Çetinkaya

Division of Peripheric Vascular Surgery, Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Arteriovenous fistulas (AVFs) created for hemodialysis (HD) may cause rare but clinically significant complications due to long-term high-flow-related hemodynamic stress on the arterial system. In this report, we present the surgical management of a brachial artery aneurysm secondary to a previously created and subsequently closed left brachiocephalic AVF following renal transplantation.

Material and Methods: The patient's medical records, clinical data, and imaging findings were retrospectively reviewed. Demographic characteristics, medical history, previous hemodialysis AVF, renal transplantation details, clinical presentation, and surgical course were evaluated. Preoperative physical examination and imaging studies were used to determine the location and size of the brachial artery aneurysm. The surgical procedure was performed under elective conditions. Surgical technique, intraoperative findings, vascular reconstruction method, and early postoperative outcomes were analyzed. Postoperative anastomotic patency and distal limb perfusion were assessed by clinical examination and duplex ultrasound.

Results: A 65-year-old male patient presented with pain and a palpable pulsatile mass in the left upper extremity. His medical history included a left brachiocephalic arteriovenous fistula created for HD and a cadaveric renal transplantation performed in 2015. The AVF had been closed after successful renal transplantation. Physical examination and imaging studies revealed an aneurysmal dilation measuring approximately 2×2 cm at the level of the left brachial artery. The patient underwent elective surgery. Intraoperatively, a brachial artery aneurysm was confirmed, and aneurysm resection was performed. Arterial continuity was restored with an end-to-end brachial artery anastomosis. In the postoperative period, the anastomosis was patent. Due to the development of a surgical site hematoma, hematoma drainage and surgical hemostasis were performed. Distal pulses remained palpable during follow-up, and no additional vascular complications were observed. The patient was discharged in stable condition on postoperative day three.

Conclusion: Although rare, upper extremity arterial aneurysms should be considered in patients with a history of HD arteriovenous fistula creation and closure after renal transplantation. In suitable cases, aneurysm resection with primary end-to-end anastomosis represents a safe and effective surgical treatment option. Early diagnosis and timely surgical intervention are crucial to prevent potential rupture and thromboembolic complications.

Keywords: Arteriovenous fistula, brachial artery aneurysm, renal transplantation, end-to-end anastomosis

Large and vascular mass in the rectus abdominis muscle of a young male patient: A case of intramuscular angioma

Gizem Nur Akay, Emre Atmaca, Kemal Eyvaz, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Abdominal wall tumors constitute a rare subgroup of soft tissue tumors. Lesions originating from the rectus abdominis muscle are particularly infrequent. Masses seen in this region include desmoid tumors, soft tissue sarcomas, and vascular lesions. Intramuscular angiomas belong to the group of benign vascular tumors and constitute less than 1% of all hemangiomas. They are usually seen in young adults and most often occur in the extremities; abdominal wall localization is quite rare. When they are large and have a dense vascular structure, they can mimic malignancy. Their etiology is still unknown 1. Pathogenic somatic mutations in the *MAP2K1* and *KRAS* genes have been identified in a subset of cases that overlap with mutations found in arteriovenous malformations.

Material and Methods: A 35-year-old male patient presented with a palpable mass in the right lower-middle quadrant. He had no history of trauma, anticoagulant use, or systemic disease. Physical examination revealed a deep-seated mass, approximately 8-10 cm in diameter, with restricted mobility, located at the level of the right rectus abdominis muscle. Laboratory findings were within normal limits.

Results: CT scan revealed: • Within the right rectus abdominis muscle • Approximately 73×78 mm in size • Showing heterogeneous signal characteristics • A solid mass expanding along the muscle • Significant contrast enhancement • Dilated tubular venous structures in the inferior section. Radiologically, a distinction could not be made between low-grade sarcoma and vascular malformation. Further evaluation was recommended due to the vascular character. No malignancy was detected in the initial core biopsy samples. Histopathological examination after surgical excision revealed: • Proliferation between striated muscle fibers • Dilated vascular channels the lesion was reported as an intramuscular angioma. No evidence of malignancy was found.

Conclusion: Intramuscular angiomas are rare and often misdiagnosed. Their large size, rapid growth, and dense vascularity may raise suspicion of malignancy. Abdominal wall localization is quite rare, and there are a limited number of cases in the literature. Especially in lesions ≥5 cm and with significant vascularity: Tru-cut biopsy is prone to sampling error. They may be radiologically confused with sarcoma.The vascular structure should be carefully evaluated before surgical planning. Complete surgical excision is curative, but incomplete excision may lead to local recurrence. While malignancy is primarily considered in the presence of a large, vascular mass in the rectus abdominis muscle, intramuscular angioma must be included in the differential diagnosis. In cases with imaging-pathology discrepancies, a multidisciplinary approach and careful surgical planning are critically important.

Keywords: Rectus abdominis, abdominal wall tumor, intramuscular angioma

Small cell neuroendocrine carcinoma of the breast: Experience of two cases following neoadjuvant therapy

Mariya Maşta[1], Miray Maden[2], Aziz Hakkı Civriz[3], Seda Duman Öztürk[3], Nihat Zafer Utkan[1]

[1]*Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli*

[2]*Clinic of General Surgery, Kocaeli City Hospital, Kocaeli*

[3]*Department of Pathology, Kocaeli University Faculty of Medicine, Kocaeli*

Objective: Primary neuroendocrine carcinomas (NEC) of the breast are exceptionally rare, accounting for less than 0.1% of all mammary malignancies. According to the 2019 WHO classification, the small cell subtype is characterized by high proliferative activity and an aggressive clinical course. To diagnose primary breast NEC, other organ metastases must be ruled out. Due to the paucity of reported cases in the literature, data regarding definitive therapeutic strategies remain limited. This study presents the clinical and histopathological characteristics of two rare cases referred for surgery following neoadjuvant chemotherapy (NAC).

Material and Methods: A retrospective analysis was conducted on two female patients diagnosed with small cell NEC via biopsy between 2023 and 2024. Systemic staging was performed in both patients using positron emission tomography-computed tomography. The pathological responses of patients who underwent curative surgery after NAC, as decided by a multidisciplinary council, were evaluated using the Residual Cancer Burden (RCB) score.

Results: Case 1: A 45-year-old female patient presented with a 10.5 cm mass in the right breast and metastatic axillary lymph nodes. Tru-cut biopsy was reported as Grade 3 small cell NEC (ER-/PR-/HER2- (triple negative), Ki-67 100%). Clinical and radiological regression was observed after NAC. Right subcutaneous mastectomy, sentinel lymph node biopsy (SLNB), and axillary dissection were performed. Pathology revealed a 1.1 cm residual tumour focus (triple negative, Ki-67 4%), metastasis in 2/12 lymph nodes, and extranodal spread (ypT1cN1a, RCB-III). Case 2: A 50-year-old female patient presented with a 2.7 cm mass in the left breast. Tru-cut biopsy was reported as Grade 3 small cell NEC (ER-/PR 50% positive/HER2-, Ki-67 90%). Clinical and radiological regression was observed after NAC. Left simple mastectomy and SLNB were performed. Pathology revealed a 0.5 cm residual tumour focus (triple negative, Ki-67 40%). No lymph node metastasis was detected (ypT1aN0, RCB-I). Patients are being followed up with disease-free survival for an average of 18 months.

Conclusion: Breast NECs may exhibit different clinical behaviour and treatment responses depending on their histological subtypes and immunophenotypes. While most primary breast NECs in the literature exhibit high ER and PR expression, the small cell subtype is generally triple negative. The dramatic decrease in the Ki-67 index after NAC is considered a strong predictor of chemosensitivity and survival prognosis. In these rare and aggressive cases, despite the heterogeneous pathological response, the combination of neoadjuvant therapies planned with a multidisciplinary approach and surgery is critical for local control and survival.

Figure 1. A Meckel's diverticulum that cannot be reduced laparoscopically, with a lipomatous lesion at its tip.

[P-277]

A rare cause of adult intestinal intussusception: Meckel's diverticulum

Tamer Akay, Eren Gürbüz, Ramazan Serdar Arslan, Serkan Şengül, Yılmaz Güler, Zülfikar Karabulut

Alanya Alaaddin Keykubat University Faculty of Medicine, Antalya

Objective: Meckel's diverticulum is one of the most common gastrointestinal tract anomalies, with an estimated prevalence of approximately 2% in the general population. In adults with symptomatic Meckel's diverticulum, obstruction occurs in 35.6% of cases, gastrointestinal bleeding in 27.3%, and inflammation in 29.4%. Imaging studies commonly reveal intestinal loop distension and intussusception, followed by free fluid, edematous thickening, and cystic lesions. Symptoms and imaging findings are not specific to Meckel's diverticulum, which poses a diagnostic challenge as other etiologies of acute abdomen must be considered. Therefore, diagnostic laparoscopy and intraoperative findings often lead to resection and primary anastomosis.

Material and Methods: A 30-year-old male patient presented to the emergency department with diffuse abdominal pain, mild nausea, and intermittent hematochezia. The patient had a history of intermittent chronic pain for six months. Abdominal ultrasound and laboratory tests performed in the emergency department were within normal limits. Abdominal computed tomography revealed an approximately 6 cm segment in the right lower quadrant with telescoping of intestinal loops consistent with intussusception. The patient showed no clinical signs of acute intestinal complications, and elective surgery was planned.

Results: The surgical procedure was performed under general anesthesia via videolaparoscopy. The intussuscepted small bowel loops were laparoscopically reduced. The segment containing the diverticulum could not be separated laparoscopically and was exteriorized through the trocar site. Meckel's diverticulum with a lipomatous lesion at its tip was identified. Resection and end-to-end anastomosis were performed. The postoperative period was uneventful, and pathology confirmed Meckel's diverticulum with a benign lipomatous lesion at the tip.

Conclusion: This report presents a case of intestinal intussusception secondary to invagination of Meckel's diverticulum. Considering that Meckel's diverticulum is a common intestinal malformation, this etiology should be considered an important differential diagnosis in patients presenting with abdominal complaints. Diagnostic laparoscopy and laparoscopic reduction of the intussuscepted bowel segment facilitate surgical management without the need for laparotomy.

Keywords: Meckel's diverticulum, small intestine, intussusception, laparoscopy

Figure 1. An approximately 6 cm segment of telescoping intestinal loops is observed in the right lower quadrant of the abdomen.

Acute appendicitis in trocar site herniation

Mert Kaptan, Taha Berkay Türkmen, Akın Fırat Kocaay

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Trocar site hernias are rare but clinically significant complications following laparoscopic surgery. The hernia sac most commonly contains the small intestine and omentum, while the appendix is rarely found within the hernia sac. Acute appendicitis developing within the hernia sac has been reported in very limited numbers in the literature. This study presents an elderly female patient with a history of laparoscopic cholecystectomy who was found to have an incarcerated appendix and acute appendicitis within a trocar site hernia.

Material and Methods: 74-year-old female patient with a history of laparoscopic cholecystectomy presented with pain and swelling in the area of an old trocar scar in the inferior umbilicus. Physical examination revealed a lesion approximately 3×3 cm in size in the inferior umbilicus, accompanied by skin hyperemia, consistent with an incarcerated hernia. Laboratory investigations showed elevated acute phase reactants. Ultrasonography was reported as bowel loops and omental fat tissue visible within an approximately 3.5 cm defect consistent with an incarcerated herniation. Urgent surgery was performed. Exploration via a infraumblical incision revealed an incarcerated, edematous, hyperemic appendix within the hernia sac. It was diagnosed as acute appendicitis, and appendectomy was performed. Following excision of the hernia sac, the defect was repaired with prosthetic mesh due to the absence of perforation/contamination. Histopathological examination revealed findings consistent with acute appendicitis. The patient had an uneventful postoperative course and was discharged on the second day.

Results: Trocar site hernias are rare but potentially serious complications after laparoscopic surgery. Most cases develop at trocar insertions ≥10 mm, and failure to close the fascia is a significant risk factor. The presence of the appendix within a port-site hernia is extremely rare in the literature. Trocar site hernia should be considered in the differential diagnosis, especially in elderly patients and those with a history of abdominal surgery, in the presence of a painful, non-reducible mass at the incision site. The appendix's location within the hernia sac and the development of inflammation can be explained by extraluminal compression and impaired vascular circulation. Surgical treatment involves appendectomy along with hernia repair, and in appropriate cases, mesh use can reduce recurrence.

Conclusion: The presence of the appendix within a trocar site hernia and the resulting development of acute appendicitis is extremely rare. In patients presenting with pain at the incision site and a suspected incarceration mass, early imaging and surgical intervention are crucial for preventing complications.

Keywords: Acute appendicitis, hernia, trocar

Chylous ascites following laparoscopic cholecystectomy: Successful management with conservative treatment- a case report

Enes Malik Üçkan

Clinic of General Surgery, Isparta City Hospital, Isparta

Objective: Laparoscopic-cholecystectomy is considered the gold-standard-surgical-method in the treatment of symptomatic gallstone-disease. Chylo-ascites is a clinical condition characterized by the accumulation of triglyceride-rich-chylous-fluid originating from the intestinal-lymphatic-system in the peritoneal cavity. The development of chylous-ascites after laparoscopic-cholecystectomy is extremely rare,and only a limited number of case reports exist in the literature. This condition is due to damage to the lymphatic-structures around the hepatoduodenal ligament, portahepatis, and Calot's triangle during surgical dissection. This case report presents a patient who developed chylous-ascites after laparoscopic-cholecystectomy and was successfully treated with short-term total parenteral nutrition (TPN) initiated early, without the need for pharmacological or surgical intervention.

Material and Methods: A 74-year-oldfemale patient was admitted for elective-laparoscopic-cholecystectomy. Her medical history included diabetes mellitus, hypertension, and coronary artery disease. She had undergone endoscopic retrograde cholangiopancreatography (ERCP) one month prior. Laparoscopic-cholecystectomy was performed using the standard-four-trocartechnique, and the surgical procedure was completed without complications. The patient was transferred to the ward with a intra-abdominal drain. Postoperatively, approximately 500 mL of milky-white-fluid was observed draining from the drain. With a preliminary diagnosis of chylous-ascites, triglyceride levels in the drain fluid were measured at 466 mg/dL. Postop 2, the patient's oral intake was stopped, and TPN was initiated. Postop 3 the drain became serous in character. On postoperative days 4, 5 and 6, the drainage volume was observed as 300 mL of serous fluid,while TPN was continued. On postop 7, the drainage volume decreased to 200 mL. Controlled oral intake was initiated on the 8th postoperative day. Drainage continued at approximately 200 mL of serous character until the 11th postoperative day. One week later, minimal drainage was observed, and the drain was removed. No recurrence was detected during the follow-up period.

Results: Chylo-ascites is a complication-resulting from damage to the abdominal-lymphatic-system and is most frequently reported in the postoperative period after retroperitoneal and oncological-surgeries. The diagnosis is confirmed by detecting a triglyceride level above 110 mg/dL in the drainage-fluid. In our case, triglyceride level of 466 mg/dL. Conservative treatment is usually the first step; discontinuation of oral intake, TPN, medium-chain-triglyceride-diet, and somatostatin-analogs are recommended. In some cases, long-term TPN treatment, octreotide-use,or surgical-exploration has been required. In the case reported by Al Ghamdi et al., longer-term conservative treatment and different treatment strategies are included in the literature review for the management of chylousascites. In contrast, in our case,with the early initiation of TPN, the chylous character of the drainage disappeared within five days and progressively decreased. This suggests that early diagnosis and rapid intervention can shorten the treatment process. It is noteworthy that our patient had a recent history of acute pancreatitis and ERCP. It can be considered that peripancreatic inflammation and previous interventions may have affected lymphatic flow in the hepatoduodenal region and increased susceptibility to lymphatic damage during surgery.

Conclusion: Conclusion, although chylosacitis developing after laparoscopic-cholecystectomy is rare,it can be successfully managed with short-term conservative-treatment when diagnosed early. Early-initiation of TPN, in-particular, can reduce need for pharmacological/surgical intervention.

Keywords: Laparoscopy, cholecystectomy, chylous ascites

Malignant gastrocolic fistula: Clinical course, surgical intervention, and pathological findings in two acute cases

Hüseyin Bayram, Beyza Gümüştekin, Levent Uğurlu, Tayfun Kaya, Mert Gacemer

University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Gastrocolic fistulas represent a rare pathological occurrence, manifesting as fistulous connections between the stomach and the transverse colon. In Western societies, colorectal cancers are most commonly implicated in the etiology of cancer, while in Eastern societies, stomach cancers are typically held responsible. In the contemporary medical context, the implementation of screening programs has led to the ability to detect cases of colon cancer at an early stage, thereby reducing the prevalence of malignant gastrocolic fistulas. This study presents the surgical management of two cases presenting to the emergency department with acute fecal vomiting and abdominal pain, in whom malignant gastrocolic fistulas were identified.

Material and Methods: A retrospective review was conducted of two cases that presented to our clinic's emergency department with complaints of acute abdominal pain and fecal vomiting. The patients were subsequently diagnosed with malignant gastrocolic fistula based on the results of investigations. The patients' demographic data, diagnostic imaging findings (video/photographic documentation), surgical procedures performed, and histopathological results were compiled from hospital records.

Results: Case 1: A 56-year-old male with known synchronous adenocarcinoma of the colon and stomach presented with acute symptoms while awaiting neoadjuvant chemotherapy. Imaging confirmed a gastrocolic fistula. Following stabilization, the patient underwent en bloc resection comprising extended right hemicolectomy, distal gastrectomy, and D2 lymph node dissection. The hepatic flexure tumor had infiltrated the greater curvature of the stomach. Histopathology revealed pT4b colon adenocarcinoma invading the gastric wall, with one metastatic lymph node (pN1a/83) and clear surgical margins. Case 2: A 60-year-old female, treated conservatively for perforated diverticulitis six months prior, presented with abdominal pain and fecaloid vomiting. Imaging revealed a mass at the splenic flexure with a fistula tract. She underwent en bloc resection involving segmental colon resection, gastric wedge resection, and anterior abdominal wall resection. Intraoperatively, the mass invaded the stomach and abdominal wall. Histopathology confirmed pT4b adenocarcinoma, one metastatic lymph node (pN1a/14), and clear surgical margins.

Conclusion: Typically manifesting with chronic diarrhea and weight loss, malignant gastrocolic fistulas can rarely present as acute surgical emergencies. In locally advanced and fistulized tumors, aggressive en bloc surgical approach aiming for R0 resection remains the most effective modality for both cure and palliation.

Isolated splenic sarcoidosis mimicking primary splenic angiosarcoma: Radiological misdiagnosis and surgical management

Hüseyin Bayram[1], Yiğit Bıçakçıoğlu[1], Göksever Akpınar[1], Mert Gacemer[1], Ugur Hazal Saban[2]

[1]*University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir*

[2]*İzmir Urla State Hospital, İzmir*

Objective: Sarcoidosis is a multisystemic non-caseating granulomatous disease of unknown etiology. The disease primarily affects the lungs and mediastinal lymph nodes,while isolated spleen involvement is a relatively uncommon complication (1-5%). Splenic sarcoidosis,when observed radiologically as multiple hypodense nodules in the spleen, can be misinterpreted as malignancies such as lymphoma, metastasis, or primary splenic angiosarcoma. The objective of this study is to present a case that initially raised suspicion of angiosarcoma radiologically, but was subsequently diagnosed with isolated splenic sarcoidosis following splenectomy.

Material and Methods: A 25-year-old male patient presented to our outpatient clinic, reporting a complaint of pain in the left upper quadrant. A thorough review of the patient's medical history did not reveal any additional complaints, such as weight loss, fever, or night sweats, other than the pain being experienced. A physical examination was conducted, yielding no pathological findings. Laboratory tests revealed normal hemogram and biochemistry parameters. A subsequent abdominal computed tomography (CT) scan revealed a hypodense lesion measuring approximately 3.5x4 cm in the spleen, containing calcifications in its periphery and interior. Thoracic CT, performed for systemic screening, revealed a normal appearance of the lung parenchyma and mediastinal lymph nodes. Abdominal magnetic resonance imaging performed for lesion characterization revealed a mass lesion with central cystic areas, appearing hypointense on T2-weighted sequences relative to the spleen parenchyma, and showing peripheral contrast enhancement after intravenous contrast material. Given the inability to exclude lymphoma or vascular malignancy (angiosarcoma) based on the available radiological findings, a decision was made to proceed with surgical intervention. The patient, who was scheduled for elective surgery, received the necessary vaccinations (Pneumococcal, Meningococcal, Hib) two weeks prior to the operation. The patient underwent an open splenectomy for diagnostic and therapeutic purposes and was discharged after a smooth postoperative follow-up.

Results: A macroscopic examination of the excised spleen material revealed numerous white-yellow nodules on the cut surface. The histopathological evaluation revealed no malignancy; however, non-caseating granulomas with epithelioid cells showing a tendency to coalesce were detected in the tissue. No bacilli were observed in the histochemical acid-resistant bacilli staining performed for the differential diagnosis of tuberculosis. The diagnosis of the case was determined to be "isolated splenic sarcoidosis," a determination that was made based on the findings that were available at the time of the diagnosis.

Conclusion: Isolated splenic sarcoidosis is a rare clinical condition that can be misdiagnosed as aggressive malignancies, such as angiosarcoma, due to the absence of specific radiological findings. In instances where imaging methods are inadequate for differential diagnosis and suspicion of malignancy persists, splenectomy is regarded as the gold standard approach for establishing a definitive histopathological diagnosis and providing curative treatment.

A diagnostic pitfall in colorectal cancer surgery: Hepatic metastasis of uveal melanoma mimicking colorectal liver metastasis

Reyhan Taşkın[1], Özgür Kurtkulağı[2], Mustafa Kaya[1]

[1]*Çanakkale Onsekiz Mart University, Çanakkale*

[2]*Çanakkale Mehmet Akif Ersoy State Hospital, Çanakkale*

Objective: Acute appendicitis in elderly populations may serve as a sentinel clinical presentation for underlying right-sided colonic malignancy. Consequently, current literature supports colonic evaluation in selected patients following appendicitis to rule out occult pathology. In patients subsequently diagnosed with colorectal cancer, hepatic lesions identified during the staging process are predominantly interpreted as colorectal metastases, given that the liver is the most common site of spread. This presumption typically dictates surgical strategies, favoring synchronous or sequential resections in resectable cases. However, diagnostic pitfalls exist; limitations in oncologic imaging and the presence of "mimicker" lesions can lead to misclassification, particularly in patients with a history of malignancy. Uveal melanoma is distinct for its specific hepatic tropism and potential for metastatic recurrence many years after primary ocular treatment. This report discusses a rare instance where a presumed colorectal liver metastasis was histopathologically confirmed as late-stage uveal melanoma.

Results: A 68-year-old male presented with acute abdominal pain and generalized peritonitis, undergoing emergency appendectomy for perforated acute appendicitis. While the appendectomy specimen was benign, the patient's age and complicated presentation prompted a postoperative colonoscopy, which revealed a villous mass in the cecum diagnosed as adenocarcinoma. Staging imaging identified a solitary hepatic lesion, radiologically interpreted as a colorectal metastasis. Following multidisciplinary review, the patient underwent simultaneous right hemicolectomy and hepatic metastasectomy with curative intent. Intraoperative exploration showed no further dissemination. Although the colonic specimen confirmed primary adenocarcinoma, histopathological examination of the liver lesion unexpectedly revealed metastatic malignant melanoma. A detailed retrospective review disclosed that the patient had undergone ocular enucleation for uveal melanoma 15 years prior, with no intervening recurrence. The patient was diagnosed with synchronous primary colorectal cancer and late-onset metastatic uveal melanoma.

Conclusion: Not every hepatic lesion detected during colorectal cancer staging represents a colorectal metastasis. Uveal melanoma may clinically and radiologically mimic colorectal dissemination through late-onset hepatic metastases that develop years after primary treatment; this risk is particularly heightened in the presence of synchronous colorectal cancer. A detailed oncologic history and histopathological confirmation are of paramount importance for the prevention of misclassification and the optimization of appropriate multidisciplinary management

A rare differential diagnosis in supraclavicular lymph node: Castleman disease or IgG4-related lymphoid proliferation?

Sümeyra Güler[1], Şevket Barış Morkavuk[1], Kemal Berkay Tekin[2], İsmail Burak Lale[2], İbrahim Burak Bahçecioğlu[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: In supraclavicular lymph node pathology, metastatic solid tumors-particularly lymphoma and lung or thyroid malignancies-are the primary diagnostic considerations. However, viral infections, autoimmune disorders such as Hashimoto thyroiditis and Graves' disease, and rarer entities including Castleman disease (CD) and IgG4-related lymphoid proliferation (IgG4-RLP) should also be considered. Although CD and IgG4-RLP are generally regarded as benign or premalignant conditions, their overlapping histopathological and immunohistochemical features make accurate differentiation crucial, as management and therapeutic approaches differ. This case report presents a rare supraclavicular lymph node lesion and addresses the challenges encountered in the differential diagnosis within a multidisciplinary framework.

Material and Methods: A 39-year-old woman under follow-up for Hashimoto thyroiditis, without active symptoms,was found to have multiple pathological lymph nodes in the right supraclavicular fossa on routine ultrasonography,the largest measuring 36×18mm. Thoracic computed tomography revealed a 35×23 mm pathological lymphadenopathy in the right lower jugular chain-supraclavicular region. PET-CT demonstrated heterogeneous increased FDG uptake in a 17×21 mm lymph node at the same site (SUV_{max}:10.33). Targeted ultrasonography identified conglomerated lymph nodes at right level IV, posterolateral to the jugular vein,considered unrelated to thyroid pathology,and a tru-cut biopsy was performed. Histopathological evaluation revealed atypical lymphoid proliferation;due to suspicion of low-grade lymphoma,complete excision of the lymph node was subsequently performed.

Results: Microscopic examination showed follicular hyperplasia, regressive germinal centers, and focal follicular "twinning" consistent with features of hyaline-vascular type CD. Concentric mantle zone arrangement, perivascular hyalinization, and prominent capsular fibrosis were observed. Interfollicular areas demonstrated sheets of plasma cells and focal storiform fibrosis. Immunohistochemically, plasma cells were highlighted by CD138 and showed polyclonality on kappa and lambda *in situ* hybridization. CD20 and CD3 staining revealed preserved B-and T-cell compartments, while CD21 and CD23 highlighted intact follicular dendritic cell networks. CyclinD1, Bcl-2, CD30, HHV8, and EBV (EBER) were negative. Although focal areas showed an IgG4/IgG ratio exceeding 40%, the overall ratio was approximately 20%. Normal serum IgG4 levels and polyclonal plasma cells precluded a definitive diagnosis of IgG4-RLP.

Conclusion: Rare lymphoid proliferative disorders involving supraclavicular lymph nodes should be carefully considered in the differential diagnosis once malignant processes have been excluded.This case demonstrates that CD and IgG4-RLP may exhibit substantial overlap in histopathological and immunohistochemical features. While excisional biopsy plays a pivotal role in achieving definitive diagnosis and local disease control, pathological evaluation constitutes the cornerstone of a multidisciplinary approach. The integration of clinical findings, laboratory data, and detailed histopathological assessment enables accurate diagnosis and appropriate treatment planning. Systemic steroid therapy is generally effective in IgG4-RLP, whereas CD may require surgical excision or systemic immunomodulatory therapy. This case highlights the importance of close collaboration among surgery, pathology, and hematology disciplines in the management of rare lymphoid proliferations and underscores the critical contribution of excisional biopsy combined with immunohistochemical analysis in the diagnostic process.

It could not have been worse: Obstructive colonic malignancy on a background of Crohn's disease and a colon diverticulum perforated into the retroperitoneum

Emir Mehmet Yünlüel[1], Görkem Uzunyolcu[1], Mehtap Kılıçoğlu[2]

[1]*Clinic of General Surgery, İstanbul Arnavutköy State Hospital, İstanbul*

[2]*Clinic of Medical Pathology, İstanbul Arnavutköy State Hospital, İstanbul*

Objective: Chronic inflammation is one of the fundamental mechanisms underlying the development of malignancy. Inflammatory bowel diseases (IBD) are also considered predictive factors for the development of colorectal cancer (CRC). Although the incidence of IBD-associated CRC has decreased with advances in diagnostic and therapeutic processes, its prognosis is known to be worse compared to sporadic CRC. As a result of chronic inflammation and obstruction, increased intraluminal pressure may create a predisposition for the development of diverticular disease of the intestine. Diverticular perforation and/or colonic perforation constitute a not-uncommon surgical emergency. In the present case, we report a patient in whom several colorectal pathologies—each not rare in isolation but seldom encountered simultaneously—coexisted, and we present the emergency surgical intervention performed along with the pathological findings.

Material and Methods: The present study is a case report.

Results: In the present case, we report the emergency surgical intervention performed in a patient in whom several colorectal pathologies—each not uncommon when considered individually but rarely encountered together—coexisted, along with the pathological findings.

Conclusion: CRCs arising in the setting of Crohn's disease are associated with aggressive histopathological features, advanced-stage disease at diagnosis, and poorer prognosis. Perforation is a rare but serious complication of Crohn's disease and is more likely in the presence of concomitant malignancy. Chronic transmural inflammation and tumor-related luminal narrowing predispose the colonic wall to perforation. In emergency settings, surgical management usually involves segmental resection or subtotal colectomy; however, chronic inflammation and poor nutritional status increase surgical morbidity. Because of the high risk of anastomotic leakage in cases with perforation, stoma formation is often preferred over primary anastomosis. Considering the increased risk of malignancy and perforation in Crohn's disease, resection should include the involved segment with its vascular and lymphatic drainage. In patients with suspected infection or high surgical risk, primary anastomosis should be avoided. Further multicenter studies with larger cohorts are needed to better define CRC management in patients with IBD.

Table 1. Literature comparison table

Study	Design / N	Typical Biology in MCC (MMR/MSI)	LN / Invasion Pattern	Clinical Message (Prognosis / Treatment)	Comparison With Our Case
Scott et al., 2021 (Histopathology; PubMed)	Single-center pathology audit; re-evaluation of 302 "poorly differentiated" CRCs	Majority of MCCs were dMMR; predominantly right colon/cecum localization	Lower LN metastasis and lower vascular invasion tendency compared with PD adenocarcinoma NOS	"MCC is frequently misclassified; MMR staining strengthens diagnosis"	Our case is consistent with right colon involvement + dMMR (MLH1/PMS2 loss) + MSI-H; however, LN (+) and LVI (+) were present → Stage III and high-risk features
Maung et al., 2024 (Open access; single-center series + literature review)	11 cases (2016–2023) + pooled literature data	MLH1/PMS2 loss in 11/11 cases (MSH2/MSH6 preserved)	LVI in 8/11 and PNI in 2/11; literature reports variable LVI/PNI rates	Authors emphasize similar demographic and tumor characteristics; longer follow-up needed for survival outcomes	MLH1/PMS2 loss consistent; LVI (+) consistent with series; PNI (-) closer to favorable profile
Netto, 2025 (Springer; case-based review and evidence summary)	Case-based review; hazard ratios from meta-analyses discussed	Predominance of MMRd MCC and importance of specific risk factors highlighted	Association of LVI and tumor size >7 cm with relapse discussed	Key message: MCC does not always demonstrate uniformly favorable outcomes; some series report lower 5-year OS compared with PDA (MSI-H)	Despite Stage III and LVI (+), our patient remains recurrence-free at 22 months, reinforcing "not all MCCs behave aggressively," while acknowledging existence of high-risk MCC subsets
Gómez-Álvarez et al., 2017 (Medical journal PDF; MSI-related MCC comparisons)	Comparative approach	MSI-associated MCC phenotype discussed	Stage-dependent differences in LVI, tumor size, and clinical course reported	"MCC is not universally advantageous; subgroups exist"	Our case represents the favorable outcome subgroup, but should be interpreted as a selected case due to LVI and LN positivity
Chen et al., 2019 (CRC biomarker practical guide)	Review/practical guideline	Prognostic and therapeutic importance of MSI/MMR testing in CRC	—	Emphasizes the role of dMMR/MSI-H in prognosis and treatment planning, particularly immunotherapy decisions	MMR/MSI reporting is central to the clinical message of our MCC case
Our case (Etlik City Hospital)	Single case	MLH1/PMS2 loss + MSI-H	pT3, pN1a (1/28), LVI (+), PNI (-)	22 months: no recurrence, no mortality	Consistent with literature on dMMR predominance; favorable short-to-mid-term outcome despite Stage III disease supports the prognostic "paradox"

[P-313]

Is poor differentiation always associated with poor prognosis? MSI-H colonic medullary carcinoma: clinical, pathological, and molecular evaluation (case report)

Uğurcan Bulut[1], Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Alper Yavuz[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Colonic medullary carcinoma is a rare subtype of colorectal cancer and is frequently associated with microsatellite instability (MSI) and loss of mismatch repair (MMR) proteins. Despite exhibiting poor histological differentiation, it has been reported to demonstrate a relatively favorable prognosis compared with conventional colorectal adenocarcinomas due to the prominent presence of tumor-infiltrating lymphocytes (TILs). This study aimed to present the clinical, pathological, and molecular characteristics of a patient diagnosed with colonic medullary carcinoma in the context of the current literature.

Material and Methods: A patient who underwent surgery with a diagnosis of colonic medullary carcinoma was retrospectively evaluated. Demographic data, mode of presentation, preoperative clinical and laboratory findings, surgical procedure, pathological examination results, tumor stage, lymph node status, TIL density, presence of lymphovascular and perineural invasion, as well as MMR immunohistochemical and MSI analyses were assessed. During the postoperative follow-up period, recurrence, metastasis, and mortality were recorded.

Results: The patient was of advanced age and presented with lower gastrointestinal bleeding. Histopathological examination following surgical resection revealed a prominent solid growth pattern, gland-poor architecture, and dense lymphocytic stromal infiltration consistent with medullary carcinoma. TIL density was markedly increased, suggesting the presence of an active immune response within the tumor microenvironment. No metastasis was detected in the dissected lymph nodes, and the absence of lymphovascular and perineural invasion supported limited local tumor aggressiveness. Surgical resection margins were reported as negative. Immunohistochemical analysis demonstrated loss of MLH1 and PMS2 protein expression, a finding consistent with MSI. Molecular analysis confirmed an MSI-H tumor phenotype. The patient received adjuvant chemotherapy, and no local recurrence, distant metastasis, or mortality was observed during a 22-month follow-up period. This clinical course is consistent with the relatively favorable prognosis of medullary carcinoma reported in the literature, despite its poor histological differentiation (Table 1).

Conclusion: Colonic medullary carcinoma is a distinctive colorectal cancer subtype that may lead to inaccurate prognostic assessment due to rarity and aggressive histological appearance. However, studies demonstrate frequent association with MSI-H phenotype and MMR loss, and improved outcomes related to immune cell infiltration.In this case, high TIL density, MLH1/PMS2 loss, nodal negativity, and recurrence-free follow-up support distinct biological behavior compared with conventional adenocarcinomas. These findings emphasize that poor differentiation alone should not indicate unfavorable prognosis.Routine MMR/MSI analysis in medullary morphology tumors is essential for prognostic assessment, individualized adjuvant treatment, and rational follow-up strategies. Accurate recognition and molecular evaluation can directly contribute to surgical clinical decision-making.

Keywords: Colonic medullary carcinoma, MSI-H, mismatch repair protein loss, poorly differentiated colorectal cancer, prognosis, tumor-infiltrating lymphocytes

Superior mesenteric vein injury occurring during right hemicolectomy

Özde Baştar, Ayşe Tuğba Kurt, Mehmet Fatih Ekici, Ali Cihat Yıldırım

Department of General Surgery, Kütahya City Hospital, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Mesenteric vascular structures, particularly the superior mesenteric artery and vein, play a fundamental role in intestinal circulation. Although injury to these structures is rare, it carries a risk of massive bleeding and high mortality. Mezocolic dissection performed during right hemicolectomy can lead to serious vascular complications due to working close to central vascular structures. Superior mesenteric vein (SMV) injuries, reported in a limited number of cases in the literature, are generally related to anatomical variations and surgical traction. This case report presents an SMV injury that developed during right hemicolectomy and its management.

Material and Methods: A 76-year-old female patient presented to the general surgery outpatient clinic with complaints of abdominal pain and constipation. Colonoscopy revealed an ulcerative lesion at the hepatic flexure level, narrowing the lumen by approximately 40%. A biopsy was taken. Although the pathological examination reported adenocarcinoma, the patient and her relatives declined surgical treatment. Five months later, a follow-up colonoscopy revealed that the lesion was growing, and a decision was made to proceed with surgical treatment. Right hemicolectomy and mesocolic excision were planned.

Results: The patient was explored under general anesthesia via a midline median incision. Injury to the SMV occurred during mesenteric dissection. Venous bleeding was observed. Manual compression was applied to control the bleeding. With the help of a vascular clamp, proximal and distal control was achieved, and the damaged SMV segment was primarily repaired with non-absorbable prolene sutures. After abdominal irrigation, complete hemostasis was achieved. The operation was concluded with the placement of a drain to monitor the anastomosis line and repair site. The patient was extubated and transferred to the intensive care unit for monitoring. Clexane therapy was initiated at 12 hours postoperatively. Due to hemodynamic stability, the patient was transferred to the general surgery ward on the first postoperative day. No significant decrease was observed in postoperative hemogram follow-ups. The drain was serous in character. The regimen was started on the 4th postoperative day and gradually increased. The patient was discharged on the 9th postoperative day.

Conclusion: SMV injuries are rare during right hemicolectomy but carry a serious risk of morbidity and mortality. Early diagnosis, rapid control of bleeding, and appropriate surgical repair can successfully manage these potentially devastating complications. Thorough knowledge of vascular anatomy, careful mesenteric dissection, and avoidance of excessive traction on venous structures are critical in preventing such injuries.

Keywords: Superior mesenteric vein injury, mesocolic excision, intraoperative complication

[P-315]

Isolated splenic metastasis from mucinous adenocarcinoma of the colon located at the splenic flexure: A case report

Engin Erdoğan, Gizem Polat Özcan, Doğuşhan Sevgen, Hikmet Pehlevan Özel

Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Colorectal cancers most commonly metastasize to the liver and lungs. Mucinous adenocarcinomas may show more aggressive biological behavior and a tendency for peritoneal dissemination. Splenic metastasis in colorectal cancer is rare. This rarity may be explained by the sharp angulation of the splenic artery, the high phagocytic and immunologic activity of the spleen, and its limited lymphatic drainage.

Material and Methods: This study was designed as a single case report. Colonoscopy and biopsy were initially performed. In May 2019, the patient underwent left hemicolectomy, end colostomy, small bowel resection and anastomosis due to invasion, and peritonectomy for thoracic wall invasion. On postoperative day 2, hyperthermic intraperitoneal chemotherapy (mitomycin and carboplatin) was administered. The patient was diagnosed with T4bN0 mucinous adenocarcinoma and received adjuvant chemotherapy (5 cycles of FOLFOX and 1 cycle of FUFA) until January 2020. He was followed in remission. Two years later, Positron emission tomography-computed tomography revealed an 18×22 mm splenic lesion (SUV_{max}: 4.32) suspicious for metastasis. In June 2021, splenectomy and closure of the end colostomy were performed.

Results: A 45-year-old male patient presented with complaints of abdominal pain that began in 2018. Colonoscopy revealed a mass at the level of the splenic flexure. Macroscopic examination of the colectomy specimen demonstrated a malignancy measuring approximately 13×13 cm, consistent with mucinous adenocarcinoma. Pathological evaluation showed T4b disease (invasion of the abdominal wall, left thoracic wall, and small intestine) and N0 status (0/35 lymph nodes). There was no lymphovascular or perineural invasion. An R0 resection was achieved, and no tumor infiltration was observed at the surgical margins. Histopathological and molecular analysis revealed loss of *MLH1* and *PMS2* expression, MSI-H status, *KRAS* mutation, and HER2 negativity. After being followed in remission for two years, follow-up imaging revealed splenic metastasis. The patient underwent splenectomy, and pathological examination demonstrated a 2.5×2.5×2 cm metastatic lesion in the spleen, located approximately 0.1 cm from the surgical margin, consistent with metastatic mucinous adenocarcinoma.

Conclusion: This case is notable for the absence of lymph node metastasis despite T4b disease, mucinous histology, mismatch repair deficiency, and the development of isolated splenic metastasis after curative treatment. Although mucinous tumors typically spread intraperitoneally, this finding suggests a possible hematogenous route. Splenectomy is recommended as both a diagnostic and therapeutic approach in such cases. Although rare, splenic lesions detected during follow-up should be carefully evaluated for metastasis, and splenectomy remains an effective treatment option.

Keywords: Colorectal cancer, splenic metastasis, mucinous adenocarcinoma

Figure 1. Macroscopically, the mass was oval in shape, had a smooth surface and was firm. It measured 3.5 cm in diameter.

Case presentation: Incidentally detected peritoneal loose body in a patient undergoing surgery for Ileus

Ahmet Şimşek, Abdullah İnal, İsmail Güzeliş

İzmir Buca Seyfi Demirsoy Training and Research Hospital, İzmir

Objective: Peritoneal loose bodies are usually asymptomatic and are found incidentally during abdominal surgery. Their size varies. They are generally thought to be caused by torsion and autoamputation of the appendix epiploica. Cases of peritoneal loose bodies larger than 2 cm are rare in the literature. We report the case of a patient who had difficulty in obtaining a diagnosis of tumor ileus.

Material and Methods: A 60-year-old male patient with hypertension and type 2 diabetes presented to our emergency department with abdominal pain and the absence of gas and stool passage for three days. On physical examination, he had generalized tenderness and distension in the abdomen. Rectal examination revealed no fecal contamination. An upright plain abdominal X-ray showed colonic distension but no air-fluid levels. Intravenous contrast abdominopelvic CT scan revealed fecalith at the level of the sigmoid colon and gas and stool distension proximal to this level. Laboratory findings showed no leukocytosis, no electrolyte imbalance, and normal renal function tests. Suspecting ileus due to fecalith, the patient was admitted to the general surgery ward for observation. Following symptomatic treatment and subsequent follow-up, the absence of gas and stool passage led to a planned colonoscopy. The colonoscopy revealed a mass encircling the lumen of the sigmoid colon and obstructing the passage. The patient was then taken to surgery. Anterior resection and anastomosis were performed due to a sigmoid colon mass. During the operation, a mass approximately 3.5 cm in diameter was detected in the peritoneal cavity and sent separately for histopathology.

Results: The mass detected intraoperatively was macroscopically oval-shaped, had a smooth surface, and was firm. Its size was 3.5 cm in diameter. Histopathological evaluation reported this mass as a peritoneal loose body. The patient's postoperative process was uneventful, and they were discharged.

Conclusion: In the case we present, imaging was insufficient to rule out fecaliths, peritoneal loose bodies, and malignant processes that could cause the patient's ileus, and the diagnosis was reached via colonoscopy. We encountered a peritoneal loose body in the patient, whom we operated on for tumor ileus. Peritoneal loose bodies can be confusing when investigating the pathology in a patient. Despite numerous examinations and imaging studies, they can be confused with both malignant and benign causes. Smaller ones are more common, but peritoneal loose body lesions larger than 2 cm are much rarer. The most optimal diagnostic and treatment option is surgery.

Keywords: Peritoneal loose bodies, calcified masses, colon malignancy

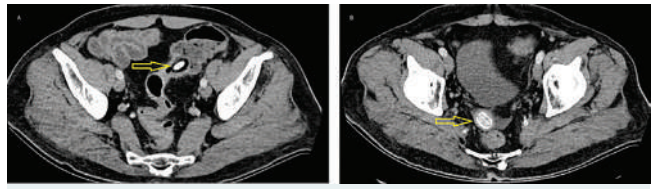

Figure 1. A) Contrast-enhanced abdominal CT scan shows fecalith in the sigmoid colon (arrow). B) Although not mentioned in the CT report, a calcified focus (arrow) was detected in the pelvis in the image.

Figure 2. Macroscopically, the mass was oval-shaped, had a smooth surface, and was hard. Its size was 3.5 cm in diameter.

Rectovaginal fistula after vaginal delivery: Diagnosis and surgical management

Emre Keskin, Merve Yeşilsancak, Ayşe Yüksekkaya, Emine Sena Cünük, Hakan Demir

Sakarya Training and Research Hospital, Sakarya

Objective: Vaginal delivery can cause perineal trauma ranging from minor lacerations to obstetric anal sphincter injuries (OASIS) and, rarely, rectal injury leading to rectovaginal fistula (RVF). OASIS is strongly associated with postpartum anal incontinence and reduced quality of life, and reported rates vary by center due to differences in delivery practices and systematic postnatal examination. Although uncommon, RVF is a severe complication characterized by passage of flatus or feces per vagina, causing hygiene problems, infection risk, and psychosocial distress; it may occur even when the sphincter is intact and the perineum appears externally normal. Early, careful assessment is crucial for accurate anatomic diagnosis and appropriate surgical planning.

Material and Methods: A 23-year-old woman with no comorbidities or prior surgery underwent spontaneous vaginal delivery at an outside hospital on December 24 after onset of labor. Postpartum pelvic examination revealed a laceration on the lower posterior vaginal wall. Digital rectal examination raised suspicion of a rectovaginal defect when the examining finger was noted to pass into the vagina, and primary surgical repair was performed. She was referred to our clinic on January 10 due to development of a postoperative RVF. On examination in the lithotomy position, a RVF tract measuring approximately 1-3 cm was identified at the 12 o'clock position. Endorectal ultrasonography revealed disruption of the integrity of the internal anal sphincter and external anal sphincter along a line of approximately 150 degrees in the anterior region. Fecal passage from the anal canal to the vagina was observed in this region. The injury was classified as Type 4 according to the Sultan classification prior to repair. Although it was classified as Type 3c after surgical repair, the clinical presence of a RVF persists. A heterogeneous hyperechoic appearance was observed in the suture area, and these findings were considered to be changes secondary to hematoma or inflammation. In addition, disruption of the perineal body integrity and a distinct defect extending to the puborectal muscle were detected.

Results: Under spinal anesthesia in the lithotomy position, exploration revealed a previously sutured but dehisced ~4-cm rectovaginal defect consistent with Sultan type 4, with intact anal canal mucosa. The defect was closed with full-thickness continuous Vicryl sutures and the rectovaginal septum was reconstructed. Suspected internal and external sphincter fibers were repaired in an overlap fashion to reconstruct the perineal body, and the vaginal repair was completed by the obstetrics-gynecology team in separate planes. Oral intake (regimen 1) was started at postoperative hour 6, and the patient was discharged on postoperative day 5.

Conclusion: The main challenge in postpartum perineal trauma is missed injury in the early period; underdiagnosed OASIS may lead to anal incontinence and pelvic floor dysfunction. Systematic examination, standardized classifications, and—when suspicion persists—objective assessment of sphincter integrity with endoanal/endorectal ultrasonography can guide surgical planning. Although historical management of rectal injuries has emphasized diversion, repair, presacral drainage, and distal washout, selected patients may be successfully treated with primary repair without diversion. Surgical strategy should be individualized according to defect location and size, tissue quality, degree of contamination or infection, and the presence of sphincter injury.

Keywords: Rectovaginal fistula, obstetric anal sphincter injury, perineal trauma

Table 1. Sultan classification of obstetric perineal injuries

Degree	Injury description
Intact	No visible laceration.
First-degree	Limited to the perineal skin only.
Second-degree	Involvement of the perineal muscles; no anal sphincter involvement.
Third-degree	Injury involving the anal sphincter complex: 3a: <50% of EAS thickness involved. 3b: >50% of EAS thickness involved. 3c: Involvement of both EAS and IAS.
Fourth-degree	Injury involving the anal sphincter complex and the anal mucosa.
Rectal buttonhole tear	Isolated rectal buttonhole tear; may be observed with or without a third-degree injury.

EAS: External anal sphincter, IAS: Internal anal sphincter.

A rare proctological case: Anal leiomyoma case report

Ünal Yağmur, Mehmet Gök, Yılmaz Türk

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Leiomyomas are benign mesenchymal tumors of smooth muscle origin, most commonly found in the uterus, esophagus, and stomach. Perianal localization is quite rare and can often be confused with benign anorectal diseases. This case report presents a 65-year-old male patient who was followed for a long time with a diagnosis of hemorrhoids and was diagnosed with perianal leiomyoma after surgical excision. This case highlights the importance of considering rare tumor lesions in the differential diagnosis of perianal masses.

Material and Methods: A 65-year-old male patient presented to our clinic with a complaint of long-standing swelling in the anal region. Perianal examination in the knee-elbow position revealed a well-defined, non-pedunculated, elastic, and mobile mass approximately 3 centimeters in size, located at the 4-5 o'clock position. Preoperative perianal MRI was planned. The MRI showed a 2x2 cm solid lesion with diffuse homogeneous contrast enhancement and mild diffusion restriction at intermediate T2 intensity, resembling a GIST or leiomyoma. After clinical evaluation, surgical excision was planned for the patient. The mass was carefully dissected from the surrounding tissues and removed in its entirety.

Results: The excised material appeared as an oval-shaped, well-defined, cream-brown mass approximately 4 cm in diameter, with a slightly elastic consistency. A homogeneous solid structure was observed on the cut surface. Immunohistochemical staining was positive for Desmin and SMA, while S100 and DOG1 were partially weakly positive. No staining was observed with CD117. Although Desmin and SMA positivity suggested leiomyoma, the presence of partial DOG1 positivity did not rule out GIST. Pathology was reported as leiomyoma.

Conclusion: Although perianal leiomyomas are rare, they should always be considered in the differential diagnosis of perianal masses. Anal region diseases should also be considered during the preoperative examination.

Keywords: Anal leiomyoma, proctology

Perineal scar endometriosis developing in an episiotomy scar: Case report

Ersin Kılıç[1], Ceylan Kiy Kılıç[2]

[1]*Clinic of General Surgery, Gebze Fatih State Hospital, Kocaeli*

[2]*Department of Anesthesiology and Reanimation, Kocaeli University Faculty of Medicine, Kocaeli*

Objective: Endometriosis is a chronic inflammatory condition characterized by the presence of functional endometrial glands and stroma outside the uterus. Scar endometriosis is rare and most commonly occurs following obstetric or gynecologic procedures. Perineal endometriosis developing in an episiotomy scar is an uncommon localization and diagnosis is often delayed. This report presents the clinical features, diagnostic process, and surgical management of a case of perineal scar endometriosis arising from an episiotomy scar.

Material and Methods: A 35-year-old woman presented with pain and swelling in the perineal region. She had a history of right mediolateral episiotomy during vaginal delivery in 2008. The patient reported a painful perineal mass for approximately 10 years, with symptoms increasing during menstruation. Physical examination revealed a tender subcutaneous mass adjacent to the episiotomy scar. The lesion was evaluated using ultrasonography and magnetic resonance imaging. Following clinical suspicion, surgical excision was performed and histopathological examination was conducted.

Results: Imaging demonstrated a solid lesion measuring approximately 3×3.5 cm beneath the episiotomy scar. No fistulous connection was identified and perianal fistula was excluded. Based on clinical findings and obstetric surgical history, scar endometriosis was suspected. The lesion was totally excised. Histopathological evaluation revealed endometrial glands and stroma. Immunohistochemistry showed diffuse CD10 positivity in stromal cells and cytokeratin-7 positivity in glandular structures, confirming the diagnosis of endometriosis.

Conclusion: Although rare, perineal endometriosis in an episiotomy scar typically presents with cyclical pain and a palpable mass. It should be considered in the differential diagnosis of perineal masses in patients with a history of obstetric surgery. Clinical suspicion is essential, and imaging supports the diagnosis. Definitive treatment is complete surgical excision with histopathological confirmation.

Keywords: Episiotomy, endometriosis, perineal mass

Extramedullary plasmacytoma of the breast mimicking primary breast carcinoma: A case report

Melis Ece Şahiner, İsmail Zihni, Veli Vural, Bahar Akkaya, Cumhur Arıcı

Akdeniz University, Antalya

Objective: Multiple myeloma is a systemic plasma cell malignancy that may rarely present with extramedullary involvement. Breast plasmacytoma is extremely uncommon and often mimics primary breast carcinoma. This case highlights breast plasmacytoma as a rare initial manifestation of multiple myeloma and underscores the importance of accurate histopathological diagnosis.

Material and Methods: A 72-year-old woman was evaluated after bilateral suspicious breast masses were detected on routine screening mammography and breast ultrasonography. Imaging revealed irregular, solid, hypervascular lesions classified as BI-RADS 4C and BI-RADS 5, which were newly developed compared with prior examinations, prompting ultrasound-guided tru-cut biopsy. Subsequent PET/CT demonstrated intensely hypermetabolic breast lesions accompanied by widespread lymph node, soft tissue, and skeletal involvement. These findings were consistent with a systemic plasma cell neoplasm exhibiting extensive extramedullary and osseous disease involvement.

Results: Multiple myeloma is a systemic plasma cell malignancy that primarily involves the bone marrow but may rarely present with extramedullary disease. Extramedullary plasmacytoma of the breast is exceedingly rare and is most often reported in patients with known or relapsed multiple myeloma. Presentation as the initial manifestation of multiple myeloma is particularly uncommon. Clinically and radiologically, breast plasmacytomas frequently mimic primary breast carcinoma, representing a significant diagnostic pitfall. Definitive diagnosis relies on histopathological and immunohistochemical evaluation. Following diagnosis, comprehensive systemic assessment is essential to identify underlying multiple myeloma and to ensure timely initiation of appropriate hematologic management.

Conclusion: Extramedullary plasmacytoma of the breast, although rare, represents an important diagnostic pitfall as it can mimic primary breast malignancies. This case demonstrates that breast plasmacytoma may present as the initial clinical manifestation of multiple myeloma and highlights the necessity of combined histopathological evaluation and comprehensive systemic assessment to establish the correct diagnosis.

Skeletal recovery without biochemical cure in glucagon receptor-positive BMAH: Is unilateral adrenalectomy sufficient?

Recep Temel[1], Sarp Tunalı[1], Utku Emre Soyaltın[2], Yiğit Türk[1], Özer Makay[3], Murat Özdemir[1]

[1]*Division of Endocrine Surgery, Department of General Surgery, Ege University Hospital, İzmir*

[2]*Division of Endocrinology, Department of Internal Medicine, Ege University Hospital, İzmir*

[3]*Centre for Endocrine Surgery, Özel Sağlık Hospital, İzmir*

Objective: Bilateral macronodular adrenal hyperplasia (BMAH) typically mandates bilateral adrenalectomy for cure, inevitably causing lifelong steroid dependency. While unilateral adrenalectomy (UA) has emerged as a cortisol-debulking strategy, its efficacy in reversing severe metabolic complications, particularly osteoporosis, in patients with mild autonomous cortisol secretion (MACS) remains debated. We evaluate UA's impact in a glucagon receptor-positive BMAH case.

Material and Methods: A 70-year-old female patient presented with uncontrolled hypertension, diabetes, and severe osteoporosis (lumbar T-score: -4.1). Computed tomography (CT) revealed bilateral giant adrenal masses (left: 60 mm, right: 50 mm). Although no overt cushingoid features were observed, MACS was confirmed (DST: 9.3 µg/dL). While genetic testing (*ARMC5*) was negative, aberrant glucagon receptors were identified. Following the failure of somatostatin analog therapy—intended to suppress glucagon—the patient underwent laparoscopic left adrenalectomy. The postoperative course was uneventful, and the patient was discharged on the 3rd day. Biochemical cure was not achieved due to the activity of the contralateral gland; 1 mg-DST levels remained non-suppressed (4.3 µg/dL). Despite this, the clinical outcomes are striking:

Steroid independence: During the 56-months follow-up, it was observed that the patient did not require any steroid replacement.

Hypertension management: Hypertension was successfully controlled with a reduced medication dosage.

Skeletal recovery: Most importantly, a dramatic improvement in bone mineral density was recorded, with the T-score rising from -4.1 to -1.6.

Clinical interpretation: This outcome indicates a significant improvement in osteoporotic changes, demonstrating that clinical benefits can be achieved through "cortisol debulking" despite persistent autonomous cortisol secretion.

Results: Biochemical cure was not achieved; the 1 mg-DST remained non-suppressed (4.3 µg/dL) due to contralateral gland activity. However, clinical outcomes were striking. At the 56-month follow-up, the patient required no steroid replacement. Hypertension was regulated with reduced medication. Most notably, bone mineral density improved dramatically (T-score -4.1 to -1.6), indicating significant skeletal recovery despite persistent autonomous cortisol secretion.

Conclusion: This case challenges the dogma of strict biochemical normalization. UA-mediated "cortisol debulking" successfully reversed severe osteoporotic changes associated with MACS. In elderly BMAH patients, preserving endogenous function through UA offers a superior balance between metabolic control and quality of life compared to bilateral adrenalectomy.

Keywords: Bilateral macronodular adrenal hyperplasia, mild autonomous cortisol secretion (MACS), unilateral adrenalectomy, cortisol debulking, osteoporosis

Table 1. Preoperative and postoperative comparison

Variable	Preoperative	Postoperative (56 months)	Outcome
Lumbar T-score	**-4.1 (severe osteoporosis)**	**-1.6 (osteopenia)**	**Major recovery**
DST (1 mg)	9.3 µg/dL	4.3 µg/dL	No biochemical cure
Anti-HT meds	1 (uncontrolled)	1 (regulated)	Improved control
HbA1c	6.1%	5.6%	Improved
Steroid need	-	None	Adrenal sufficiency preserved
Adrenal size	Bilateral (60 mm/50 mm)	Right only (50 mm)	Debulking achieved

Primary thyroid anjiosarcoma: A rare case report

Kerem Talha Düz, Mustafa Özgün Yüksek, Furkan Yağmur, Hasan Fehmi Küçük

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Primary angiosarcoma of the thyroid gland is an exceptionally rare and highly aggressive malignant tumor originating from endothelial cells, accounting for only a very small proportion of thyroid malignancies. Although it has been most frequently reported in the Alpine regions, it has been shown to be associated with a long-standing history of multinodular goiter; nevertheless, sporadic cases have also been described worldwide. Clinically, thyroid angiosarcoma typically presents with a rapidly enlarging neck mass accompanied by compressive symptoms, while radiological and cytological findings often mimic poorly differentiated thyroid neoplasms, thereby complicating early diagnosis.

Material and Methods: We evaluated of a 53-year-old male patient who presented with a six-month history of progressive neck swelling, dyspnea, and dysphagia.

Results: Neck ultrasonography revealed a large solid nodule measuring approximately 10 cm in the left thyroid lobe, characterized by a heterogeneous internal structure, hypoechoic appearance, areas of cystic degeneration, and coarse calcifications. Additionally, suspicious lymphadenopathies were detected at levels II-III, and fine-needle aspiration biopsy (FNAB) was performed. The initial FNAB result was reported as non-diagnostic. A second FNAB again yielded a non-diagnostic thyroid nodule biopsy; however, lymph node aspiration demonstrated very sparse malignant epithelial cells, favoring metastatic carcinoma. Nevertheless, the primary tumor origin could not be determined cytologically, and histopathological confirmation was recommended for definitive diagnosis. The patient subsequently underwent total thyroidectomy with left lateral and central neck dissection. No postoperative complications occurred, and the patient was discharged on postoperative day two. At follow-up, the patient was asymptomatic; however, histopathological examination revealed angiosarcoma measuring 5.5 cm in greatest diameter localized in the left thyroid lobe. Regarding lymph node findings, two reactive lymph nodes were identified in the right central compartment, while a total of 30 lymph nodes were dissected from the left central and lateral compartments, three of which demonstrated metastatic angiosarcoma. The patient was referred to medical oncology, and postoperative positron emission tomography/computed tomography (PET/CT) showed no evidence of distant organ metastasis.

Conclusion: This case highlights that repeated non-diagnostic FNAB results do not exclude malignancy in patients presenting with giant thyroid nodules, and that rare aggressive tumors should be considered, particularly in lesions demonstrating rapid growth, heterogeneous characteristics, and suspected invasiveness. Furthermore, early incorporation of endothelial markers into the immunohistochemical panel should be emphasized, as it may facilitate and expedite the diagnostic process.

Keywords: Total thyroidectomy, thyroid angiosarcoma, fine-needle aspiration biopsy (FNAB)

Papillary thyroid carcinoma presenting with femoral fracture: A rare case report

Fırat Erdoğan, Meryem Günay Gürleyik, Begüm Irmak Çoban

University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Papillary thyroid carcinoma (PTC) is the most common histological subtype of thyroid cancer and usually has a favorable prognosis. Distant metastases are rare, with bone involvement reported in approximately 4% of cases. Bone metastases may lead to pathological fractures and significantly worsen prognosis. We present a rare case of PTC diagnosed following a pathological femoral fracture.

Material and Methods: A 66-year-old female presented to the emergency department with right hip pain and limited mobility. Imaging revealed a pathological intertrochanteric fracture of the right femur. Open biopsy demonstrated metastatic carcinoma of thyroid origin. Following orthopedic resection, further evaluation of the thyroid gland was performed using ultrasonography and fine-needle aspiration biopsy.

Results: Thyroid ultrasonography revealed a 3 cm solid nodule in the right lobe, and fine-needle aspiration biopsy was classified as Bethesda category V. The patient underwent total thyroidectomy with bilateral central neck dissection. Intraoperatively, parathyroid glands were identified using a PT eye device, and intracapsular glands were autotransplanted into the sternocleidomastoid muscle. Histopathological examination confirmed invasive encapsulated follicular variant PTC, with no metastatic involvement of central lymph nodes (pT2N0M1).

Conclusion: This rare case highlights that PTC may present with aggressive behavior despite its generally favorable prognosis. Metastatic malignancy should be considered in patients presenting with atypical fractures, and a multidisciplinary approach is essential for optimal management.

Keywords: Bone metastasis, papillary thyroid carcinoma, pathological femoral fracture

[P-324]

Brachial cleft cyst: A rare case report

Mehmet Olgun, Ali Toprak, Mehmet Ali Halaç, Niyazi Karaman

Department of General Surgery, University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara

Objective: Brachial anomalies result from changes in the development of the brachial apparatus during embryogenesis between the second and sixth to seventh weeks of fetal life. Persistence of brachial remnants can lead to the development of cysts, sinuses, fistulas, or cartilage islands. Secondary branchial cleft anomalies are the most common cause of this type of neck mass, accounting for approximately 90% of all cases. Although the masses are congenital, they are usually detected during the second to fourth decades of life when they enlarge due to infection or cyst rupture. They occur with equal frequency in men and women. Preoperative diagnosis requires precise determination of the lesion's location, with clinical and radiological findings being crucial.

Material and Methods: The patient was a 50-year-old woman with no significant medical history and no symptoms. She presented to our center with swelling in her right neck that had appeared approximately 6 months ago and had been progressively increasing since then. Physical examination revealed a 2 cm mass in the right submandibular area that was difficult to palpate and had well-defined borders. Ultrasonographic imaging revealed a hypoechoic lesion measuring 29x18 mm, located between the submandibular gland and the jugular vein in the right submandibular region, containing internal cystic areas in places, with no significant vascularization noted on Doppler evaluation. (Epidermoid cyst? Necrotic complicated LAP?) "Based on the MRI report stating," a lesion measuring approximately 25x20x28 mm, hyperintense on T1A and T2A, extending between the submandibular gland and the vascular bundle in the right submandibular region," surgery was planned for the patient. The pathology result was reported as a brachial cleft cyst.

Results: The vast majority of brachial anomalies (90%) originate from secondary clefts. These can be bilateral and present as soft, mobile, and asymptomatic masses under the skin. Depending on their size (ranging from 1 to 10 cm) and location, they may cause local symptoms such as dysphagia, dysphonia, dyspnea, and stridor. Cysts may become painful or tender due to infection, and abscess formation and fistula formation may occur. Sonographically, secondary brachial cleft cysts appear as well-defined, round-oval, hypo- to anechoic masses. Magnetic resonance imaging allows for better preoperative evaluation of the cyst.

Conclusion: Secondary brachial cleft cysts are rare and constitute the vast majority of brachial anomalies. They are usually asymptomatic but can become infected and lead to abscess and/or fistula formation. Clinical and radiological findings are valuable in preoperative evaluation. Treatment consists of surgical excision of the lesion.

Keywords: Brachial, cleft, cyst

[P-325]

Acute airway compression following thyroid fine-needle aspiration biopsy: A rare case requiring emergency lobectomy

Merve Yeşilsancak[1], Tuba Yavuz Akça[1], Talan Tahtacı[1], Zülfü Bayhan[2], Barış Mantoğlu[2]

[1]*Sakarya Training and Research Hospital, Sakarya*

[2]*Sakarya University Faculty of Medicine, Sakarya*

Objective: Thyroid fine-needle aspiration biopsy (FNAB) is a safe and minimally invasive diagnostic procedure widely used for the evaluation of thyroid nodules. Although complications are rare, cervical hematoma can occur and may lead to life-threatening airway compression. In this case report, we present our emergency surgical approach to a compressive thyroid hematoma that developed following FNAB and required urgent surgical intervention.

Material and Methods: A 72-year-old female patient underwent FNAB due to a nodule located in the left lobe of the thyroid gland. Approximately four hours after the procedure, the patient presented to the emergency department with shortness of breath. Physical examination revealed significant neck swelling and tachypnea. Neck computed tomography demonstrated a hematoma in the thyroid bed. Due to progressive respiratory distress, the patient was intubated in the critical care area and taken to emergency surgery. During the operation, active bleeding originating from the anterior thyroid artery of the left thyroid lobe was identified. A left lobectomy was performed to achieve definitive bleeding control. Postoperatively, the patient was admitted to the intensive care unit while intubated and was successfully extubated four hours later. On postoperative day one, the patient was transferred to the surgical ward, and calcium and parathyroid hormone levels were within normal limits. On postoperative day two, with no complications observed, the drains were removed and the patient was discharged.

Results: Although thyroid FNAB is considered a safe procedure with a low complication rate, rarely occurring cervical hematomas may result in life-threatening clinical conditions such as acute airway obstruction. The primary mechanism of hematoma formation is iatrogenic vascular injury, particularly damage to branches of the thyroid arteries, which may lead to rapid volume expansion. Due to the rapid progression of symptoms, early clinical recognition and prompt airway management are critical. Emergency surgical exploration may be required in the presence of progressive dyspnea and increasing neck swelling. In our case, early intubation was performed due to progressive respiratory distress, and active arterial bleeding was identified during surgical exploration, with definitive treatment achieved by lobectomy. This case demonstrates that although post-FNAB hematoma is rare, it may lead to rapid clinical deterioration, and early surgical intervention can be life-saving.

Conclusion: Cervical hematoma after thyroid FNAB is a rare but potentially life-threatening complication. Patients presenting with rapidly progressive neck swelling and respiratory distress require immediate evaluation, prompt airway management, and timely surgical intervention when indicated.

[P-326]

Concomitant gallbladder hydatid cyst and Mirizzi syndrome: A rare case report

Levent Uğurlu, Ekrem Kocatürk, Savaş Yakan

Department of General Surgery, University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Hydatid disease is a parasitic infection, most commonly caused by *Echinococcus granulosus*, and it predominantly involves the liver and lungs. Primary involvement of the gallbladder is extremely rare. Mirizzi syndrome (MS) is an uncommon but serious clinical condition secondary to cholelithiasis, characterized by obstruction and erosion of the main biliary ducts. The coexistence of a primary gallbladder hydatid cyst (PGHC) and type IV MS has been reported only in a very limited number of cases in the literature. In this poster, we aimed to present our case with this rare association.

Material and Methods: In a patient presenting with right upper quadrant pain and jaundice, physical examination and laboratory tests were performed. Ultrasonography and MRI were obtained. After an unsuccessful ERCP attempt, surgery was planned; intraoperative assessment was performed via laparotomy and the appropriate procedure was undertaken. Postoperatively, albendazole was initiated and long-term follow-up was performed.

Results: A 79-year-old male patient had a positive Murphy's sign on physical examination. Laboratory tests revealed leukocytosis and cholestasis (total bilirubin: 12.5 mg/dL). Ultrasonography and MRI demonstrated a stone in the gallbladder fossa, dense biliary sludge, and findings compatible with MS. Endoscopic retrograde cholangiopancreatography (ERCP) was unsuccessful. At laparotomy, the gallbladder was markedly inflamed and densely adherent to the common bile duct. During cholecystectomy, perforation of the gallbladder resulted in spillage of hydatid membranes and daughter vesicles. Concomitantly, full-thickness erosion of the common bile duct wall was observed. As no cyst was detected on preoperative imaging and no other focus was identified intraoperatively, the case was considered PGHC. Cholecystectomy and Roux-en-Y hepaticojejunostomy were performed. Albendazole therapy was initiated, and the patient was followed for 4 years without recurrence.

Conclusion: PGHC is a rare localization and is difficult to diagnose preoperatively; hydatid membranes and daughter vesicles may be mistaken for biliary sludge or gallstones on imaging. In our case, the finding interpreted as "biliary sludge" on ultrasonography and MRI was recognized intraoperatively as hydatid material. The coexistence of MS and PGHC is exceedingly rare. Although cholecystectomy with adjuvant albendazole is generally sufficient for PGHC, concomitant type IV MS in this patient required bile duct resection and Roux-en-Y hepaticojejunostomy, resulting in a successful clinical outcome during postoperative follow-up. Because this rare association may cause diagnostic confusion, primary hydatid disease should be considered in atypical cholecystitis and MS cases—particularly in endemic regions—and the surgical strategy should be planned to prevent parasitic dissemination while ensuring adequate biliary reconstruction.

Keywords: Primary hydatid cyst of the gallbladder, Mirizzi syndrome

Gallbladder torsion: A rare case report

Cem Aykent, Eylem İlayda Doğan, Kadir Can Şahin, Erdal Karagülle

University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Acute cholecystitis is one of the most common surgical emergencies in patients presenting with acute abdomen; however, gallbladder torsion is reported as a rare condition. This rare pathology was first described in 1898, and since then, more than 500 cases have been reported. Although the exact etiology of gallbladder torsion is not fully understood, certain anatomical variations are thought to predispose patients to torsion. Preoperative diagnosis is challenging, and it is possible in less than 10% of cases. Gallbladder torsion is difficult to distinguish because its clinical and physical examination findings are similar to those of acute cholecystitis. While acute cholecystitis does not always require emergency surgery, delayed intervention in gallbladder torsion increases morbidity and mortality. The aim of this case report is to emphasize that gallbladder torsion should always be considered in the differential diagnosis of elderly patients presenting with clinical features of acute cholecystitis.

Material and Methods: An 82-year-old woman presented to the emergency department with sudden-onset right upper quadrant pain, nausea, and vomiting. Her medical history included Parkinson's disease, Alzheimer's disease, and hypertension. Laboratory tests and imaging studies raised the suspicion of gallbladder torsion, and the patient was admitted to the general surgery department for laparoscopic cholecystectomy. Intraoperatively, the gallbladder was found to be nearly detached from its posterior wall and displaced inferiorly. The hilum had rotated three complete turns, resulting in complete torsion, and the gallbladder was necrotic. The procedure was completed laparoscopically without complications.

Results: On physical examination, the patient had diffuse abdominal tenderness and a positive Murphy sign. Laboratory findings revealed elevated C-reactive protein (376.1 mg/L) and white blood cell count (12.25×10^3/μL), while other laboratory values were within normal limits. Hepatobiliary ultrasonography demonstrated inferior displacement of the gallbladder, with torsion of the neck and cystic duct. Further evaluation with computed tomography showed a hydropic gallbladder with torsion involving the cystic artery, confirming the diagnosis. Postoperatively, the patient's clinical and laboratory parameters normalized, and no complications occurred. She was discharged on the seventh postoperative day.

Conclusion: Although acute cholecystitis is a common cause of acute abdomen, gallbladder torsion is often overlooked preoperatively. In our case, the patient presented with typical acute cholecystitis symptoms, including right upper quadrant pain, nausea, and vomiting, along with elevated inflammatory markers. This case highlights the importance of considering gallbladder torsion in elderly patients, particularly women, who present with clinical signs of acute cholecystitis.

[P-328]

Is free intraperitoneal air always indicative of gastrointestinal perforation?

Efehan Kutad Karakaya[1], Hüseyin Esin[1], Furkan Taş[1], Orhan Üreyen[2], Enver İlhan[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir City Hospital, İzmir*

Objective: Gallbladder perforation is a rare but potentially life-threatening complication of acute cholecystitis. The fundus, which has a relatively sparse vascular supply, is the most frequently affected anatomical site. While the presence of free intraperitoneal air (pneumoperitoneum) on computed tomography (CT) is typically associated with gastrointestinal (GI) perforation requiring urgent surgery, this case highlights that it can also arise from atypical etiologies such as a contained gallbladder perforation.

Material and Methods: A 75-year-old male presented with abdominal pain. One week prior, he had been managed for acute pancreatitis with elevated amylase (1089 U/L) and lipase (1814 U/L) levels, supported by CT findings. Following medical treatment, he was discharged. Upon re-admission, physical examination revealed no signs of peritonitis. Contrast-enhanced CT showed peripancreatic necrotizing collections and widespread pneumoperitoneum; however, no extraluminal contrast leakage was observed on oral contrast imaging. Laboratory follow-up showed a significant rise in CRP (from 18 mg/L to 138 mg/L) and leukocyte count (from 8.4 to 13.7×10^3/μL). Due to the clinicoradiological mismatch, a diagnostic laparotomy was performed. No GI perforation was found; instead, a contained perforation covered by the omentum was identified at the posterior fundus of the gallbladder. A cholecystectomy was performed. The postoperative course was uneventful, and the patient was discharged on day 6. No issues were noted at the one-month follow-up.

Results: Free intraperitoneal air is an important radiological finding most commonly associated with GI perforation. However, it has been reported that free air is not always secondary to luminal perforation and may rarely be related to alternative etiologies such as gallbladder perforation. Gallbladder perforations are classified according to the Niemeier classification as acute free perforation (type I), subacute localized perforation (type II), and chronic fistulized form (type III). The present case is consistent with a sealed (type II) perforation limited by the omentum. CT has high diagnostic value in suspected perforation for determining localization and evaluating accompanying intra-abdominal pathologies. In this case, despite the presence of widespread free air on CT, the absence of contrast extravasation and the lack of prominent clinical findings created a clinicoradiological discrepancy. This situation demonstrates that the etiology of free air should not always be considered GI perforation.

Conclusion: Although the detection of free intraperitoneal air is most commonly associated with GI perforation, rare but clinically significant etiologies such as sealed gallbladder perforation should also be considered in the differential diagnosis.

Keywords: Free intraperitoneal air, gallbladder perforation, pneumoperitoneum

A rare cause of gastric outlet obstruction: A case of Bouveret syndrome

Muhammed Hallaç[1], Şükran Çavdar[2], Muhammed Salih Süer[1], Faruk Yazıcı[3], Serkan Demir[1], Şener Balas[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Payas State Hospital, Hatay*

[3]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Bouveret syndrome is a rare cause of gallstone ileus in which a gallstone passes through a bilioenteric fistula into the duodenum, leading to gastric outlet obstruction. In elderly patients with multiple comorbidities, delayed diagnosis may limit endoscopic treatment and increase surgical morbidity. This report describes the clinical, laboratory, imaging, and management features of an elderly patient with a high comorbidity burden diagnosed with Bouveret syndrome.

Material and Methods: A case presenting to the emergency department with signs of gastric outlet obstruction and diagnosed with Bouveret syndrome by USG/BT was retrospectively evaluated. Demographic data, comorbidity indices (ASA, Charlson), symptom duration, laboratory parameters (WBC, CRP, lactate), imaging findings, and characteristics of the ectopic gallstone (location, size, number, calcification, Hounsfield units), diagnostic delay, endoscopic interventions (endoscopy/ERCP), surgical approach, postoperative complications, intensive care unit and hospital length of stay, and follow-up outcomes were recorded.

Results: A 99-year-old female patient presented to the emergency department with a 19-days history of nausea, vomiting, and impaired oral intake. Owing to multiple comorbidities, the patient was classified as ASA-IV with a Charlson comorbidity index of 5 (BMI: 19). Laboratory evaluation revealed a marked inflammatory response (WBC: 23,960/mm^3, CRP: 146 mg/L), with a lactate level of 2 mmol/L. Abdominal ultrasonography and contrast-enhanced computed tomography demonstrated a single ectopic gallstone localized in the duodenum, measuring 52 mm in diameter, calcified, and of high density (617 HU). Based on these findings, together with signs of gastric outlet obstruction, a diagnosis of Bouveret syndrome was established. Due to a diagnostic delay exceeding 48 hours and the patient's high-risk profile, endoscopic interventions were limited. Following unsuccessful stone extraction after endoscopy and ERCP, the patient underwent surgical treatment. The obstructing stone was successfully removed via open enterolithotomy (operative time: 60 minutes). No additional surgical intervention was performed for the bilioenteric fistula. In the postoperative period, the patient developed surgical site infection and sepsis, requiring intensive care unit follow-up for 36-days; the total hospital stay was 60 days. The patient was discharged, and no mortality or recurrence was observed during a 12-months follow-up period.

Conclusion: Bouveret syndrome is prone to delayed diagnosis in elderly patients with multiple comorbidities and carries a high risk of morbidity. However, this case demonstrates that despite advanced age (99 years), ASA-IV status, a Charlson comorbidity index of 5, prolonged symptom duration, and a diagnostic delay exceeding 48 hours, a favorable clinical outcome can be achieved through accurate identification of a 52 mm calcified duodenal stone and performance of an open enterolithotomy aimed solely at relieving the obstruction, without fistula repair. Despite severe postoperative complications and prolonged intensive care unit stay, the patient was discharged without mortality, and no recurrence was observed during 12-months of follow-up. This case underscores the importance of early consideration of Bouveret syndrome in elderly patients presenting with gastric outlet obstruction and highlights that, in high-risk patients, the shortest, safest, and most targeted surgical strategy may be life-saving.

Keywords: Advanced age, Bouveret syndrome, enterolithotomy, gallstone ileus, gastric outlet obstruction

Emergency management of jejunal perforations distal to gastrojejunostomy: A two-case series treated with Graham omental patch

Hasan Kumru, Gültekin Hoş, Süleyman Ümit Emanet, Aylin Acar, Tolga Canbak

Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul

Objective: Marginal ulcers and jejunal perforations following bariatric surgery are rare but carry a significant risk of morbidity and mortality. In this study, we present the diagnostic approach, surgical management, and clinical outcomes of two patients who underwent emergency surgery due to perforation occurring distal to the gastrojejunostomy (GJ) anastomosis.

Material and Methods: Two patients with a history of bariatric surgery who presented with an acute abdomen between June and December 2024 were retrospectively evaluated. The patients' clinical findings, laboratory parameters, imaging results, intraoperative findings, and postoperative courses were reviewed. In both cases, jejunal perforations were repaired by primary suturing followed by the application of a Graham omental patch.

Results: Between June and December 2024, two patients with a history of bariatric surgery who presented with an acute abdomen were evaluated emergently. The first case was a 50-year-old female patient with a previous history of sleeve gastrectomy and Roux-en-Y gastric bypass; computed tomography revealed free air consistent with perforation. The second case was a 56-year-old male patient who had recently undergone Roux-en-Y gastric bypass; diffuse free air was observed on CT. In both cases, intraoperative exploration revealed jejunal perforations distal to the GJ anastomosis. The perforations were repaired by primary suturing and reinforced with a Graham omental patch. Leak tests were negative. No major postoperative complications occurred; one patient was discharged after short-term intensive care unit monitoring. The clinical course was stable in both patients, and the surgical repairs were deemed successful.

Conclusion: Marginal ulcers after Roux-en-Y gastric bypass are uncommon but may result in serious morbidity and mortality when complicated by perforation. Although computed tomography is considered the gold standard for diagnosis, perforation findings may be subtle due to altered postoperative anatomy, requiring high clinical suspicion. In this poster, two patients with a history of bariatric surgery who presented with acute abdomen were evaluated. In both cases, jejunal perforation distal to the GJ anastomosis was identified during emergency surgery. Perforations were repaired with primary suturing reinforced by a Graham omental patch. Despite minimal radiological findings in one patient, intraoperative exploration confirmed perforation, emphasizing the importance of early surgical intervention. No major postoperative complications occurred, and clinical outcomes were favorable in both patients. These cases demonstrate that Graham omental patch repair is a safe, effective, and easily applicable technique for distal GJ perforations. A low threshold for surgical exploration should be maintained in bariatric patients presenting with acute abdomen to prevent delayed diagnosis and outcomes.

Keywords: Bariatric surgery, marginal ulcer, jejunal perforation, gastrojejunostomy, emergency surgery

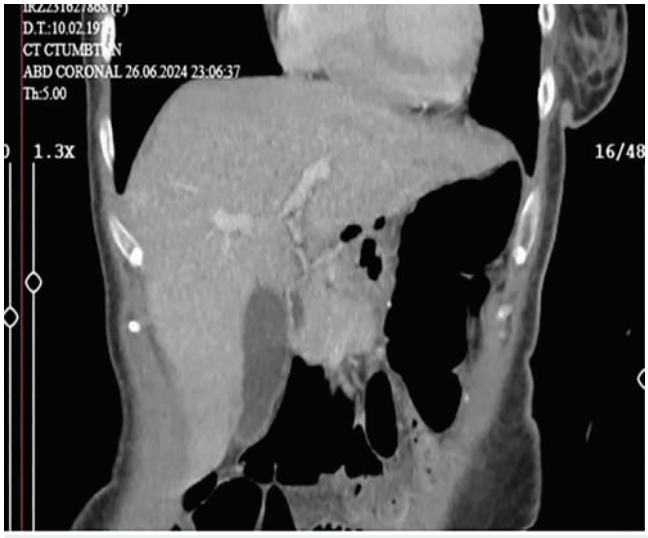

Figure 1. Case 1: preoperative contrast-enhanced CT image (coronal). Thin fluid-air levels consistent with perforation are observed in the hepatogastric region, along with localized millimetric free air foci at the level of the hepatogastric ligament and adjacent to the lesser curvature of the stomach.

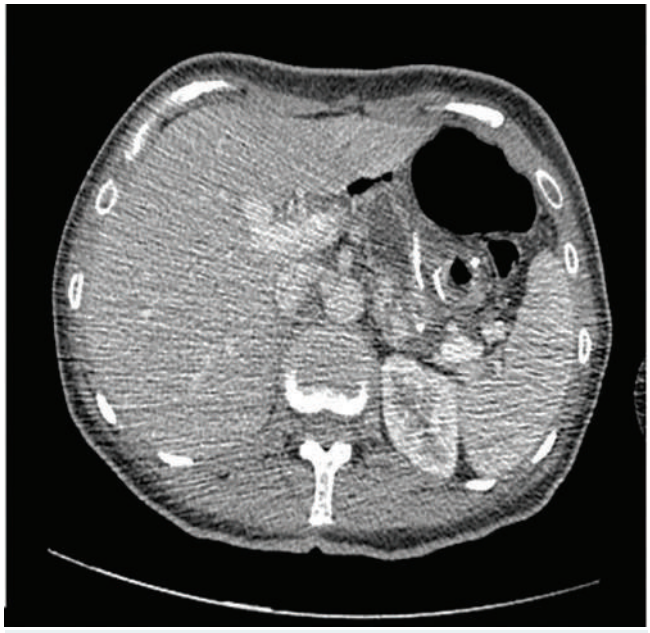

Figure 2. Case 1: preoperative contrast-enhanced CT image (axial). Minimal free fluid is observed in the pelvic cavity, along with metallic suture materials related to previous surgery. No obstructive pathology is identified.

Figure 3. Case 2: preoperative contrast-enhanced CT image (axial). Free air consistent with perforation is observed anterior to the liver, in front of the spleen, and surrounding the stomach.

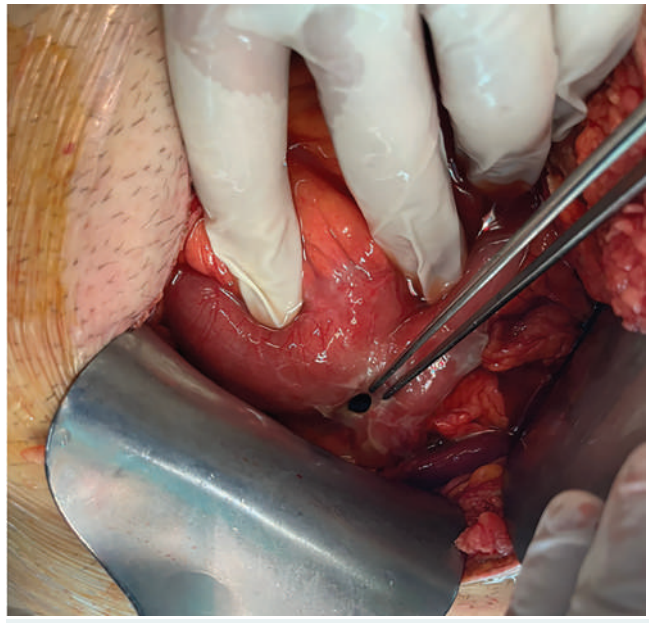

Figure 4. Case 2: Intraoperative image. Approximately 500 cc of free intraperitoneal fluid and a 1 cm perforation focus distal to the gastrojejunostomy anastomosis were observed.

Choice of surgical approach for gallstone ileus

Ahmet Ağların, Emine Büküm, Berge Ede, Tuba Göçmen

University of Health Sciences Türkiye, Bursa City Hospital, Bursa

Objective: Gallstone ileus is the obstruction of the intestinal tract by stones due to gallbladder or biliary fistulas. Gallstone ileus accounts for 1-4% of all intestinal obstructions. Cholecystoduodenal fistula is frequently seen. Gallstone ileus occurs in 0.3-0.5% of all cases of cholelithiasis. Gallstone ileus develops when the gallstone is larger than 2.5 cm. Obstruction usually occurs in the terminal ileum (70%). Contrast-enhanced abdominal CT is the gold standard in imaging. Surgical treatment is performed as one-stage or two-stage.

Material and Methods: Case 1: a 54-year-old woman with no comorbidities or prior surgery presented with abdominal pain, nausea, and vomiting. Contrast-enhanced abdominal CT showed pneumobilia and small-bowel air-fluid levels, suggesting ileus. At laparotomy, a mass was palpated 170 cm distal to the ligament of Treitz; enterolithotomy was performed, the gallstone was removed, and the bowel was primarily repaired. Two cholecystoduodenal fistulas were identified, so cholecystectomy and fistula resection were performed in the same session. She was discharged uneventfully on postoperative day tenth. Case 2: An 87-year-old woman with comorbidities and known gallstones, with no prior surgery, presented with nausea, vomiting, abdominal pain, and constipation. Contrast-enhanced CT demonstrated pneumobilia and small-bowel intussusception in the left lower quadrant. At laparotomy, a mass was palpated 40 cm distal to the ligament of Treitz; the gallstone was removed via enterotomy and the bowel was repaired. Due to advanced age and comorbidities, cholecystectomy was deferred. She was discharged uneventfully on postoperative day sixth.

Results: Gallstone ileus is a rare cause of intestinal obstruction. In patients without prior abdominal surgery, Rigler's triad can aid diagnosis, and laparotomy may be required in up to 50% of cases. Surgical management may be one-stage (enterolithotomy with cholecystectomy and fistula repair in the same session) or two-stage (enterolithotomy alone initially). The choice depends on age, comorbidities, and obstruction site: one-stage surgery was preferred in the first case due to the absence of comorbidities, whereas advanced age and comorbidities led to a two-stage approach in the second case. In high-risk patients, two-stage surgery is associated with lower morbidity and mortality, supporting an individualized approach.

Conclusion: Although gallstone ileus is a rare condition, it should be kept in mind in the prediagnosis of elderly patients who do not have a history of previous abdominal surgery but present with signs of obstruction. Enterolithotomy, fistula repair and cholecystectomy can be performed in one or two surgical sessions in the treatment of these cases, or enterolithotomy may be sufficient in elderly and comorbid patients.

Small bowel intussusception caused by cavernous hemangioma: A rare case

Ferdi Cambaztepe, Begüm Irmak Çoban, Emre Berat Akçay, Erva Bengü Balaban

University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Intussusception is a rare cause of mechanical intestinal obstruction, resulting from telescoping of one bowel segment into an adjacent segment. In adults, it accounts for less than 5% of all intussusception cases and is usually associated with an underlying structural lesion. Cavernous hemangiomas are rare benign vascular tumors of the gastrointestinal tract that are often asymptomatic but may require surgical intervention when obstruction occurs.

Material and Methods: A 35-year-old male presented to the emergency department with abdominal pain accompanied by nausea and vomiting. Clinical evaluation, laboratory findings, and radiological imaging were performed. Plain abdominal radiography and contrast-enhanced abdominal computed tomography suggested mechanical intestinal obstruction secondary to intussusception. Surgical exploration was planned accordingly.

Results: Intraoperatively, intussusception was identified approximately 60 cm proximal to the ileocecal valve in the terminal ileum. After manual reduction, a well-circumscribed solid intraluminal lesion measuring approximately 5-6 cm was detected as the leading point. Segmental ileal resection of approximately 10 cm with clear surgical margins was performed, followed by primary anastomosis. The postoperative course was uneventful. The patient passed flatus and stool on postoperative day 2, resumed oral intake on day 3, and was discharged without complications on postoperative day 5. Histopathological examination revealed a cavernous hemangioma.

Conclusion: Cavernous hemangioma is a rare cause of intussusception in adult patients. Although diagnosis in asymptomatic cases is challenging, surgical resection remains a safe and effective treatment option in patients presenting with intestinal obstruction. Adult intussusception cases should be managed with an individualized surgical approach, considering the high likelihood of an underlying organic lesion.

Keywords: Cavernous hemangioma, intussusception, small bowel obstruction

A rare cause of ileus: Giant mesenteric cystic tumoral mass

Ramazan Serdar Arslan, Yusuf Veli, Tamer Akay, Serkan Şengül, Yılmaz Güler, Zülfikar Karabulut

Alanya Alaaddin Keykubat University Faculty of Medicine, Antalya

Objective: Although giant mesenteric cysts are rare, they can present with acute surgical conditions such as ileus due to compression and invasion of adjacent organs. While imaging techniques guide the diagnostic process, definitive diagnosis in most cases is established through surgical exploration and histopathological examination.

Material and Methods: An 85-year-old male patient presented to the emergency department with complaints of abdominal pain, abdominal distension, and inability to pass gas or stool. Physical examination revealed abdominal distension and generalized tenderness. Abdominal ultrasonography detected a large soft tissue tumor, prompting an abdominal MRI. Magnetic resonance imaging revealed a large tumoral mass measuring approximately 28×18 cm, characterized by thick walls, septations, poorly defined margins, and diffusion restriction. The patient was admitted to the surgical ward for operative management.

Results: During emergency laparotomy, a giant tumoral mass measuring approximately 30×20 cm extending from the epigastric region to the pelvis was observed. The mass caused extensive adhesions to the small bowel and colon loops, invaded the appendix, and completely obstructed the intestinal passage due to compression. After adhesiolysis, the mass was completely resected along with the appendix. Other intra-abdominal solid organs were evaluated as normal. The patient had an uneventful postoperative course and was discharged with surgical cure. Histopathological examination revealed undifferentiated pleomorphic sarcoma (UPS), and the patient was referred to oncology for follow-up.

Conclusion: UPS, is a high-grade soft tissue sarcoma and one of the most common soft tissue sarcomas in adults. It is a rare and aggressive type of cancer that typically originates in the soft tissues of the body. These cancers often present with symptoms at a late stage and can reach advanced sizes by the time of diagnosis. In cases presenting with ileus (intestinal obstruction), emergency surgical intervention can be life-saving. Although imaging methods provide information about the size and spread of the mass, definitive diagnosis and treatment are often only possible through surgical exploration.

Keywords: Intra-abdominal mass, ileus, soft tissue tumor, emergency surgery

Abdominal cocoon syndrome presenting with illeus due to internal hernia (idiopathic sclerosing encapsulated peritonitis): Case report

Halil Berkay Uzuncu, Erkan Karacan, Ömer Faik Ersoy

Karabük Training and Research Hospital, Karabük

Objective: Abdominal cocoon syndrome (idiopathic sclerosing encapsulating peritonitis) is a rare cause of mechanical obstruction characterized by partial or complete encapsulation of small bowel loops within a fibro-collagenous membrane. Clinical findings are often non-specific, presenting as recurrent episodes of subileus/ileus, and preoperative diagnosis is difficult.

Material and Methods: A 53-year-old male patient with no known comorbidities or history of surgery presented with nausea-vomiting, abdominal pain, and inability to pass gas or stool. Contrast-enhanced abdominal CT revealed suspected internal hernia at the duodenal level and dilatation/air-fluid levels in the jejunal loops. Emergency surgery was planned with a preliminary diagnosis of mechanical obstruction; laparotomy was performed during laparoscopic exploration due to suspected abdominal cocoon.

Results: Approximately 80 cm distal to the Treitz ligament, segments of the small intestine extending to the terminal ileum were found to be trapped within a cocoon-like fibrous membrane, with dense adhesions between the loops. The membrane was carefully opened, and the intestinal loops were freed using careful enterolysis; resection was not performed as viability was preserved. Gas and stool passage began on postoperative day 2; oral intake was tolerated, and the patient was discharged on postoperative day 5.

Conclusion: Abdominal cocoon syndrome must always be considered in the differential diagnosis of patients presenting with recurrent ileus/intestinal obstruction attacks who have no prior history of abdominal surgery; this possibility should be considered, especially in the presence of clinical and radiological findings suggestive of internal herniation. The diagnosis is often made intraoperatively; the mainstay of treatment consists of opening/excision of the membrane and careful enterolysis.

Keywords: Abdominal cocoon, sclerosing encapsulating peritonitis, small bowel obstruction, internal hernia

Figure 1. Appearance suggestive of midline duodenal internal herniation on contrast-enhanced abdominal CT. Dilatation up to 3 cm and air-fluid levels are observed in the jejunal loops at the same levels, consistent with subileus.

Figure 2. The intraoperative view shows that the small bowel loops are encapsulated in a fibrous, thick membrane in a cocoon-like manner, and following the release of the loops, it is observed that this membrane is the mechanical cause of the obstruction (consistent with abdominal cocoon syndrome).

[P-335]

The role of inflammatory myofibroblastic tumor in adult intussusception: Clinical and pathological findings

Sadık Peker, Alı Bekrakı, Emin Büyüktalancı

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Intussusception is a condition in which segments of the intestine telescope into each other, creating a telescopic appearance and leading to transient or permanent gastrointestinal obstruction. It is less common in adults compared to children. Adult intussusceptions account for less than 1% of all cases of intussusception. Its incidence in adults is extremely rare and has been reported in fewer than one out of every 1,300 abdominal operations. Intussusception may cause ileus and bowel dilatation, which can subsequently lead to ischemia, necrosis, perforation, intra-abdominal sepsis, and mortality. Inflammatory myofibroblastic tumor (IMT) is an extremely rare neoplasm composed of myofibroblastic and fibroblastic spindle cells accompanied by a dense inflammatory infiltrate consisting of plasma cells, lymphocytes, and occasionally eosinophils. IMT may arise in almost any part of the body. In the gastrointestinal tract, IMT may be confused with inflammatory fibroid polyps (IFP). However, IFP can be distinguished histopathologically by the presence of stellate cells, reactive blood vessels, and a prominent infiltrate rich in eosinophils.

Material and Methods: A 50-year-old male patient presented to our emergency department with a five-day history of abdominal pain. The patient had no previous history of abdominal surgery, no known comorbidities, no regular medication use, and no history of drug allergy. He reported the onset of vomiting on the day of admission. Physical examination revealed a distended abdomen. Vital signs were stable. Due to persistent nausea, a nasogastric tube was inserted and oral intake was discontinued. Abdominal computed tomography was performed as an additional diagnostic evaluation. The presence of a target sign, which is pathognomonic for intussusception, was detected on computed tomography, and surgery was planned with a preliminary diagnosis of intussusception. Intraoperatively, an intussuscepted small bowel segment was identified 250 cm distal to the ligament of Treitz. The involved small bowel segment, including the intussusception site, was laparoscopically resected with proximal and distal margins, and primary anastomosis was performed. Figure 1: HE-stained section showing the relationship between intestinal mucosa and mass at 4x magnification, Figure 2: ALK-D5F3 positive staining area in the tumor during immunohistochemical examination at 10x magnification.

Results: The pathological examination revealed a submucosal, polypoid inflammatory mass measuring 5.5×3.5×3 cm, composed of spindle cells with focal myxoid and fibroid stroma. Immunohistochemical analysis demonstrated ALK positivity, and the lesion was diagnosed as an inflammatory myofibroblastic tumor.

Conclusion: Adult intestinal intussusception is a rare clinical condition. Contrast-enhanced computed tomography is a useful radiological modality and plays a crucial role in the diagnosis of the disease. IMT is a rare pathological entity with low rates of recurrence and metastasis after surgical resection. However, the diagnosis may be overlooked in the preoperative period.

A rare concurrence in acute abdomen: Simultaneous acute appendicitis, acute cholecystitis, acute pancreatitis

Mert Gacemer, Hüseyin Bayram, Ozan Barış Namdaroğlu

Department of General Surgery, University of Health Sciences Türkiye, İzmir Tepecik Education and Training Hospital, İzmir

Objective: Acute appendicitis, acute cholecystitis, and acute pancreatitis are common causes of acute abdomen; however, the concomitant occurrence of all three conditions is exceedingly rare. Overlapping clinical presentations may pose significant diagnostic and therapeutic challenges. This case report presents this uncommon coexistence.

Material and Methods: This case report describes the coexistence of acute appendicitis, acute cholecystitis, and acute pancreatitis in a patient presenting to the emergency department with acute abdomen. Clinical presentation, laboratory findings, and radiological imaging were retrospectively reviewed. Contrast-enhanced whole-abdominal computed tomography was used for diagnostic evaluation. Diagnostic laparoscopy was performed, and intraoperative findings were documented. The postoperative clinical course, laboratory parameters, and treatment response were assessed through review of the patient's medical records.

Results: A 48-year-old female patient with no known comorbidities presented to the emergency department with a two-day history of epigastric and lower quadrant abdominal pain accompanied by loss of appetite. Physical examination demonstrated tenderness in the epigastric region and right lower quadrant. Laboratory evaluation revealed the following values: leukocyte count, 12.82×10^3/μL; C-reactive protein, 2.2 mg/dL; aspartate aminotransferase, 107 U/L; alanine aminotransferase, 52 U/L; lipase, 5041 U/L; total bilirubin, 1.01 mg/dL; and direct bilirubin, 0.52 mg/dL. Contrast-enhanced abdominal computed tomography was performed at presentation. Imaging demonstrated fluid accumulation extending to the umbilical region at the level of the pancreatic head and body. The gallbladder appeared hydropic, with inflammatory wall thickening and pericholecystic fluid collection (Figure 1). A millimetric image suggestive of a gallstone was noted within the gallbladder lumen. The distal segment of the appendix measured approximately 10 mm in diameter and exhibited an inflammatory appearance, suggesting acute appendicitis (Figure 2). Based on the clinical, laboratory, and radiological findings, diagnostic laparoscopy was performed. Intraoperatively, the gallbladder was found to be edematous and inflamed, without evidence of necrosis (Figure 3). Appendectomy was performed due to the edematous and inflamed appearance of the appendix. Examination of the excised appendix revealed the presence of a fecalith (Figure 4). Postoperatively, the patient was managed with medical therapy and close monitoring. With improvement in clinical and laboratory parameters, the patient was discharged on postoperative day 4.

Conclusion: The simultaneous presence of multiple pathologies in acute abdomen is uncommon but may complicate diagnosis. In this case, contrast-enhanced abdominal CT was crucial in identifying concurrent acute pancreatitis, acute cholecystitis, and acute appendicitis. Successful outcomes were achieved with appropriate surgical and medical management. Clinicians should consider the possibility of multiple coexisting pathologies in patients presenting with acute abdomen.

Keywords: Acute abdomen, acute appendicitis, acute cholecystitis, acute pancreatitis, concurrent abdominal pathologies

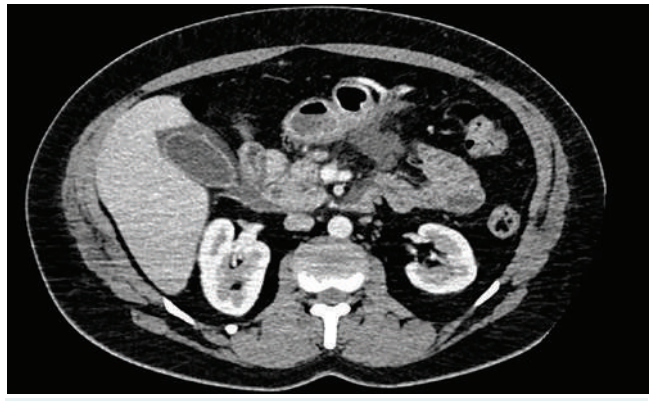

Figure 1. Computed tomography image of the gallbladder and pancreas. Contrast-enhanced CT image showing a hydropic gallbladder with wall thickening and pericholecystic and peripancreatic fluid collection, suggestive of acute cholecystitis and acute pancreatitis.

Anterior abdominal wall necrosis following horse serum injection: A rare case

Büşra Ekici, Yasin Ekici

Clinic of General Surgery, Kütahya City Hospital, Kütahya

Objective: To date, tissue necrosis following subcutaneous horse serum injection in humans has not been reported. However, immune-mediated reactions to heterologous sera, such as the Arthus reaction, a type III hypersensitivity response caused by immune complex deposition in small vessels, and systemic reactions including serum sickness after equine-derived rabies immunoglobulin have been described. In addition, Nicolau syndrome, a rare complication of parenteral drug administration characterized by pain, edema, erythema, and necrotic plaque formation, is well recognized. To the best of our knowledge, this case represents the first report of localized tissue necrosis following parenteral horse serum administration in humans.

Material and Methods: A 46-year-old woman with invasive carcinoma of the left breast was started on neoadjuvant doxorubicin-cyclophosphamide (AC) chemotherapy. Her medical history was significant for diabetes mellitus and obesity. During active chemotherapy, she reported self-administering a preparation containing equine serum, obtained from a veterinarian, without medical supervision, by subcutaneous injection into the abdominal wall at eight different sites, repeated weekly for a total of seven injections. Five days after receiving the third chemotherapy cycle, she presented with malodorous, exudative necrotic lesions on the anterior abdominal wall. Laboratory evaluation revealed leukopenia (4.530/µL), anemia (Hb 9.9 g/dL), and elevated inflammatory markers (CRP 65 mg/L). Abdominal computed tomography showed no intra-abdominal involvement. Early surgical debridement was performed, and eight separate necrotic/gangrenous lesions were excised and sent for histopathological analysis. Postoperatively, oral intake was resumed, antibiotic therapy was initiated, and chemotherapy was temporarily suspended due to infection. The patient was discharged on postoperative day 3 with outpatient wound care. Two sites developed superficial wound dehiscence during follow-up and were managed conservatively. Complete wound healing was achieved by postoperative day 21, after which the patient was referred back to oncology.

Results: Histopathological findings: All eight skin and subcutaneous tissue specimens showed epithelial ulceration, chronic inflammation, and fat necrosis, with no evidence of malignancy.

Conclusion: This case demonstrates that subcutaneous injection of horse serum into the abdominal wall, performed without medical supervision, can result in severe local soft tissue necrosis in an immunosuppressed breast cancer patient receiving active chemotherapy. Inappropriate use of heterologous animal sera may lead to rapidly progressive complications requiring surgical intervention, particularly in immunocompromised individuals. The clinical course and pattern of tissue injury in this case show similarities to Nicolau syndrome, a rare complication characterized by necrotic plaque formation following parenteral drug administration. This report highlights the potential risks associated with uncontrolled injections used for alternative treatment purposes.

Keywords: Horse serum, necrosis, nicolau syndrome, immunosuppression, case report

Gastric perforation secondary to incarcerated hiatal hernia associated with severe lactic acidosis in a 98-year-old patient

Hakan Ataş

Department of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Hiatal hernias are anatomical defects characterized by the displacement of the gastric fundus into the mediastinum. Paraesophageal hernias (types II-IV) may predispose patients to life-threatening surgical emergencies such as gastric volvulus and strangulation. In the literature, perforations due to gastric strangulation are associated with high mortality rates. This presentation discusses a case of hiatal hernia perforation at an extreme age, accompanied by a severe lactic acidosis profile.

Material and Methods: A 98-year-old female patient presented to the emergency department with sudden-onset, severe left-sided chest pain radiating to the back, dyspnea, and hematemesis. Initial examination revealed hypertension (140/85 mmHg), tachycardia (110 bpm), tachypnea (24 bpm), and hypoxia (SpO_2: 88%). Auscultation showed diminished breath sounds in the left lung; the abdomen was soft and non-tender.

Results: Chest X-ray revealed a widened mediastinum and a mass appearance with an air-fluid level in the left retrocardiac area (Figure 1). Arterial blood gas analysis demonstrated severe metabolic acidosis (pH: 7.23, lactate: 6.43 mmol/L). Thoraco-abdominal CT showed significant herniation of the stomach into the posterior mediastinum, 25 mm of free fluid, and free intraperitoneal air. The patient was taken for emergency surgery. Exploration revealed a strangulated gastric fundus herniated through a 4 cm hiatal defect. A 2 cm perforation was identified in the herniated fundus (Figure 2). Following irrigation and debridement, a wedge resection including the perforated area was performed, and the hiatal defect was repaired primarily. The patient, followed postoperatively in the intensive care unit under intubation, succumbed 48 hours later.

Conclusion: In elderly patients, strangulation of hiatal hernias may be masked by chest pain and respiratory distress instead of typical acute abdominal findings. As stated in the literature, lactate levels above 6 mmol/L are among the strongest predictors of tissue necrosis and poor prognosis. Despite early radiological diagnosis and surgical intervention, mortality may be inevitable in the presence of extreme age and profound acidosis. This case emphasizes the importance of considering hiatal hernia complications in the differential diagnosis of acute chest pain in the elderly.

Keywords: Incarcerated hiatal hernia, gastric perforation, lactic acidosis,

A rare cause of acute abdomen: Spontaneus rupture of a splenic hydatic cyst

Erhan Kızılkaya, Furkan Yazıcıoğlu, Bilal Aydoğmuş, Denizhan Kılıç, Gökhan Söğütlü

Department of General Surgery, Turgut Özal University, Malatya Training and Research Hospital, Malatya

Objective: Echinococcus, or hydatid disease, has four main subtypes: *Echinococcus granulosus, Echinococcus multilocularis, Echinococcus vogeli*, and *Echinococcus oligarthrus. Echinococcus granulosus* causes cystic echinococcosis (CE) and is the most commonly encountered clinical form. Although hydatid disease most commonly involves the liver and lungs, splenic involvement is reported in approximately 5% of cases. Cyst rupture in these patients is usually associated with trauma; however, spontaneous rupture may rarely occur. In this study, we aimed to increase awareness among general surgeons of a rare, life-threatening cause of acute abdomen.

Material and Methods: We present the case of a 45-year-old female patient who was admitted with sudden onset of severe abdominal pain and was diagnosed with spontaneous rupture of a splenic hydatid cyst.

Results: A 45-year-old female patient with no comorbidities presented with sudden, severe abdominal pain without any history of trauma. Physical examination revealed generalized abdominal guarding and rebound tenderness, more pronounced in the left upper quadrant. Contrast-enhanced abdominal CT demonstrated diffuse free intraperitoneal fluid in all quadrants and a splenic lesion consistent with a hydatid cyst. No hepatic lesions were detected. The patient presented within two hours of pain onset. Laboratory evaluation showed mildly elevated C-reactive protein and leukocyte levels. Emergency exploratory laparotomy was performed. Intraoperatively, widespread free fluid compatible with cyst contents, a perforated cyst capsule originating from the spleen, and germinative membranes were observed. Cystotomy and extensive peritoneal lavage were performed. No daughter cysts were identified. The postoperative course was uneventful. Albendazole therapy was initiated at a dose of 15 mg/kg/day divided into two doses. The patient was discharged in good condition on postoperative day four.

Conclusion: Although splenic hydatid cysts are rare, cyst rupture represents a life-threatening cause of acute abdomen and may lead to anaphylactic shock. Early recognition and prompt surgical management are crucial.

Keywords: Splenic hydatid cyst, acute abdomen, spontaneous rupture

Ileal ischemia due to superior mesenteric vein thrombosis: A case managed with emergency surgery

Elif Yılmaz

Ordu Umut Private Hospital, Ordu

Objective: Superior mesenteric vein (SMV) thrombosis is uncommon but can quickly progress to bowel ischemia if missed. This case highlights that symptoms mimicking obstruction may actually reflect mesenteric venous thrombosis.

Material and Methods: Sixty sevenyearold man presented with 3 days of obstipation, nausea, and vomiting. He had hypertension, cirrhosis, and peripheral arterial disease, with no prior abdominal surgery. After contrast-enhanced CT, emergency laparotomy was performed.

Results: CT showed marked small-bowel dilatation, diffuse wall thickening of ileal loops in the right lower quadrant, and mesenteric heterogeneity. A thrombus completely occluding the SMV with extension toward the portal vein was detected, and the liver had a cirrhotic appearance. At surgery, an approximately 100 cm ileal segment starting ~20 cm proximal to the ileocecal valve was ischemic/necrotic with absent peristalsis. Segmental small-bowel resection was performed and a Mikulicz (doublebarrel) ileostomy was created. The patient resumed oral intake on postoperative day 1 and was discharged uneventfully on day 7. Pathology confirmed transmural ischemia/necrosis with hemorrhage and edema.

Conclusion: In patients presenting with an ileus-like picture, SMV thrombosis should be considered-especially when cirrhosis or vascular disease is present. Prompt CT and timely surgery can limit bowel loss and improve outcomes.

Keywords: Ileal ischemia, mesenteric vein thrombosis, ileus, emergency surgery

Gas embolism following hydrogen peroxide ingestion: A case successfully treated with hyperbaric oxygen

Fatma Dikişer, Selen Öztürk, Saltuk Yıldız, Ozan Barış Namdaroğlu, Savaş Yakan

University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Hydrogen peroxide (H_2O_2) ingestion can result in gas embolism, a rare but potentially serious morbidity and mortality event. The extent of vascular involvement varies, and early diagnosis is crucial. Hyperbaric oxygen therapy (HBOT) is the primary treatment for gas embolisms.

Material and Methods: A 54-year-old male cleaning worker with no significant medical history presented to the emergency department with severe nausea and retrosternal pain after ingesting approximately 250 mL of 3% H_2O_2 orally. He was oriented, cooperative, vital signs were stable. Systemic examination was normal. Abdominal examination revealed no tenderness, guarding; rebound tenderness.Laboratory tests showed moderate leukocytosis ($12.68x10^3/\mu L$). Liver function parameters were normal. Contrast-enhanced abdominal CT scan revealed widespread gas emboli within the portal venous structures and mesenteric vascular structures but no perforation. Admitted to the ICU for close vital sign monitoring and systemic examination. Following a control CT, HBOT was administered. A subsequent CT showed a dramatic regression of the gas emboli. The patient was transferred to the ward for observation and continued monitoring with closed oral access. During follow-up, nausea subsided, abdominal examination was comfortable, and oral intake was gradually increased after symptomatic treatment. The patient was discharged in good health on the 7th day of follow-up.

Results: When H_2O_2 is ingested in high concentrations and large quantities, systemic effects can occur in addition to damage to the gastrointestinal and respiratory systems. In this case, the detection of widespread gas emboli in the portal venous system on CT findings indicates that the gas formed after H_2O_2 ingestion entered the systemic circulation. Even when H_2O_2 is ingested in low concentrations, it is rapidly broken down into water and oxygen by the catalase enzyme in the gastrointestinal system. The volume of released gas can increase; this can lead to the development of gas emboli in the portal venous system,mesenteric vessels,and even the cerebral circulation. Clinical findings can vary widely, from mild symptoms to fatal outcomes. If swallowed, 30 mL of 35% H_2O_2 is sufficient to produce 3.4 L of oxygen gas. In the literature, studies on the systemic effects of H_2O_2 and gas embolism frequently highlight the effectiveness of oxygen therapy and HBOT. The effectiveness of HBOT in the direct treatment of gas embolism has been proven in many studies. A review titled "Hyperbaric Oxygen Therapy for the Treatment of Decompression Sickness and Gas Embolism" reported that hyperbaric oxygen therapy improves patient outcomes in gas embolism by accelerating the dissolution of gases.

Conclusion: Gas embolism developing after H_2O_2 ingestion is a serious condition requiring urgent diagnosis and treatment. This case clearly demonstrates the effectiveness of HBOT in gas embolism management. Early intervention can improve the patient's prognosis and reduce the risk of complications. Monitoring and treating such conditions plays a crucial role in healthcare systems.

A rare cause of acute abdomen: Isolated mixed-type gastric volvulus unaccompanied by hiatal hernia

Saltuk Yıldız, Selen Öztürk, Savaş Yakan

Department of General Surgery, University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Gastric volvulus is a rare but life-threatening surgical emergency resulting from abnormal rotation of the stomach. Although commonly associated with hiatal hernia, primary volvulus due to ligamentous laxity is infrequent. GV is classified as organo-axial, mesentero-axial, or mixed-type. While hiatal hernia or diaphragmatic defects accompany approximately 70% of cases, we aim to present a rare case of isolated mixed-type gastric volvulus without any anatomical defects.

Material and Methods: Ninety-one-year-old male with dementia presented to the emergency department with sudden onset abdominal pain and distension. Physical examination revealed severe abdominal distension. Contrary to Borchardt's triad, which typically includes the inability to pass a nasogastric (NG) tube, an NG tube was successfully inserted, and gastric content was drained. Although the initial non-contrast computed tomography (CT) did not explicitly report volvulus, the non-visualization of the spleen and high clinical suspicion prompted a contrast-enhanced CT. Imaging revealed massive gastric dilation with air-fluid levels. The orientation of the stomach and the medialization of the spleen were consistent with mixed-type volvulus. No hiatal hernia or diaphragmatic defect was identified, suggesting a primary etiology due to ligamentous laxity. Endoscopic detorsion was attempted but failed.

Results: The patient underwent emergency laparotomy. Intraoperative exploration confirmed the absence of a hiatal hernia and the presence of mixed-type rotation. The stomach was detorsed to its anatomical position, and the spleen was reduced. Serosal tears caused by distension were repaired primarily. A gastropexy was performed to prevent recurrence. Considering the patient's advanced age, dementia, and nutritional requirements, a Stamm gastrostomy was utilized. This procedure reinforced the gastropexy and established a secure route for enteral feeding. The patient was discharged on postoperative day 15 without complications.

Conclusion: The successful passage of an NG tube should not rule out gastric volvulus, especially in mixed-type or incomplete torsion cases where the gastroesophageal junction may remain patent. CT is the gold standard for diagnosis and surgical planning, particularly for identifying primary volvulus. In elderly patients with comorbidities, Stamm gastrostomy serves as a life-saving adjunct, providing both effective fixation and a reliable avenue for postoperative care.

Keywords: Gastric volvulus, volvulus

Figure 1. Axial plane computed tomography image. The NG tube have entered the stomach, and there was no diaphragmatic anomaly. The spleen was also observed to be retracted medially.

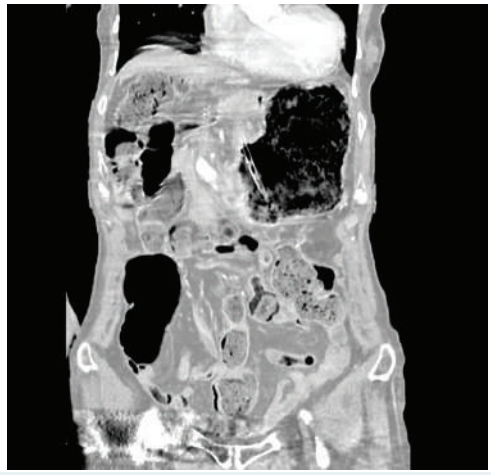

Figure 2. Coronal plane computed tomography image.

Complicated jejunal diverticular perforation: Our case experience

Saltuk Yıldız, Selen Öztürk, Savaş Yakan

Department of General Surgery, University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Jejunal diverticular disease is a rare clinical entity with an incidence ranging from 0.06% to 1.3%. While the majority of cases remain asymptomatic, complications such as diverticulitis and, more rarely, perforation can develop. We aim to present two cases of complicated jejunal diverticular disease managed with emergency surgery.

Material and Methods: Case 1 A 94-year-old female with no known comorbidities presented with abdominal pain persisting for one week. Examination revealed bilateral spontaneously reduced inguinal hernias and generalized abdominal tenderness. Laboratory results showed CRP: 244.2 mg/L and procalcitonin: 3.3 µg/L. Abdominal CT suggested intestinal perforation with free air and fluid. During emergency laparotomy, diffuse purulent fluid was observed. Extensive jejunal diverticula were noted 30-100 cm distal to the ligament of Treitz, with a perforation identified at the 50 cm mark. Segmental small bowel resection and double-layer isoperistaltic side-to-side anastomosis were performed. The patient was transferred to the ICU but unfortunately developed cardiac arrest and passed away 6 hours postoperatively. Cultures grew *Klebsiella pneumoniae* and *E. coli*.

Results: Case 2 A 69-year-old male with hypertension and diabetes presented with generalized abdominal pain of one-day duration. Examination revealed generalized tenderness and rebound in the left lower quadrant. CRP was elevated (245 mg/L). CT imaging showed inflammatory density increases in the small bowel mesentery and diverticula in the colon. Upon exploration, purulent fluid and a perforated area with diffuse diverticula were found 20-60 cm distal to the ligament of Treitz. Segmental resection and double-layer isoperistaltic side-to-side anastomosis were performed. The patient recovered well, started oral intake on postoperative day 4, and was discharged on day 7. Pathology confirmed phlegmonous diverticulitis.

Conclusion: Jejunal diverticulitis is far less common than colonic diverticular disease and typically affects patients in their sixth and seventh decades. Consequently, jejunal diverticulitis, which can be life-threatening due to delayed diagnosis, must be considered in the differential diagnosis of acute abdomen, particularly in elderly patients.

Gastrointestinal manifestations of rheumatoid arthritis

Musa Serin, Hakkı Çoşkun, Abdülkadir Safa

Sivas Cumhuriyet University Faculty of Medicine, Sivas

Objective: Rheumatoid arthritis (RA) and related spondyloarthropathies are primarily systemic inflammatory diseases affecting the joints; however, they may occasionally present with extra-articular involvement, including the gastrointestinal system and intra-abdominal tissues. The literature reports that such involvement can pose diagnostic difficulties and is often confused with infectious or malignant processes. Granulomatous and necrotizing lesions, in particular, require the exclusion of infectious causes, especially tuberculosis, in the differential diagnosis.

Material and Methods: Case A 30-year-old female patient had been followed up by rheumatology since 2019 with a diagnosis of ankylosing spondylitis. She presented to the emergency department on 31.01.2024 with acute abdominal pain. She reported pain in the right lower quadrant, suprapubic region, and left lower quadrant. Physical examination revealed acute abdomen. Laboratory findings: WBC: 8.03×10^9/L, neutrophils 43%, lymphocytes 49.4%, Hgb: 13.2 g/dL, PLT: 305×10^9/L, CRP: 2.2 mg/L, ALT: 43, AST: 33, LDH: 223, non-contrast upper abdomen CT scan revealed areas with fatty density and contamination in the surrounding fatty planes were detected at the umbilical level adjacent to the right anterior abdominal wall, and omental infarction was considered as the primary diagnosis. Based on the clinical and radiological findings, a decision was made to perform surgical exploration.

Results: During the operation, abnormal tissues were observed on the uterus and in the vicinity of the bladder, and excision was performed. Pathological examination revealed a necrotizing palisading granulomatous reaction in yellow-beige colored tissue samples. The pathology report stated that the findings were consistent with RA and extra-articular involvement of rheumatoid variants, and recommended further investigation for granulomatous diseases (especially tuberculosis). These findings are consistent with the literature on rare gastrointestinal and intra-abdominal involvement in rheumatological diseases.

Conclusion: The PPD (tuberculin) test and ARB staining microscopy performed on the patient were negative. Tuberculosis has been ruled out. This case highlights the rare extra-articular involvement that can present with an acute abdominal picture in inflammatory rheumatic diseases such as ankylosing spondylitis. In cases where granulomatous and necrotizing lesions are detected, infectious causes must be ruled out; however, the systemic effects of rheumatological disease should also be considered in the differential diagnosis. A multidisciplinary approach is critical for accurate diagnosis and appropriate management.

Primary necrotizing fasciitis of the breast: Case report

Barış Rafet Karakaş[1], Duygu Dikici[1], Özlem Vardar Gök[2], Arsenal Sezgin Alikanoğlu[3], Arif Aslaner[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya*

[2]*Department of Radiology, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya*

[3]*Department of Pathology, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya*

Objective: Necrotizing fasciitis is a life-threatening infection of the soft tissue and fascia, most often affecting the abdominal wall, extremities, and perineum. We aimed to present a case of primary necrotizing fasciitis with no identifiable risk factors, including trauma, surgery, insect bites, breastfeeding, diabetes, or immunosuppression.

Material and Methods: This is a case presentation of primary breast necrotizing fasciitis.

Results: A 60-year-old woman was treated with oral antibiotics for one week for pain, redness, and swelling in the left breast. She presented to the emergency department with worsening symptoms. Examination revealed erythema, edema, and severe tenderness in a 4x4 cm area from the inner quadrant of the left breast to the sternum (Figure 1A). Laboratory tests showed leukocytosis (17.970 103/mm^3, neutrophils 77%) and elevated C-reactive protein (143.7 mg/L). The LRINEC score was 7. Ultrasound revealed an abscess-like lesion measuring approximately 45×30 mm. Intravenous broad-spectrum antibiotics (piperacillin/tazobactam 3x4.5 g and clindamycin 3x900 mg) and fluid support were initiated. Under general anesthesia, multiple foul-smelling abscesses were drained. A wide surgical resection was performed to remove necrotic tissue extending to the pectoral fascia and sternum. No organisms grew in culture. Vacuum-assisted wound therapy began on postoperative day 5 (Figure 1B). On day 11 a partial-thickness skin graft from the right thigh was applied (Figure 1C-D). Pathology showed abscess and fat necrosis without malignancy. During two years of follow-up, no comorbidities or breast pathology were detected on examination or imaging.

Conclusion: Early diagnosis and combined treatment are essential to reduce mortality and morbidity in primary breast necrotizing fasciitis, due to its rarity and rapid progression.

Keywords: Breast, necrotizing fasciitis, primary

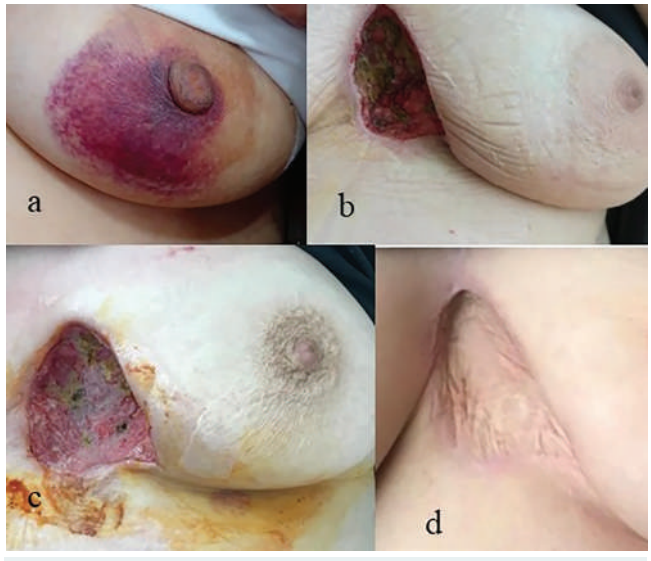

Figure 1. Case of primary necrotizing fasciitis of the breast. a. Necrotizing fasciitis was located in the inner quadrant of the left breast; b. Surgical debridement, 5th postoperative day; c. Partial-thickness skin graft, 11th postoperative day; d. Partial-thickness skin graft, 8th postoperative month.

[P-346]

Small bowel obstruction caused by a mesodiverticular band associated with Meckel's diverticulum: A rare cause of ileus

Güzin Aygün[1], Meltem Hızal[1], Mehmet Mert Demircioğlu[1], Halil Çınar[1], Aslan Teoman Günday[1], Kubilay Kenan Özlük[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, occurring in approximately 2-3% of the general population. It usually remains clinically silent throughout life and is often detected incidentally. Although most patients are asymptomatic, clinical symptoms develop in only about 16% of cases. The most common complications include gastrointestinal bleeding, small bowel obstruction, and diverticulitis. A rare cause of obstruction is the formation of a mesodiverticular band, which can lead to mechanical small bowel obstruction and acute abdomen. In this case report, we present the diagnostic process and surgical management of a rare ileus caused by a mesodiverticular band associated with Meckel's diverticulum.

Material and Methods: An 18-year-old female patient presented to the emergency department with sudden-onset abdominal pain that began in the morning and was accompanied by nausea and vomiting. She reported no passage of flatus or stool. The patient had no known comorbidities. Her surgical history included an appendectomy and an abdominal operation performed six years earlier for ileus. Physical examination revealed abdominal distension and diffuse tenderness without guarding or rebound tenderness. Digital rectal examination showed an empty rectal ampulla. Laboratory tests demonstrated a C-reactive protein level of 0 mg/L, a white blood cell count of 11.7×10^9/L, and a lactate level of 1.7 mmol/L. Contrast-enhanced abdominal computed tomography revealed dilated small bowel loops with air-fluid levels, reaching a maximum diameter of approximately 34 mm. A transition zone was identified at the ileal level, consistent with mechanical small bowel obstruction.

Results: Based on the clinical and radiological findings, surgical exploration was performed. Intraoperatively, a band originating from the Meckel's diverticulum and extending toward the anterior abdominal wall was identified. This mesodiverticular band caused adhesion and mechanical obstruction of the small bowel. An ischemic area was observed in the bowel segment distal to the diverticulum due to compression by the band. Consequently, segmental small bowel resection with side-to-side anastomosis was performed. The postoperative course was uneventful, and the patient was discharged without complications.

Conclusion: In conclusion, although Meckel's diverticulum is typically asymptomatic, it can rarely cause mechanical small bowel obstruction via a mesodiverticular band. In young patients presenting with acute abdomen, especially those with a history of adhesive ileus, this rare etiology should be considered. Early diagnosis and timely surgical intervention are crucial to prevent bowel ischemia and associated morbidity.

Keywords: Meckel's diverticulum, mesodiverticular band, small bowel obstruction

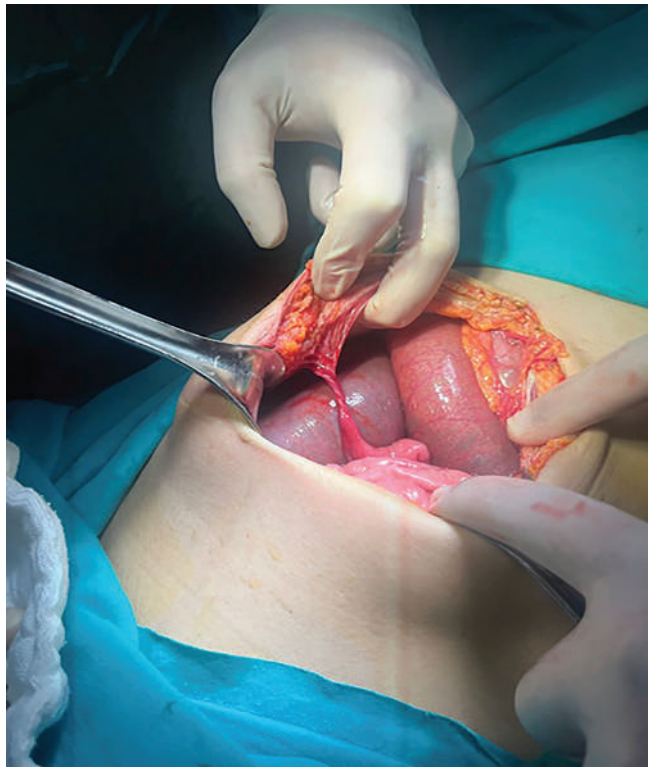

Figure 1. Intraoperative view of a mesodiverticular band arising from Meckel's diverticulum.

[P-347]

Laparoscopic repair of traumatic diaphragmatic injury with gastric incarceration: A rare case

Barış Rafet Karakaş[1], Selahattin Asi[1], Muharrem Özkaya[2], Kemal Eyvaz[1], Uğur Doğan[1], Arif Aslaner[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya*

[2]*Department of Thoracic Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya*

Objective: The incidence of diaphragmatic rupture following thoracoabdominal blunt trauma ranges from 0.8% to 5%. Acute gastric incarceration associated with diaphragmatic hernia in the early period after blunt trauma is exceedingly rare, and delayed diagnosis or treatment can be life-threatening. This report describes a case of traumatic diaphragmatic rupture with gastric incarceration, managed laparoscopically after hemodynamic stabilization in the acute phase in a patient with multiple traumatic injuries.

Material and Methods: This is a case presentation of laparoscopic repair of traumatic diaphragmatic injury with gastric incarceration.

Results: A 50-year-old woman was admitted to the emergency department following a non-vehicular traffic accident. On presentation, she was in poor general condition, intubated, hypotensive, and tachycardic. Laboratory evaluation revealed a hemoglobin of 7.79 g/dL, a creatinine of 0.53 mg/dL, and a C-reactive protein of 2 mg/L. Hemodynamic stabilization was achieved with intravenous fluid resuscitation. Chest computed tomography demonstrated gastric herniation and diaphragmatic rupture in the left hemothorax. Additional imaging identified multiple fractures of the pelvis and bilateral lower extremities. Laparoscopic abdominal exploration under general anesthesia confirmed a gastric herniation incarcerated into the thoracic cavity through an approximately 6x7 cm defect in the left diaphragm (Figure 1). The stomach was reduced into the abdominal cavity using an endo-grasper (Figure 2). Further exploration identified a collapse of the left lung, and a 28-French chest tube was inserted by a thoracic surgeon via the left mid-axillary line at the sixth intercostal space. The diaphragmatic defect was primarily closed with 2/0 polyglycolic acid sutures and reinforced with a 15 cm×10 cm piece of dual-mesh, which was fixed with an absorbable tacker. Orthopedic surgical intervention was subsequently performed for the extremity and pelvic fractures. The patient was discharged without complications at the end of the first postoperative month.

Conclusion: Gastric incarceration after diaphragmatic rupture is rare. Early diagnosis and prompt surgical intervention are essential once hemodynamic stability is achieved, and major injuries are excluded. Laparoscopic repair is a safe and effective treatment option.

Keywords: Trauma, diaphragm, incarceration

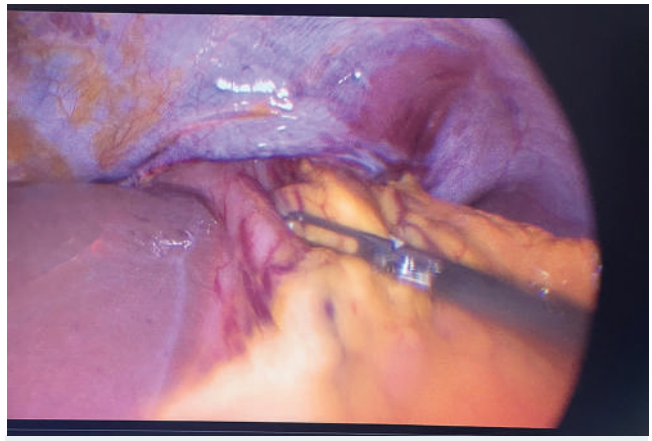

Figure 1. Laparoscopic view of gastric incarceration.

[P-348]

Diagnosis and management of esophageal injury in cervical gunshot wounds: A case report

Bülent Toksöz, Hakan Köksal, Abdülkadir Çalışkan, Ali İmran Küçük, Mehmet Aziret

University of Health Sciences Türkiye, Balıkesir Atatürk City Hospital; Balıkesir University Health Practice and Research Hospital, Balıkesir

Objective: Cervical gunshot injuries are associated with a high risk of morbidity and mortality due to the close anatomical proximity of vital structures, including major vascular components, the trachea, and the esophagus. Although esophageal injuries are relatively uncommon, delayed diagnosis may result in severe and potentially life-threatening complications. In this case report, we present an esophageal injury secondary to a cervical gunshot wound, in which the diagnostic process was particularly challenging.

Material and Methods: This study comprises evaluation of a single patient managed with suspected esophageal injury following a cervical gunshot wound. The patient's clinical findings, imaging modalities, and endoscopic examination results were analyzed in detail. Following the diagnostic workup, surgical exploration was performed. A mucosal defect identified during intraoperative endoscopic assessment was primarily repaired. The patient was subsequently monitored in terms of postoperative clinical course, enteral nutritional management, and the development of potential complications.

Results: A 20-year-old male presented on February 2, 2026, with a gunshot wound to the neck. He was conscious (GCS: 15) and hemodynamically stable on admission. Physical examination revealed two entry wounds on the left cervical region and one exit wound over the left scapula. A bullet was palpated subcutaneously in the right cervical area. Minimal cervical and mediastinal emphysema were detected. Tetanus prophylaxis and intravenous antibiotics were initiated. A left clavicle fracture was identified, and the patient was admitted for observation. During follow-up, serous discharge from the cervical wound raised suspicion of esophageal perforation, and he was referred to a tertiary center. Imaging demonstrated pneumomediastinum without definitive evidence of perforation. Upper gastrointestinal endoscopy revealed a lesion in the cervical esophagus consistent with a fistulous opening, and surgical exploration was undertaken. Exploration via a left cervical oblique incision showed no clear transmural defect. Intraoperative endoscopy identified a blunt mucosal injury, which was repaired primarily. A drain was placed, a surgical gastrostomy was performed, and the retained bullet was removed. The postoperative course was uneventful. Enteral feeding was initiated via gastrostomy, oral intake was gradually resumed, and the patient was discharged without complications.

Conclusion: Despite two separate bullet penetrations to the cervical region, the absence of major vascular or vital organ injury is noteworthy. However, even in hemodynamically stable patients without major organ damage, esophageal injuries may lack clear clinical or radiological findings, leading to potential diagnostic delay. Early endoscopic evaluation in suspicious cases is therefore essential. When indicated, timely surgical exploration reduces morbidity. A multidisciplinary approach and early enteral support further improve clinical outcomes.

Keywords: Cervical gunshot wound, esophageal injury, penetrating neck trauma

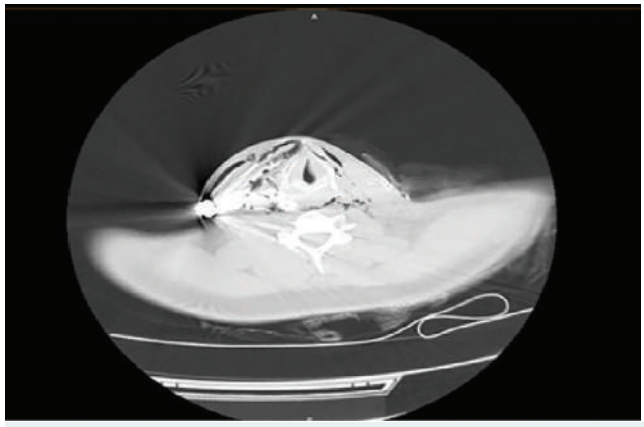

Figure 1. Contrast-enhanced cervical computed tomography demonstrating pneumomediastinum secondary to a cervical gunshot wound and a subcutaneously located bullet in the right cervical region.

[P-349]

Portal and mesenteric venous thrombosis following non-perforated laparoscopic appendectomy: Pylephlebitis in a thrombophilic patient

Mahsum Adıbelli, Yunus Yüksel, Özkan Demiroğlu

University of Health Sciences Türkiye, Diyarbakır Gazi Yaşargil Training and Research Hospital, Diyarbakır

Objective: Pylephlebitis is a rare and life-threatening form of septic thrombophlebitis involving the portal venous system, typically arising as a complication of intra-abdominal infections. While frequently associated with perforated appendicitis, its occurrence following non-perforated (suppurative) cases is exceptionally rare. It is hypothesized that the venous stasis induced by laparoscopic pneumoperitoneum, when combined with a genetic thrombophilic predisposition, may trigger thrombosis within the portal and mesenteric vascular beds. This report presents a unique case of extensive portal vein thrombosis (PVT) and superior mesenteric vein (SMV) occlusion following non-perforated laparoscopic appendectomy.

Material and Methods: A 39-year-old female (G6P5A1) with a medical history of type 2 DM, coronary artery disease, and recurrent pericardial effusion (on chronic colchicine therapy) underwent laparoscopic appendectomy for acute appendicitis. Preoperative contrast-enhanced computed tomography (CT) demonstrated normal portal and mesenteric vasculature. Following a non-perforated appendectomy, the patient was discharged on postoperative day one. On the second day, she developed nausea, vomiting, abdominal pain, and fever, eventually presenting to the emergency department one week later. Laboratory findings revealed leukocytosis and elevated CRP, along with increased ALP and GGT levels. Notably, AST, ALT, and lactate levels remained within normal limits throughout the clinical course. Contrast-enhanced CT revealed extensive thrombosis in the portal vein and total occlusion of the proximal SMV, though distal vascular perfusion was preserved. The patient was hospitalized and treated with intravenous broad-spectrum antibiotics and systemic anticoagulation. By day ten, biochemical parameters normalized, and she was discharged on anticoagulant therapy. Subsequent thrombophilia screening at a transplant center identified MTHFR C677T (heterozygous mutant) and PAI-1 (4G/5G) (heterozygous) mutations.

Results: Pylephlebitis can develop even in the absence of macroscopic perforation due to microscopic bacterial translocation triggered by increased intraluminal pressure. Laparoscopic pneumoperitoneum-induced stasis further facilitates the progression of this septic process into PVT and SMV occlusion. The preservation of normal transaminase and lactate levels, despite total proximal SMV occlusion, is attributed to maintained distal collateral perfusion preventing intestinal ischemia. The identified *MTHFR* and *PAI-1* mutations, exacerbated by surgical stress and systemic inflammation, likely catalyzed the coagulation cascade.

Conclusion: Pylephlebitis following non-perforated appendicitis is a silent, catastrophic vascular event that can be masked by normal transaminase and lactate levels. Surgeons must not be misled by a "false sense of security" provided by conventional laboratory findings; high clinical suspicion and early radiological evidence are paramount to prevent this surgical tragedy.

Keywords: Laparoscopic appendectomy, pylephlebitis, portomesenteric vein thrombosis

[P-350]

Necessity of endoscopic screening in liver donors: A donor diagnosed with rectal cancer

Muzaffer Çınar, Alper Sözütek, Muhammed Mustafa Özdemir

University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Donor safety is maintained at the highest level during living-donor liver transplantation processes. Although donor candidates are routinely screened for malignancy, the scope of screening protocols—particularly the necessity of endoscopic imaging—remains a subject of debate. In this presentation, we aimed to discuss donor screening processes in light of the literature, based on a case diagnosed with advanced-stage rectal cancer one year after becoming a liver donor.

Material and Methods: This study presents a retrospective analysis of a patient managed in our clinic.

Results: A 42-year-old female patient, who had served as a living liver donor at an external center one year ago, presented to our clinic with the complaint of rectal bleeding. Rectoscopy revealed a mass encircling approximately 270 degrees of the lumen at a distance of 10 cm from the anal verge, and multiple biopsies were performed. The pathological examination reported a focus of adenocarcinoma *in situ* within an adenomatous polyp. No distant metastasis was detected on chest computed tomography and abdominopelvic magnetic resonance imaging. Since there was no diagnosis of invasive carcinoma, neoadjuvant therapy was not administered. The patient underwent a low anterior resection and a protective loop ileostomy. Following an uneventful postoperative period, the patient was discharged in good health. The final pathology was reported as adenocarcinoma (grade 3, pT3) with a tumor diameter of 5 cm and 13 tumor-free lymph nodes. The patient was referred for oncology follow-up to plan adjuvant therapy.

Conclusion: This case opens for discussion the necessity of endoscopic screening, particularly in donor candidates over the age of 40 or those with familial risk factors. To enhance donor and recipient safety, updating screening algorithms based on age and risk factors would provide a significant contribution to the literature.

Keywords: Living liver donor, rectal cancer, donor evaluation

[P-351]

Middle aortic syndrome (MAS)

Zekeriya Uçur, Metin Tilki

University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Middle aortic syndrome (MAS) is a rare vascular disorder characterized by segmental stenosis of the abdominal aorta and/or the distal descending thoracic aorta, frequently involving its major branches, and arising from either congenital or acquired etiologies. The condition predominantly affects young patients and typically manifests as refractory hypertension, lower extremity claudication, and signs of impaired end-organ perfusion. Owing to the non-specific nature of its clinical presentation, diagnosis is often delayed, thereby increasing the risk of severe cardiovascular complications. Herein, we report a case of MAS with delayed diagnosis in a young female patient.

Material and Methods: The clinical, laboratory, and imaging findings of a patient with a history of refractory hypertension, lower extremity claudication, and cardiac complications were retrospectively evaluated. The diagnostic workup included physical examination findings in conjunction with computed tomography angiography. The anatomical characteristics of the abdominal aorta and its major branches, as well as the presence of potential vascular anomalies, were examined in detail.

Results: The 24-year-old female patient initially presented with symptoms of claudication in 2019. In 2021, she required admission to the intensive care unit due to pulmonary edema secondary to heart failure. Between 2022 and 2023, she had recurrent hospitalizations for refractory hypertension. Computed tomography angiography demonstrated complete narrowing of the abdominal aorta. Marked anatomical variations were identified in the origin and course of the celiac trunk, superior mesenteric artery, and renal arteries. The left renal artery was not clearly visualized, and the distal segment of the celiac artery appeared short and hypoplastic. These findings were considered consistent with MAS.

Conclusion: MAS should be considered in the differential diagnosis of young patients presenting with refractory hypertension and lower extremity claudication. Early diagnosis is critical for preventing heart failure and other serious vascular complications. Appropriate imaging modalities and a multidisciplinary approach play a pivotal role in establishing the diagnosis.

Stoma management in a patient with high-output ileostomy following mesenteric ischemia: A case report

Sibel Turgut, Erkan Güler

Department of General Surgery, Mersin University Faculty of Medicine, Mersin

Objective: Acute mesenteric ischemia caused by mesenteric artery thrombosis is a life-threatening condition associated with high morbidity and mortality. In emergency bowel resections, stoma site marking is often not feasible, increasing the risk of postoperative stoma-related complications. High-output ileostomy is a challenging clinical condition that may lead to severe fluid-electrolyte imbalance and peristomal skin complications, complicating postoperative management.

Material and Methods: This report retrospectively evaluates the clinical course and stoma care management of a patient who underwent emergency surgery for mesenteric ischemia with creation of a double-barrel ileostomy. Stoma characteristics, postoperative complications, nursing interventions, and medical management strategies were reviewed.

Results: A 74-year-old female patient with a history of diabetes mellitus and hypertension underwent emergency surgery due to extensive mesenteric ischemia. Necrotic segments of the small intestine were resected, and a double-barrel ileostomy was created under emergency conditions without preoperative stoma site marking. Postoperatively, the stoma was located in the left lower quadrant, close to the umbilicus, and was irregularly shaped and mildly retracted. Peristomal skin irritation developed due to exudate leakage from the surgical field. On postoperative day 11, the patient developed a high-output ileostomy with daily output exceeding 2000-2500 mL, accompanied by electrolyte imbalances. Management included fluid and electrolyte replacement, loperamide therapy, and dietary modification. Stoma care involved the use of a two-piece convex appliance, a drainable transparent pouch, skin barrier spray, stoma powder, and a stoma belt. Due to poor compliance of the patient and relatives with stoma care, frequent pouch changes were required. Despite the high surgical risk, ileostomy closure was performed at postoperative week five, and the patient was discharged without complications.

Conclusion: Emergency stoma creation without appropriate site selection increases the risk of high-output stoma and peristomal skin complications. This case highlights the critical role of experienced stoma and wound care nurses within a multidisciplinary team in achieving favorable outcomes in complex surgical patients.

Keywords: High-output stoma, ileostomy, stoma complications

Figure 1. Appearance of a double-barrel ileostomy following emergency surgery, showing stoma retraction and peristomal skin irritation associated with a high-output stoma.

View of a double-barrel ileostomy created after emergency surgery, showing a stoma located below the skin level with surrounding widespread erythema, moisture, and areas of impaired peristomal skin integrity due to leakage.

Mesh migration after graft-reinforced hiatal hernia repair: A case report

Ertan Bülbüloğlu, Hassen Daghmoura, Naim Memmi, Ercan Önder, Uğur Arda

Bezmialem Vakıf University Hospital, İstanbul

Objective: Hiatal hernia is defined as the protrusion of the stomach or other abdominal organs into the thoracic cavity through the diaphragmatic hiatus. Hiatal hernias may be congenital or acquired, and their prevalence increases with age. Predisposing factors include conditions that increase intraabdominal pressure such as obesity, pregnancy, and chronic constipation. The most common presenting symptoms are reflux, dysphagia, and regurgitation; however, respiratory symptoms may also be observed in some cases. Treatment options vary depending on the severity of symptoms and the type of hernia.

Material and Methods: This case report presents the follow-up and treatment process applied after mesh migration that developed in the postoperative sixth month in a patient who had previously undergone grafted repair for hiatal hernia at our hospital.

Results: An 80-year-old female patient presented to the emergency department with complaints of nausea, vomiting, and dysphagia, including difficulty swallowing liquids. Chest radiography and computed tomography revealed a mixed-type giant hiatal hernia. Endoscopic evaluation was attempted but was unsuccessful. Due to persistent symptoms and the development of respiratory distress, the patient—who had a known history of coronary artery disease and hypertension—was taken to surgery under emergency conditions. After reduction of the stomach, duodenum, and colon from the hernia sac back into the abdominal cavity, graft-reinforced hiatal hernia repair was performed using a polypropylene (Prolene) mesh. The patient's postoperative course was uneventful, oral intake was tolerated, and she was discharged. At the sixth postoperative month, the patient re-presented with dysphagia. Contrast-enhanced computed tomography showed no evidence of recurrent hiatal hernia. Upper gastrointestinal endoscopy demonstrated a foreign body in the distal esophagus, which was primarily interpreted as mesh material. Endoscopic extraction attempts by the gastroenterology team and rigid bronchoscopy performed by the thoracic surgery team were unsuccessful. Consequently, the patient was re-operated on by our team. During gastrotomy, a polypropylene mesh protruding into the esophageal lumen was identified and excised. Intraoperative gastroscopy confirmed patency of the esophageal lumen. The patient tolerated an R3 diet on postoperative day 2 and was discharged.

Conclusion: The use of mesh in hiatal hernia repair remains controversial. In addition, biological mesh should be considered as an alternative to polypropylene mesh during mesh selection. Surgeons should be aware that early-term mesh migration may occur following mesh-reinforced hiatal hernia repair.

Keywords: Hiatal hernia, mesh migration

[P-364]

A challenging situation during ERCP: Impacted dormia basket – what should be done?

Hasan Doğru, Müfit Şansal, Mehmet Can Aydın

University of Health Sciences Türkiye, Bursa City Hospital, Bursa

Objective: Since 1974, endoscopic retrograde cholangiopancreatography (ERCP) has been the standard technique for the removal of bile duct stones, achieving success rates of 85-90% using sphincterotomy followed by balloon or basket extraction. Although generally safe, ERCP is associated with complications such as pancreatitis, bleeding, cholangitis, and perforation. Impaction of a Dormia basket is a rare but challenging complication that requires prompt recognition and appropriate management.

Material and Methods: Case 1: An 80-year-old male with coronary artery disease and hypothyroidism presented with jaundice, fever, abdominal pain, nausea, and vomiting. Physical examination revealed icterus and a positive Murphy's sign. Laboratory findings showed elevated bilirubin levels. Imaging demonstrated gallstones up to 11 mm and a 7 mm stone in the common bile duct. During ERCP, a filling defect was observed, and an impacted Dormia basket was encountered. Balloon dilation of the papilla was attempted but unsuccessful, necessitating emergency surgery. Open exploration of the common bile duct was performed, and the impacted basket and stones were removed through a choledochotomy. The patient was monitored in intensive care postoperatively and discharged on postoperative day ten with a cystic duct drain, which was removed after 45 days. Case 2: A 61-year-old male with chronic obstructive pulmonary disease and hypertension presented with similar symptoms. Imaging revealed multiple gallstones, the largest measuring 20 mm, and suspected distal bile duct stones. ERCP demonstrated type I Mirizzi syndrome. Sphincterotomy and biliary stenting were performed, leading to clinical improvement. Twenty days later, the patient returned with recurrent symptoms. Repeat imaging showed stones in the common bile duct. During repeat ERCP, the stent was removed, and an impacted stone in the distal cystic duct was identified. Basket extraction failed, resulting in basket impaction and emergency surgery. Subtotal cholecystectomy and bile duct exploration were performed. As the basket could not be removed, a duodenotomy was required to extract the impacted basket and stones. A cystic duct drain was placed, and the patient was discharged on postoperative day seven.

Results: Dormia basket impaction is reported in 0.8-5.9% of ERCP procedures, usually caused by large or hard stones. Endoscopic techniques such as balloon dilation or mechanical lithotripsy may be attempted; however, surgical intervention becomes necessary when these methods fail. Early recognition and timely surgical management are essential to prevent serious complications.

Conclusion: While ERCP remains an effective method for treating biliary stone disease, clinicians must be prepared to manage rare complications such as Dormia basket impaction. Multidisciplinary approaches and surgical backup are crucial for optimal outcomes.

Keywords: Biliary complications, common bile duct stones, Dormia basket impaction, endoscopic retrograde cholangiopancreatography (ERCP), open surgical intervention

[P-365]

A rare intraoperative pathology in recurrent inguinal hernia: Amyand's hernia

Tarık Yılmaz, Mete Varoğlu, Aydın Yavuz

Department of General Surgery, Gazi University Faculty of Medicine, Ankara

Objective: Amyand's hernia is an extremely rare clinical condition characterized by the presence of the vermiform appendix within an inguinal hernia sac, with an incidence reported between 0.19% and 1% in the literature. This condition may lead to acute appendicitis due to luminal obstruction, vascular compression, and inflammation resulting from the entrapment of the appendix within the hernia sac. Since clinical findings often overlap with incarcerated hernia, preoperative diagnosis is challenging, and definitive diagnosis is frequently made intraoperatively. The occurrence of Amyand's hernia in recurrent cases previously repaired with mesh is a phenomenon reported very limitedly in the literature. This report aims to discuss the management of an Amyand's hernia case detected in a recurrent site following laparoscopic surgery, in light of current literature.

Material and Methods: A 52-year-old male patient, who had undergone laparoscopic transabdominal preperitoneal repair for a right inguinal hernia six years prior, presented with pain and swelling in the right inguinal region for the last three months. Physical examination revealed a reducible mass in the right inguinal region; ultrasonography showed bowel loops and fatty tissue herniating through the fascial defect. The patient was operated on under spinal anesthesia with a preliminary diagnosis of recurrent inguinal hernia, utilizing an open anterior approach. During the dissection of the indirect hernia sac, it was observed that an edematous and hyperemic appendix formed one wall of the sac. According to the Losanoff-Basson classification, the clinical picture was evaluated as "type 2" (acute appendicitis confined to the sac). Following appendectomy, the hernia defect was repaired using the Lichtenstein technique with a self-gripping polypropylene mesh. The operation lasted 45 minutes; the patient had an uneventful postoperative course and was discharged at the 24th hour. Histopathological examination confirmed "acute suppurative appendicitis."

Results: The primary determinant in the surgery of Amyand's hernia is the degree of appendiceal inflammation and the presence of peritonitis. The Losanoff-Basson classification standardizes the surgical strategy at this point; in type 2 cases where contamination is limited, as in our patient, the use of polypropylene mesh alongside appendectomy is considered safe. Although adhesions from previous laparoscopic surgery may complicate dissection in recurrent cases, an open surgical approach allows for direct visualization of the sac and secure repair.

Conclusion: In conclusion, Amyand's hernia should be considered in the differential diagnosis of recurrent inguinal hernia cases. A personalized surgical approach guided by the Losanoff-Basson classification is the key to successful outcomes.

Keywords: Amyand's hernia, Losanoff-Basson classification, recurrent inguinal hernia

Recurrence of hepatocellular carcinoma after liver transplantation: Metastasis initially to the spleen followed by involvement of the pectoral muscle

Kerim Karslı, Özgür Deniz Yazıcı, Pars Tunçyürek

Department of General Surgery, Adnan Menderes University Faculty of Medicine, Aydın

Objective: Hepatocellular carcinoma (HCC) is the most common primary liver malignancy and a leading cause of cancer-related mortality worldwide. Curative options include liver resection and transplantation, the latter offering lower recurrence rates, particularly in cirrhotic patients; however, recurrence occurs in 6-20% of selected cases. Most recurrences develop within the first two years (early recurrence). Extrahepatic recurrences most commonly affect the lungs, lymph nodes, bones, and adrenal glands, whereas late recurrences after two years are rare.

Material and Methods: A 66-year-old male presented in December 2018 with elevated AFP. Imaging revealed two nodules in liver segment VI consistent with HCC. At diagnosis, the patient was Child-Pugh A, and met Milan criteria; thus, a deceased-donor liver transplantation (LT) was performed in October 2019. Explanted liver pathology s howed no viable tumor. Sixty-six months post-transplant, late extrahepatic recurrence developed in the spleen and, eight months later, in the pectoral muscle. The splenic lesion was considered consistent with HCC recurrence, and splenectomy was performed in May 2025. Histopathology confirmed metastatic HCC (3×3×2.7 cm). Postoperative course was uneventful. Eight months after splenectomy, AFP rose to 1139.8 ng/mL. CT and PET/CT revealed a 3.1×2.5 cm lesion in the pectoral muscle with increased FDG uptake (SUV_{max} 4.8). Surgical resection was performed, and pathology confirmed metastatic HCC (4.8×2.3 cm). Early follow-up showed no evidence of further recurrence.

Results: With improved survival, extrahepatic metastases after LT have gained clinical significance. Management of post-LT HCC recurrence generally follows approaches used in non-transplanted patients. Surgical resection may be considered for resectable metastases, alongside systemic therapies, RFA, and TACE. Resectable recurrence is associated with better prognosis, though overall survival remains poor. Extrahepatic metastases usually occur as part of disseminated hematogenous spread, with isolated organ involvement being rare. In our case, late recurrence involved the spleen at 66 months and the pectoral muscle at 74 months post-LT. The impact of metastasectomy on survival remains unclear; however, aggressive approaches including surgical resection may improve outcomes. Disease control for the second pectoral recurrence after splenectomy is under ongoing follow-up.

Conclusion: The survival benefit of surgical resection for isolated extrahepatic metastases of HCC remains unclear; however, in selected patients, it may offer low morbidity and potential for long-term survival. Given the uncertainties in managing recurrent HCC, long-term follow-up and additional evidence are required.

Keywords: Hepatocellular carcinoma, liver transplantation, extrahepatic metastasis

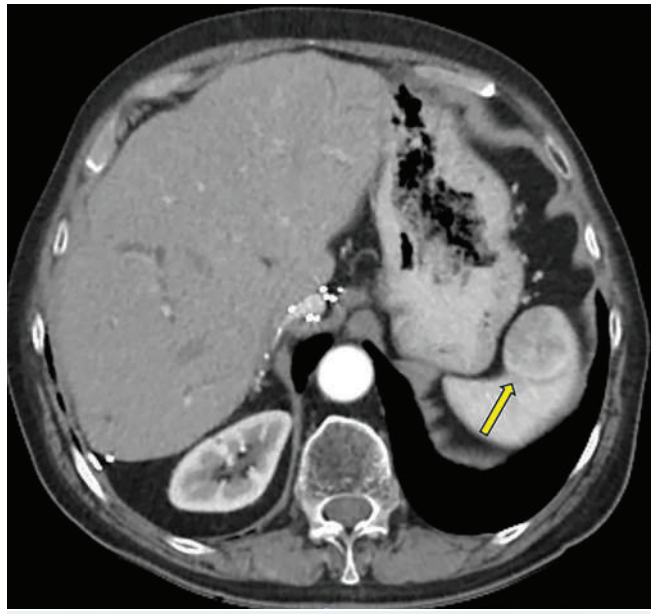

Figure 1. Splenic recurrence of HCC after liver transplantation: on contrast-enhanced axial CT, a splenic mass consistent with recurrent hepatocellular carcinoma is observed. The lesion is indicated by the yellow arrow.

A rare case report: Primary lymphoma of the breast

Miray Maden[1], Mariya Maşta[2], Ahmet Tuğrul Eruyar[3], Nihat Zafer Utkan[2]

[1]*Clinic of General Surgery, Kocaeli City Hospital, Kocaeli*

[2]*Department of General Surgery, Kocaeli University Hospital, Kocaeli*

[3]*Private Innova Pathology Laboratory, Kocaeli*

Objective: Breast lymphoma is a rare hematological malignancy. They are divided into two types: Primary and secondary. Its treatment and prognosis differ from other breast carcinomas. Primary breast lymphoma is rarer. In our case report, we aimed to present the diagnosis and treatment process of a rare primary breast lymphoma, along with a review of the literature.

Material and Methods: A 71-year-old female patient with no other medical conditions besides known hypertension presented with a mass in her right breast. Mammography and ultrasound imaging revealed a 3x2 cm lesion in the upper inner quadrant of the right breast, which was biopsied using a tru-cut biopsy. Pathology reports indicated findings suggestive of lymphoproliferative neoplasia, primarily low-grade follicular lymphoma. Peripheral blood smear, including complete blood count, came back negative for lymphoma. PET-CT scan revealed no other pathological FDG uptake in the body besides the primary tumor uptake in the breast. The oncology council recommended total excision of the lesion for histopathological typing, and the pathology result revealed a grade 1-2 follicular lymphoma. The patient has started chemotherapy.

Results: Breast lymphomas account for less than 1% of breast malignancies. The most common type is diffuse large B-cell lymphoma. It most often presents as breast involvement secondary to systemic disease. Primary and secondary breast lymphomas require different treatment regimens, making a clear distinction between them. Primary breast lymphoma is thought to originate from the lymphoid ducts in the breast, specifically from the intramammary lymph nodes. To be diagnosed as primary breast lymphoma, there must be no history of lymphoma or symptoms at the time of diagnosis, a close association between the lymphoma and breast tissue, and no involvement of organs outside the breast at the time of diagnosis. Based on these criteria, we can diagnose our case as primary lymphoma of the breast. Clinically, patients may exhibit B symptoms similar to those seen in hematological malignancies. There are no specific findings on radiological imaging. Treatment involves systemic chemotherapy and radiotherapy, depending on the histological subtype and stage of the disease. Due to the rarity of primary breast lymphoma, there are no definitive treatment guidelines yet. It is known that excision of the lesion does not contribute to the prognosis. Therefore, surgery is not recommended except for local control or diagnostic purposes. The 5-year survival rate is around 50% for primary breast lymphoma, while it is 25% for secondary breast lymphoma.

Conclusion: Breast lymphomas are clinically similar to other breast carcinomas, but their treatment differs from other breast carcinomas, and accurate diagnosis is crucial to avoid unnecessary surgery.

Keywords: Breast, lymphoma, hematology

A rare cause of asymptomatic spleen cyst: Spleen endometriosis mimicking hydatid cyst

Şükran Çavdar[1], Muhammed Salih Süer[2], Serkan Demir[2], Şener Balas[2]

[1]*Hatay Payas State Hospital, Hatay*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Spleen endometriosis is an extremely rare form of extragenital endometriosis. Diagnosis is difficult in the preoperative period because it often does not present specific clinical and radiological findings. This study aims to present a rare case diagnosed with spleen endometriosis following histopathological examination after surgery for a suspected hydatid cyst.

Material and Methods: A 39-year-old female patient with non-active complaints was evaluated after a cystic lesion was detected inthe upper pole of the spleen on abdominal ultrasound performed for suspected hydatid cyst. Ultrasound revealed a cystic lesion measuring 40×49 mm in the upper pole of the spleen, with smooth lobulated contours, septations, and calcified walls. Contrast-enhanced abdominal computed tomography revealed a cystic lesion measuring approximately 52×40 mm in the anterosuperior section of the spleen, which was multilocular and contained internal septa and calcifications; epidermoid and hydatid cysts were considered in the differential diagnosis. Upper gastrointestinal endoscopy revealed no findings suggestive of malignancy or extrinsic compression. The patient underwent planned laparoscopic splenectomy.

Results: Abdominal ultrasonography demonstrated a 40×49 mm cystic lesion with smooth lobulated contours, internal septa, and calcified walls in the upper pole of the spleen. Contrast-enhanced abdominal CT revealed a 52×40 mm multilobulated cystic lesion with internal septa and wall/septal calcifications in the anterosuperior splenic segment; the leading differential diagnoses were epidermoid and hydatid cysts with cystic neoplasm considered less likely. No free fluid, pathological lymphadenopathy, or additional solid organ pathology was identified, and upper gastrointestinal endoscopy showed no malignant or obstructive findings. Laparoscopic exploration identified an approximately 5 cm cystic lesion confined to the superior spleen without invasion of adjacent tissues, and laparoscopic splenectomy was performed uneventfully. Histopathological examination demonstrated a multilocular cyst with hyalinized walls and glandular structures lined by a single-layer epithelium within the splenic parenchyma, without evidence of malignancy; immunohistochemistry showed positivity for PAX8, ER, and PR and negativity for CA19-9 and CEA, consistent with splenic endometriosis. The postoperative course was uneventful.

Conclusion: Splenic endometriosis is an exceptionally rare form of extragenital endometriosis and is typically reported in association with symptomatic presentations or preoperative suspicion. In contrast, the present case was entirely asymptomatic, and the calcified, septated, multilocular splenic cyst was radiologically interpreted as a benign cystic lesion. The lack of endometriosis-specific findings on endoscopic, intraoperative, and laboratory evaluation further underscores the diagnostic challenge. This case highlights that, although rare, endometriosis should be considered in the differential diagnosis of splenic cystic lesions mimicking hydatid or epidermoid cysts, particularly in women of reproductive age. Consistent with the literature, definitive diagnosis relied on histopathological and immunohistochemical evaluation, emphasizing the need for a multidisciplinary approach in the assessment of splenic cystic lesions, even in asymptomatic patients.

Surgical management of a case of type 3 popliteal artery entrapment syndrome with acute thrombosis after decompression

Kemal Aygün, Kutay Demirkır, Can Yahya Boztuğ, Ömer Arda Çetinkaya

Divison of Peripheric Vascular Surgery, Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Popliteal artery entrapment syndrome (PAES) is a rare cause of lower extremity ischemia in young individuals without atherosclerotic risk factors. It is most commonly associated with anatomical variations of the medial head of the gastrocnemius muscle. In type 3 PAES, aberrant muscular slips compress the popliteal artery, leading to progressive intimal damage, thrombosis, and distal embolization. Delayed diagnosis may result in recurrent ischemic events and the need for complex revascularization procedures. We present a case of type 3 PAES requiring multistage surgical intervention following initial decompression and patch repair.

Material and Methods: A 26-year-old male with no significant cardiovascular risk factors presented with acute onset of right foot discoloration, coldness, and pain. Computed tomography angiography revealed intraluminal thrombus within the right popliteal artery. Diagnostic and therapeutic digital subtraction angiography was performed, and selective thrombolytic therapy was initiated. Magnetic resonance imaging of the knee demonstrated an abnormal superior origin of the medial gastrocnemius head compressing the popliteal artery, consistent with type 3 PAES. The patient underwent posterior surgical exploration with resection of the aberrant gastrocnemius muscle and saphenous vein patch angioplasty of the popliteal artery. Initial postoperative recovery was uneventful, and distal perfusion improved.

Results: Six months later, the patient presented again with acute limb ischemia. Angiography demonstrated occlusion of the superficial femoral artery with poor distal runoff. Thrombosis of the saphenous vein graft was identified, and thrombectomy with re-anastomosis was performed. Due to persistent perfusion impairment, femoro-distal bypass and thromboendarterectomy were subsequently carried out. Histopathological examination excluded vasculitis and revealed degenerative and inflammatory changes in the vascular wall. Following definitive surgical reconstruction, distal circulation improved clinically.

Conclusion: PAES may require more than simple decompression, particularly in cases with established arterial wall damage and thrombotic complications. Early recognition and appropriate surgical planning are essential to prevent recurrent ischemia and multiple revascularization procedures. PAES should always be considered in young patients presenting with unexplained lower extremity ischemia.

Keywords: Popliteal artery entrapement syndrome, acute arterial thrombosis, revascularization

Paraperitoneal type ureter herniation in the inguinal region: A rare case diagnosed preoperatively

Nurullah Bilen, Aziz Bulut, Nurullah Aksoy, Halil İbrahim Ertem

Department of General Surgery, Gaziantep University Faculty of Medicine, Gaziantep

Objective: Inguinal hernia repair is one of the most commonly performed surgical procedures worldwide, performed on millions of patients each year. In contrast, uretero-inguinal hernia, characterized by herniation of the ureter into the inguinal canal, is quite rare. Paraperitoneal form is constituting the vast majority of cases. Uretero-inguinal hernias often present with typical inguinal hernia findings, making preoperative diagnosis difficult and leading to diagnosis frequently being made during the intraoperative period. Cross-sectional imaging methods are critically important for diagnosis, especially in patients with unexplained hydronephrosis, renal dysfunction, or atypical hernia contents. This report presents a rare case of paraperitoneal ureteroinguinal hernia diagnosed with preoperative imaging.

Material and Methods: Laboratory results, renal scintigraphy, and computed tomography data on the urinary system from the Gaziantep University Hospital database were retrospectively reviewed.

Results: A 27-year-old male patient was referred to our clinic for further evaluation due to elevated serum creatinine levels detected during his military medical examination. The urological evaluation revealed no dysuria, hematuria, flank pain, or lower urinary tract symptoms. The abdominal physical examination was unremarkable except for a hernia, and the patient had no history of surgery. The creatinine level was 1.04 mg/dL, which was within the normal range. Renal scintigraphy showed that the right kidney contributed 57.1% to total renal function and the left kidney contributed 42.9%. Contrast-enhanced computed tomography revealed grade II ectasia in the collecting system of the left kidney. Additionally, cross-sectional imaging showed that the left ureter was herniated into the inguinal canal. Based on these findings, surgery was planned. After completing the preoperative preparations, the patient underwent surgery. Exploration during surgery confirmed that the left ureter was herniated into the inguinal canal. The ureter was carefully dissected from the surrounding tissues and reduced into the retroperitoneal space. After controlling the hernia sac accompanying the ureter, inguinal hernia repair was performed using the Lichtenstein technique. No complications were observed in the early postoperative period, and the patient was discharged on the third postoperative day when serum creatinine returned to normal levels.

Conclusion: Although ureteroinguinal hernia is rare, its recognition in the preoperative period can facilitate surgical planning and reduce the risk of intraoperative ureteral injury. The use of cross-sectional imaging methods in patients with unexplained renal dysfunction or atypical inguinal hernia findings may increase diagnostic accuracy and contribute to the prevention of possible complications.

A rare Strasberg type C injury successfully managed without surgery: A case report

Gizem Sarı, Yusuf Türker, Abdullah Kağan Zengin

İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul

Objective: Approximately 180,000-200,000 cholecystectomies are performed annually in our country, with laparoscopic cholecystectomy being the most commonly preferred surgical treatment for cholelithiasis. However, its widespread use has been associated with an increased incidence of biliary injuries. Anatomical variations, limited operative exposure, and inflammation-related distortion of tissue planes may lead to misidentification during dissection, increasing the risk of injury. The reported incidence of biliary injury in laparoscopic cholecystectomy is 0.3-0.7%, approximately three times higher than in open surgery, and many injuries present postoperatively with bile leakage or biloma. Among the available classification systems, the Strasberg-Bismuth classification is the most widely used. Type A refers to leaks from small ducts, type B to occlusion of an aberrant right hepatic duct, and type VC to bile leakage caused by transection of this duct, which may be mistaken for the cystic duct. This case report describes the successful minimally invasive management of a rare Strasberg type C injury following laparoscopic cholecystectomy using percutaneous drainage and endoscopic interventions.

Material and Methods: This study is a retrospective case report of a patient who developed a Strasberg type C biliary injury following laparoscopic cholecystectomy performed at our clinic in September 2025. Diagnostic evaluation included ultrasonography, magnetic resonance cholangiopancreatography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP), with laboratory, clinical, and imaging findings assessed together. Management consisted of percutaneous drainage and endoscopic sphincterotomy, and the patient was followed in a multidisciplinary setting by surgical and gastroenterology teams. The study was conducted in accordance with the Declaration of Helsinki, and written informed consent was obtained.

Results: Bile duct injuries may result in significant morbidity, primarily due to bile leakage and related complications. In this case, a Strasberg type C injury was successfully managed with percutaneous drainage and endoscopic stent placement, avoiding surgical repair. Regression of the biloma and normalization of laboratory findings support the effectiveness of a conservative, minimally invasive approach in appropriately selected patients.

Conclusion: In bile duct injuries following laparoscopic cholecystectomy, early diagnosis, a multidisciplinary approach, and appropriate endoscopic and percutaneous treatment strategies can substantially reduce the need for surgical intervention. In Strasberg type C injuries, preservation of the main bile ducts enables successful management through effective drainage and pressure-decompressing endoscopic procedures. This case supports that a conservative approach is a safe and effective treatment option in carefully selected patients.

Primary extranodal high-grade B-cell non-Hodgkin lymphoma extending into the abdomen, located in the rectus muscles

Mesut Tetik, Büşra Hilal Arasan, Kemal Eyvaz, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Approximately 20-40% of non-Hodgkin lymphomas (NHL) present as primary extranodal disease. Primary soft tissue involvement accounts for only 0.1-1% of all NHL cases. The clinical presentation of lymphoma in soft tissue is highly variable and can mimic other soft tissue malignancies, leading to diagnostic errors. Primary extranodal cases originating from abdominal wall muscles are quite limited in the literature.

Material and Methods: Clinical presentation: A 62-year-old male patient presented with a complaint of a palpable and painless mass in his abdominal wall that had been gradually growing for approximately one year. He had no other medical conditions besides known diabetes mellitus, and no history of abdominal surgery. On physical examination, a mass lesion approximately 8x10 cm was palpated in the upper right quadrant of the abdomen. The patient did not have systemic "B symptoms" such as fever, night sweats, or weight loss. Abdominal CT scan revealed: A mass lesion approximately 13-cm in craniocaudal dimension and approximately 11x5 cm in axial plane, extending to the rectus abdominus muscle, with a unclear boundary between the bowel loops and the mass containing cystic necrotic areas, located inferiorly adjacent to the transverse colon on the right side. Tissue diagnosis is recommended. Inferior to this lesion, two nodular lesions measuring 3-cm and 2-cm are observed in the right rectus muscle.

Results: Abdominal wall lymphomas are rare and can often be confused with sarcomas, undifferentiated carcinomas, or other soft tissue tumors. Fascial plane crossing and the presence of lymphadenopathy surrounding large vascular structures on CT are critical radiological clues that differentiate lymphoma from sarcomas. Definitive differentiation is possible with tissue biopsy and immunohistochemical panels including pan-leukocyte markers. In the treatment approach, systemic chemotherapy is vital in cases of DLBCL, an aggressive subtype. Excellent clinical outcomes have been reported with chemotherapy after surgical debulking in early-stage cases.

Conclusion: This case demonstrates that NHL should always be considered in the differential diagnosis of masses detected in the abdominal wall muscles. We believe that the diagnostic procedure should be performed by planning direct en bloc resection. Non-surgical biopsy methods may not contain sufficient tissue, leading to a delay in diagnosis and the need for re-biopsy. They also delay en bloc excision of the primary lesion by leaving residual tissue. Long-term disease-free survival can be achieved in primary soft tissue lymphomas with accurate staging and modern chemo-immunotherapy protocols.

Unexpected diagnosis of neuroendocrine tumor in a case of ileus secondary to small bowel diverticulum

Eda Cengiz, Atahan Hüseyin Karaaslan, Murat Kalın, Furkan Güngör

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Material and Methods: A 26-year-old female patient who presented with acute abdominal symptoms and was diagnosed with ileus was evaluated. Clinical findings, radiological imaging results, surgical approach, histopathological findings, and postoperative management were retrospectively reviewed. Abdominopelvic computed tomography (CT) was used for preoperative assessment. Surgical intervention was performed laparoscopically. Histopathological evaluation included tumor grading and proliferation index (Ki-67). Postoperative staging and follow-up were conducted using Ga-68 DOTATATE PET/CT, and the patient was discussed in a multidisciplinary oncology board.

Results: Preoperative imaging revealed dilated distal ileal loops with air-fluid levels, consistent with ileus. Laparoscopic exploration demonstrated a small bowel diverticulum approximately 10-cm distal to the ligament of Treitz, forming a loop that caused strangulation of the ileal segment. The diverticulum was resected at its base. Histopathological examination revealed a well-differentiated neuroendocrine tumor (Grade 1) with a Ki-67 index of 2% and a mitotic rate of 0-1. The tumor extended from the submucosa to the subserosa, and subserosal tumor foci were identified at the surgical margin. Ga-68 DOTATATE PET/CT performed during follow-up showed no pathological uptake. Due to positive surgical margins, the patient underwent laparoscopic partial small bowel resection with side-to-side anastomosis. The postoperative course was uneventful, and no early complications were observed. The patient was placed under close clinical and oncological follow-up.

Conclusion: Small bowel neuroendocrine tumors should be considered in the differential diagnosis of young patients presenting with acute ileus, although rare. Detailed histopathological evaluation and a multidisciplinary approach are crucial for optimal management, particularly in cases involving diverticular resection.

Incidental umbilical endometriosis detected during umbilical hernia repair: A case report

Kamran Mahmudzada[1], Esma Altay[2], Fisun Arduç Yükrük[2]

[1]*Elmadağ Dr. Hulusi Alataş State Hospital, Ankara*

[2]*University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara*

Objective: Umbilical endometriosis is a rare condition characterized by the presence of endometrial tissue in the umbilical region and accounts for less than 1% of all endometriosis cases. Primary umbilical endometriosis occurs spontaneously, whereas the secondary form is usually associated with previous abdominal or gynecological surgery. Incidental detection during umbilical hernia repair is extremely uncommon.

Material and Methods: A 40-year-old female patient presented with swelling in the umbilical region. Physical examination and imaging findings were consistent with an umbilical hernia. The patient reported no cyclic umbilical pain, tenderness, or skin changes related to the menstrual cycle. Elective umbilical hernia repair was performed using mesh. The excised tissue from the umbilical region was routinely sent for histopathological examination.

Results: No remarkable macroscopic pathological findings were observed intraoperatively. Histopathological evaluation revealed endometrial glands and stroma consistent with umbilical endometriosis. The patient had no history of previous abdominal or gynecological surgery. The postoperative course was uneventful, and the patient was referred for multidisciplinary follow-up.

Conclusion: Histopathological evaluation of tissues excised during umbilical hernia repair may reveal rare but clinically significant diagnoses. Umbilical endometriosis should be considered in the differential diagnosis of umbilical lesions even in the absence of cyclic symptoms, particularly in female patients. This case highlights an atypical and incidental presentation of umbilical endometriosis and aims to raise awareness among general surgeons.

Ventriculoperitoneal shunt hernia

Müslüm Çelik, İlkay Halıcıoğlu, Özcem Öfkeli, Mehmet Zengin

University of Health Sciences Türkiye, Diyarbakır Gazi Yaşargil Training and Research Hospital, Diyarbakır

Objective: Ventriculoperitoneal shunting is one of the most commonly used surgical methods in the treatment of hydrocephalus. Complications related to the shunt system can manifest as infection, mechanical dysfunction, and abdominal complications. Abdominal complications include pseudocyst, bowel perforation, catheter migration, and herniation. The presence of the shunt catheter within a hernia sac is a very rare occurrence. Reporting such cases is important for understanding the diagnosis and surgical approach.

Material and Methods: A 46-year-old patient presented with pain and swelling in the left upper quadrant. The patient's history revealed a ventriculoperitoneal shunt placement due to hydrocephalus. Physical examination revealed a reducible abdominal hernia in the left upper quadrant. Laboratory findings were within normal limits. Imaging showed a tubular structure consistent with a ventriculoperitoneal shunt catheter within the hernia sac. The patient underwent elective surgery. During the operation, the distal catheter of the ventriculoperitoneal shunt was visualized within the hernia sac. The hernia was reduced while preserving the catheter, and abdominal wall repair was performed. No postoperative complications occurred, and the patient was discharged without complications.

Results: A significant portion of VP shunt complications occur in the abdominal region. The most commonly reported complications are pseudocyst formation and catheter migration. Catheter placement within the hernia sac is a rare occurrence. The presence of an intraabdominal catheter and chronic pressure changes may contribute to abdominal wall weakness. Similar cases have been reported in both pediatric and adult patients in the literature. The basic approach to treatment is hernia repair and preservation of the shunt. Shunt revision is generally not necessary if there is no evidence of shunt dysfunction or infection.

Conclusion: In patients with VP shunts, the possibility of herniation should be kept in mind in the presence of abdominal distension and pain. Successful results can be achieved with surgical repair.

A rare cause of elevated creatinine levels in the posttransplant period: A case of graft ureter herniation

Aziz Bulut, Nurullah Bilen, Nurullah Aksoy

Department of General Surgery, Gaziantep University Faculty of Medicine, Gaziantep

Objective: Kidney transplantation is the most effective treatment method for improving survival and quality of life in end-stage renal disease. However, in transplant recipients, the risk of developing incisional hernia increases due to factors such as immunosuppressive therapy, compromised tissue integrity, and delayed wound healing. The presence of the graft ureter within the hernia sac is extremely rare; if not anticipated during surgical repair, it can lead to serious complications such as iatrogenic ureteral injury, urinary leakage, obstructive uropathy, and graft dysfunction. This report presents a rare case of posttransplant incisional hernia in which a graft ureter was detected within the hernia defect, emphasizing the decisive role of preoperative diagnosis in surgical safety.

Material and Methods: Patient records from Gaziantep University Hospital were retrospectively reviewed. The patient's demographic characteristics, transplant history, laboratory parameters, and radiological findings were evaluated.

Results: A 62-year-old patient who underwent kidney transplantation from a living donor due to renal failure for 3 years was admitted to the nephrology outpatient clinic for further investigation and treatment due to a new decrease in urine output and serum creatinine of 2.77 mg/dL after transplantation. No pathological findings were found on physical examination. An abdominal computed tomography scan revealed that the lower part of the graft ureter was herniated into the incisional hernia defect and dilation was detected proximal to the graft ureter. Surgery was planned for the patient. A percutaneous nephrostomy was placed in the graft kidney during the preoperative period. The surgical intervention was performed with careful planning to prevent possible ureteral injury. Intraoperative exploration confirmed that the graft ureter was located within the defect. The ureter was carefully dissected from the surrounding tissues using sharp and blunt dissection techniques and safely reduced into the retroperitoneal space. The hernia repair defect was repaired. No intraoperative complications developed. The postoperative course was uneventful; the patient was discharged with stable renal function.

Conclusion: It should be kept in mind that in incisional hernias developing in posttransplant patients, the graft ureter may very rarely be located within the hernia sac. Preoperative cross-sectional imaging contributes to the safe establishment of the surgical strategy by enabling the recognition of atypical hernia contents and reduces the risk of iatrogenic injury that could threaten graft function. This case demonstrates that detailed radiological evaluation is critical for optimal surgical outcomes in patients with a history of transplantation.

Nipple adenoma mimicking malignancy clinically and radiologically: Diagnostic challenges and surgical management of a rare benign lesion

Cenk Yazkan, Narmin Hajizada, Leyla Tekin, Önder Özcan

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Nipple adenoma is a rare, benign epithelial proliferation originating from the lactiferous ducts. Due to its clinical, radiological, and even macroscopic features, it can mimic malignant breast diseases, leading to diagnostic challenges.

Material and Methods: A six-year-old female patient presented to our clinic with a complaint of a palpable mass in her left breast. Physical examination revealed a palpable mass, approximately 4-cm in size, completely involving the left nipple and areola complex. The initial breast ultrasonography (USG) performed during the diagnostic imaging process revealed a mass lesion in the retroareolar area of the left breast with lobulated contours, heterogeneous hypoechoic structure, anarchic vascularity, and posterior acoustic shadowing. Subsequent dynamic contrast-enhanced breast magnetic resonance imaging (MRI) revealed a mass lesion approximately 27x22 mm in size, extending from the skin to the retroareolar area at the level of the left nipple, exhibiting intense contrast enhancement in the early stages and showing diffusion restriction. Additionally, segmental linear ductal and nodular non-mass contrast enhancement areas extending approximately 18-mm were present posterior to this mass. The MRI findings suggested an accompanying ductal carcinoma *in situ* (DCIS) or tumor spread. Due to these radiological findings, the lesion was evaluated as BI-RADS category 5 (highly malignant), and histopathological confirmation was recommended.

Results: A tru-cut (core) biopsy was performed on the patient from the retroareolar lesion of the left breast under ultrasound guidance. Histopathological and immunohistochemical examination of the biopsy material revealed papillary-like structures and ducts containing focal apocrine and columnar metaplasia. Immunohistochemically, SMMS and p63 were observed, the myoepithelial cell layer was preserved, and the ER receptor was heterogeneously positive. The biopsy report concluded that "no overt invasive malignancy was observed," but due to the high clinical and radiological suspicion, evaluation with excisional biopsy was recommended. Final histopathological examination of the excised material revealed a 2.5-cm diameter lesion consisting of partly papillary and partly solid areas. Microscopically, the lesion showed ductal hyperplasia, papilloma, adenosis, and fibrocystic changes. Immunohistochemical analysis confirmed the preservation of the myoepithelial cell layer with p63 and CD10, and the Ki-67 proliferation index was found to be 2-3%. The lesion did not extend beyond the surgical margins. All these findings were considered consistent with a diagnosis of nipple adenoma.

Conclusion: Nipple adenoma, although rare, is an important benign pathology that can mimic malignant breast diseases. Accurate diagnosis is critical to preventing unnecessary radical surgeries. Surgical excision is an effective and safe approach, both diagnostically and therapeutically.

A rare vascular suprarenal mass mimicking malignancy: A case of cavernous hemangioma

Ahmetcan Atmaca1, Faruk Yazıcı2, Muhammed Salih Süer1, Alper Yavuz1, Bahattin Bayar1, Şener Balas1

1University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

2Etimesgut Martyr Sait Ertürk State Hospital, Ankara

Objective: A rare vascular tumor of the adrenal gland, adrenal cavernous hemangioma is one of the extremely rare benign lesions, most commonly detected incidentally in the literature and described as non-functional lesions. However, when it reaches large sizes, it can present with symptoms, and due to its heterogeneous imaging characteristics, it can be challenging to differentiate from malignant adrenal neoplasms. It is reported in the literature that preoperative diagnosis is often not possible, surgical resection plays both a diagnostic and therapeutic role. In this study, the clinical, radiological, surgical, histopathological features of a symptomatic, non-functional, and large adrenal cavernous hemangioma case are presented with a review of the literature.

Material and Methods: A patient who underwent surgery for adrenal cavernous hemangioma was retrospectively reviewed. Demographic data, mode of presentation, preoperative clinical and laboratory findings, surgical method applied, pathological examination were evaluated. Postoperative follow-up was recorded.

Results: A woman in her seventies presented with abdominal pain and early satiety. Physical examination was unremarkable. Preoperative hormonal evaluation Showed no evidence of adrenal hyperfunction, and the mass was considered non-functional. Imaging studies revealed a heterogeneous, approximately 10-cm left adrenal mass with cystic, hemorrhagic, and possible vascular components, raising suspicion for malignancy. Due to the mass size and symptomatic course, surgical treatment was performed. Laparoscopic approach was initiated and converted to open surgery, resulting in left adrenalectomy. Postoperative course was uneventful. Histopathological and immunohistochemical examination confirmed cavernous hemangioma, with normal adrenal tissue and no early recurrence.

Conclusion: In the literature, it is reported that the majority of adrenal cavernous hemangiomas are non-functional, however, in particularly large cases, they can become symptomatic, and due to their heterogeneous radiological appearances, they are frequently misdiagnosed as malignant adrenal tumors. Therefore, in cases with symptomatic course and where malignancy cannot be safely excluded preoperatively, surgical resection is accepted as an appropriate approach both for diagnostic and therapeutic purposes. The presented case is instructive in highlighting the challenges in the differential diagnosis of adrenal cavernous hemangiomas and the importance of surgical treatment, with a course and successful surgical management consistent with the characteristics described in the literature.

A rare germ cell tumor of the adrenal gland: A case of mature cystic teratoma

Ahmetcan Atmaca1, Muhammed Salih Süer1, Faruk Yazıcı2, Serkan Demir1, Gürkan Değirmencioğlu1, Alper Yavuz1, Şener Balas1

1University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

2Etimesgut Martyr Sait Ertürk State Hospital, Ankara

Objective: Adrenal gland-derived masses are most often detected incidentally in clinical practice; however, rare pathologies may pose significant challenges in the differential diagnosis. Mature cystic teratoma located in the adrenal gland is an extremely rare entity among germ cell tumors and has been reported in only a limited number of cases in the literature. Due to non-specific clinical manifestations and the anatomical characteristics of the adrenal region, these lesions are frequently confused with other adrenal pathologies. In this study, we present a case of an adrenal mature cystic teratoma that was surgically treated following a detailed clinical, hormonal, and radiological evaluation in a patient who presented with a complaint of abdominal distension.

Material and Methods: The patient who was operated on with the diagnosis of an adrenal-origin mass was retrospectively evaluated. Demographic data, mode of presentation, preoperative clinical and laboratory findings, the surgical approach applied, and the results of pathological examination were analyzed. Postoperative follow-up was performed.

Results: A 22-year-old female presented with abdominal distension. Physical examination and routine laboratory tests were unremarkable. Hormonal evaluation revealed normal serum cortisol and dhea-s levels, and pheochromocytoma was excluded based on hormonal and clinical findings. Abdominal computed tomography demonstrated a well-defined, heterogeneous mass approximately 120-mm in diameter in the left adrenal lodge, containing cystic areas, macroscopic fat, and calcified/tooth-like components, without contrast enhancement, invasion, or vascular involvement. These findings favored the diagnosis of a mature cystic teratoma. A laparoscopic approach was initially attempted; however, due to the size and location of the mass, conversion to open surgery was required, and left adrenalectomy was performed. No postoperative complications occurred. Histopathological examination confirmed a mature cystic teratoma with negative surgical margins. No recurrence or mortality was observed during six months of follow-up.

Conclusion: Although adrenal mature cystic teratomas are extremely rare, they may become symptomatic when they reach large sizes. As demonstrated in this case, characteristic imaging findings—namely the coexistence of fat, cystic components, and calcifications—play a crucial role in diagnosis, while functional evaluation and exclusion of pheochromocytoma are essential for safe surgical planning. The literature indicates that preoperative diagnosis is often challenging and that this rare entity may be overlooked in the differential diagnosis of adrenal incidentalomas (Table 1). Nevertheless, in large adrenal masses containing fat and calcifications, the possibility of a mature cystic teratoma should be considered to determine the appropriate surgical strategy. Surgical resection remains the cornerstone for both definitive diagnosis and treatment, with favorable and complication-free outcomes reported when appropriate patient management is applied, consistent with the literature.

Oxidized regenerated cellulose mimicking recurrent mass after total thyroidectomy: A diagnostic pitfall

İlgiz Tüzken, Ramil Efendiyev, Kutay Demirkır, Volkan Genç

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Oxidized regenerated cellulose (ORC) is a biological material widely used for hemostasis during thyroid surgery. Although it is generally expected to be resorbed within a few weeks, in rare cases it may persist and lead to pseudotumoral lesions, which can be confused with locoregional recurrence, granuloma, or residual tumor. This situation creates a diagnostic challenge, particularly in postoperative patients presenting with cervical masses. In this case report, we aimed to present a case of persistent ORC following total thyroidectomy that demonstrated clinical progression.

Material and Methods: A 54-year-old female patient underwent total thyroidectomy on March 5, 2025, with the diagnosis of multinodular goiter. No complications were observed in the early postoperative period. However, during follow-up, progressive cervical swelling developed, prompting further evaluation. Neck ultrasonography revealed a hypoechoic, avascular, solid-appearing lesion located in the thyroidectomy bed. Although the imaging findings were initially considered compatible with benign postoperative changes, the lesion demonstrated progressive enlargement over time, caused dysphagia, and became externally visible; therefore, the patient was considered symptomatic. Due to the progression of clinical findings and significant mass effect, surgical exploration was planned. During surgery, a mass consistent with persistent oxidized regenerated cellulose material was identified in the previous surgical field and was completely excised. Histopathological examination revealed fibro-adipose tissue demonstrating focal fat necrosis and foreign body-type chronic inflammatory reaction associated with oxidized cellulose material. No evidence of neoplasia was detected.

Results: Previous reports in the literature have documented that ORC and similar surgical cellulose-based materials may mimic recurrent masses following thyroid and parathyroid surgery. On ultrasonography, these lesions typically appear hypoechoic and avascular, which may serve as an important clue in the differential diagnosis. However, diagnostic uncertainty may persist in the presence of clinical progression and symptoms. In such cases, surgical excision represents an effective approach for both definitive diagnosis and treatment.

Conclusion: In patients presenting with cervical masses after thyroidectomy, particularly in the presence of lesion progression and clinical symptoms, persistent oxidized regenerated cellulose should be considered in the differential diagnosis. Minimal and well-documented use of ORC is crucial to prevent misdiagnosis of recurrence and avoid unnecessary reoperations.

Occult thyroid carcinoma: A rare case report

Ekrem Kocatürk, Ozan Barış Namdaroğlu, Mehmet Üstün, Savaş Yakan

Department of General Surgery, University of Health Sciences Türkiye, Tepecik Training and Research Hospital, İzmir

Objective: Thyroid cancer incidence has been steadily increasing worldwide in recent years. With the more widespread use of ultrasonography and other imaging modalities, the incidence of occult thyroid carcinoma (OTC) and papillary thyroid microcarcinoma (PTMC) has also increased. The term OTC has been defined variably in the literature. In most clinical settings, OTC and PTMC are considered synonymous or closely related; however, certain discordant situations exist. Boucek et al. proposed a four-group classification for OTC, and Liu et al. additionally suggested a fifth group within this classification (Figure 1). In this case, we report an OTC presenting with isolated cervical lymph node metastasis despite normal thyroid imaging (Boucek et al., Group 3). Although lymph node metastasis in PTMC is rare and predominantly confined to the central compartment, the detection of level V lateral neck metastasis without central involvement in our patient suggests an unusual skip-metastasis pattern.

Material and Methods: The patient who presented with a complaint of neck swelling underwent thyroid ultrasonography, neck ultrasonography, and cervical MRI. An excisional biopsy was performed on a level V lymph node. To investigate the primary focus, thyroid scintigraphy was obtained, and PET/CT was performed due to a history of breast cancer. Definitive diagnosis was established by histopathological examination following total thyroidectomy with bilateral central neck dissection and left lateral neck dissection.

Results: A 52-year-old woman presented with a complaint of neck swelling. No abnormality was detected on thyroid ultrasonography. Cervical ultrasonography and MRI revealed pathological lymphadenopathy at level V. Excisional biopsy demonstrated metastasis of papillary thyroid carcinoma. Thyroid scintigraphy and PET/CT showed no pathology or primary lesion in the thyroid gland. Postoperative pathology revealed PTMC measuring 3 mm and 1 mm. Among 26 lymph nodes removed during lateral neck dissection, metastasis of papillary carcinoma was identified in one.

Conclusion: OTC is a thyroid carcinoma in which no thyroid tumor is detected or suspected clinically or radiologically, and the diagnosis is established either incidentally in the thyroidectomy specimen or through a metastatic focus. Incidentally detected PTMC is one of the most common subcategories of OTC, and its detection rate has increased with the routine use of imaging and FNAB. The present case demonstrates OTC presenting with isolated lateral cervical (level V) metastasis in a patient in whom no primary lesion could be identified preoperatively, emphasizing that even millimetric PTMC foci may carry metastatic potential. Better characterization of metastatic patterns and clarification of diagnostic and therapeutic strategies are warranted.

When gallstones do not remain confined to the gallbladder: Port-site abscess caused by a retained gallstone after laparoscopic cholecystectomy

Nebi Acar, Halil İbrahim Dündar

Department of General Surgery, Kütahya City Hospital, Kütahya Health Sciences University, Kütahya

Objective: Laparoscopic cholecystectomy is the gold standard treatment for symptomatic gallstone disease. However, gallbladder perforation and spillage of gallstones may occur, particularly in cases with acute cholecystitis or difficult dissection. Although most spilled gallstones remain clinically silent, they may rarely lead to late complications such as abscess formation, fistulas, or inflammatory masses. Port-site abscesses related to retained gallstones are extremely rare and may cause diagnostic delay. We present a case of a port-site abscess caused by a retained gallstone one year after laparoscopic cholecystectomy.

Material and Methods: A 68-year-old female patient presenting with pain, swelling, and erythema at the epigastric region and a history of laparoscopic cholecystectomy one year earlier was retrospectively evaluated. Physical examination findings, laboratory results, ultrasonography, and contrast-enhanced abdominal computed tomography were reviewed. Surgical management, intraoperative findings, and postoperative outcome were analyzed.

Results: Physical examination revealed localized erythema, tenderness, and increased temperature at the previous epigastric port-site. Laboratory tests showed elevated C-reactive protein levels. Ultrasonography demonstrated a thick-walled loculated collection containing a calcified focus with acoustic shadowing. Computed tomography revealed a subcutaneous abscess in the anterior abdominal wall with a hyperdense calcified lesion within the collection. Surgical drainage and debridement were performed without entering the peritoneal cavity. A gallstone was macroscopically identified and removed from the abscess cavity. Wound culture grew *Escherichia coli*. The patient recovered uneventfully after antibiotic therapy and was discharged in good condition.

Conclusion: Retained gallstones spilled during laparoscopic cholecystectomy may rarely cause late-onset port-site abscesses. In patients with a history of laparoscopic cholecystectomy presenting with late abdominal wall infections, retained gallstones should be considered in the differential diagnosis.

Keywords: Delayed complication, laparoscopic cholecystectomy, port-site abscess, retained gallstone

Fungal splenic abscess in a diabetic patient requiring splenectomy

Sadettin Er, Fatma Betül Özgüven

Department of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara

Objective: Splenic abscess is an uncommon but potentially fatal condition, with fungal etiologies representing a small proportion of cases (0.07-0.14%). Early diagnosis is challenging due to nonspecific clinical features. Current management strategies include targeted antimicrobial therapy, image-guided percutaneous drainage, and splenectomy. Selection of therapy is guided by abscess size, number, causative organism, clinical stability, and response to initial medical management. Fungal splenic abscesses, particularly in immunocompromised patients such as those with diabetes mellitus, are associated with poor response to conservative treatment and frequently require definitive surgical intervention.

Material and Methods: A 55-year-old woman with diabetes mellitus presented with diabetic ketoacidosis. Contrast-enhanced computed tomography of the abdomen demonstrated a solitary 5-cm cystic lesion in the spleen. Comprehensive evaluation, including blood cultures, transthoracic echocardiography, and funduscopic examination, failed to identify a primary infectious source, although imaging findings were consistent with splenic abscess

Results: Empirical intravenous antimicrobial therapy was initiated in accordance with standard management protocols. Despite adequate medical treatment, the lesion persisted, and the etiology remained indeterminate. Given the abscess size (>4 cm), lack of clinical and radiologic resolution, and the high likelihood of treatment failure with medical therapy alone in suspected fungal infection, splenectomy was pursued. Surgical management provided definitive source control and allowed for histopathological diagnosis, which confirmed a fungal splenic abscess.

Conclusion: This case illustrates the importance of a structured, guideline-based approach to the management of splenic abscesses. While antimicrobial therapy and percutaneous drainage may be considered in selected patients, splenectomy is recommended in cases of large or persistent lesions, failure of conservative management, or suspected fungal infection. In such settings, early surgical intervention offers both diagnostic certainty and definitive treatment, potentially reducing morbidity and mortality.

Successful management of congenital transmezocolic internal hernia in adult patients with second-look surgery

Abdülaziz Emek, Mahmut Burak Kılcı, Turgay Şimşek, Orhan Tatlı, Mehmet Furkan Avcı, Nuh Zafer Cantürk

Kocaeli University Faculy of Medicine, Kocaeli

Objective: Congenital internal hernias are rare in adults. However, delayed diagnosis can lead to life-threatening complications such as strangulation and intestinal necrosis. Diagnosis is particularly difficult in acute abdomen and ileus presentations in adults with no history of prior abdominal surgery. This case report presents a successful management of small bowel obstruction due to congenital transmesocolic internal herniation without resection using second-look surgery.

Material and Methods: The clinical, radiological, and surgical findings of a 27-year-old female patient with no history of surgery who presented with acute onset abdominal pain and nausea were retrospectively evaluated.

Results: Laboratory tests revealed leukocytosis and elevated C-reactive protein levels. Contrast-enhanced abdominal computed tomography showed clustering, acute dilation, wall thickening, decreased contrast enhancement, and intraperitoneal fluid in the mid-distal ileal loops. During emergency exploratory laparotomy, a segment of small bowel approximately 160 cm in length was found herniated through a congenital defect in the transverse colon mesentery. The herniated loops were reduced, and the mesenteric defect was primarily repaired. Resection was not performed due to the borderline assessment of bowel viability. A second-look surgery was planned 48 hours later. At the second look, intestinal perfusion and peristalsis were found to have improved significantly, and resection was not required. Findings of ischemia-reperfusion injury that developed in the postoperative period resolved with a conservative approach. The patient was discharged on the ninth postoperative day.

Conclusion: Although congenital transmesocolic internal hernias are rare in adults, they should always be considered in cases of unexplained acute abdomen and ileus. Computed tomography plays a critical role in early diagnosis. Second-look surgery in cases with borderline ischemia offers a bowel-preserving, safe, and effective surgical strategy by preventing unnecessary bowel resection.

Laparoscopic management of atypical appendicitis: A case of a 22 cm appendix

Faruk Yazıcı[1], Serkan Demir[2], M. Salih Suer[2], Alican Arslan[1], Berna Karabulut[1], Şener Balas[2]

[1]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[2]*University of Health Sciences Türkiye, Etlik City Hospital, Ankara*

Objective: Acute appendicitis is one of the most common surgical emergencies and a leading cause of acute abdomen. Although the clinical presentation is usually typical, rare anatomical variations in appendiceal length, position, and orientation may result in atypical symptoms and diagnostic challenges. The average length of the appendix is reported to be 8-10 cm; however, extremely long appendices exceeding 15-20 cm have rarely been described. An excessively long appendix may coil, follow an atypical course, or have its distal tip embedded within the mesoappendix, leading to misleading radiological findings and suspicion of perforation. We present a case of acute appendicitis with an exceptionally long appendix that caused preoperative diagnostic difficulty.

Material and Methods: A 23-year-old male patient presented to the emergency department with a three-day history of abdominal pain. The pain initially involved the epigastric and periumbilical regions and later localized to the right lower quadrant. Clinical, laboratory, and radiological evaluations were performed, and contrast-enhanced abdominal computed tomography was obtained.

Results: On physical examination, the patient was febrile (38 °C) with marked tenderness, guarding, and rebound tenderness in the right lower quadrant. Laboratory analysis revealed marked leukocytosis (WBC: 27.000/µL). Contrast-enhanced CT demonstrated findings consistent with acute appendicitis; however, the distal tip of the appendix could not be clearly identified, and radiological suspicion of perforation was reported. Laparoscopic exploration using a standard three-trocar technique revealed a markedly elongated, inflamed appendix with an anterior (preileal) course and a circularly coiled configuration. The distal portion of the appendix was embedded within the mesoappendix, explaining the inability to visualize the tip on preoperative imaging. No macroscopic perforation was observed. Inflammatory pelvic fluid was present and aspirated. Laparoscopic appendectomy was completed successfully. After complete separation of the mesoappendix, the appendix was straightened and measured along a single longitudinal axis, revealing a total length of 22 cm. The postoperative course was uneventful, and the patient was discharged on postoperative day one. Histopathological examination confirmed acute appendicitis.

Conclusion: Extreme appendiceal length is a rare anatomical variation that may lead to atypical clinical and radiological findings in acute appendicitis. Failure to visualize the distal appendiceal tip on imaging does not necessarily indicate perforation. Laparoscopy provides definitive diagnostic clarification and safe, effective treatment in cases with atypical appendiceal anatomy and should be considered the preferred surgical approach.

Keywords: Acute appendicitis, laparoscopic appendectomy, long appendix

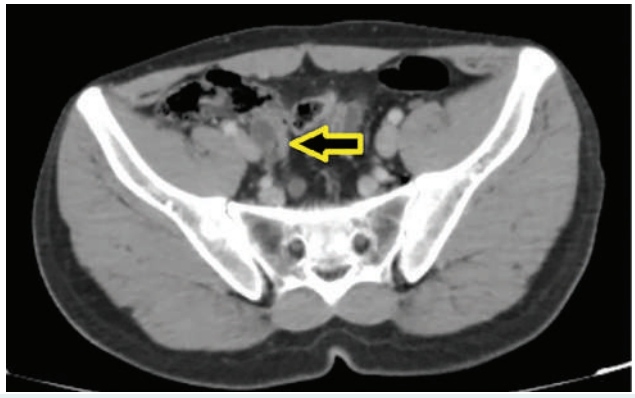

Figure 1. Contrast-enhanced abdominal computed tomography findings.

Axial contrast-enhanced abdominal computed tomography demonstrating inflammatory changes consistent with acute appendicitis. The appendiceal lumen follows a curved and circular course; however, the distal tip cannot be clearly identified as a separate structure, leading to preoperative suspicion of perforation.

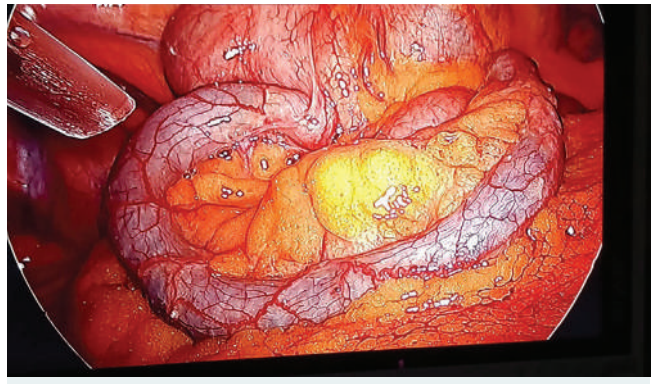

Figure 2. Intraoperative laparoscopic view.

Intraoperative laparoscopic view showing a markedly elongated and inflamed appendix with an anterior (preileal) course and a circularly coiled configuration. The atypical orientation and coiling account for the difficulty in identifying the distal appendiceal tip on preoperative imaging.

Figure 3. Gross appearance of the resected appendix.

Gross appearance of the resected appendix demonstrating marked elongation and a coiled configuration. The specimen is shown adjacent to a surgical ruler for reference. After complete separation of the mesoappendix, the appendix was straightened along a single longitudinal axis and measured to be 22 cm in length.

[P-403]

A rare clinical presentation in acute mesenteric ischemia: Gallbladder ischemia

Saltuk Yıldız, Selen Öztürk, Göksever Akpinar, Savaş Yakan

Department of General Surgery, University of Health Sciences Türkiye, İzmir Tepecik Training and Research Hospital, İzmir

Objective: Acute mesenteric ischemia (AMI) is rarely encountered in the general population; however, it is a cause of acute abdominal pain that is difficult to diagnose and requires early detection due to its high mortality rate. Etiologies of AMI include arterial occlusion, non-occlusive mesenteric ischemia, and venous occlusion. We aim to present this case because the coexistence of AMI and gallbladder ischemia has not been previously reported in the literature.

Material and Methods: Patient with a history of hypertension and no known hematological disorders presented to the emergency department with nausea, vomiting and generalized abdominal pain that had started 7-8 hours prior. Laboratory analysis revealed a WBC count of $30.6\times 10^{3}\mu L$, creatinine 1.6 mg/dL, lipase 245 U/L, CRP 62.1 mg/dL, and procalcitonin 2.22 µg. Sequential lactate levels were 4.6, 4.7, and 4.5 mmol/L despite aggressive hydration. An IV contrast-enhanced abdominal CT was performed. Considering the laboratory findings and the patient's clinical status, a CT Angiography of the abdomen was subsequently ordered. Although the CT Angiography report did not explicitly state findings favoring AMI, an emergency laparotomy was planned after a detailed review of the imaging by the surgical team and obtaining informed consent from the patient and relatives.

Results: Upon exploration, ischemia and necrosis were observed in all small bowel segments, sparing only 120 cm distal to the Treitz ligament and 140 cm proximal to the ileocecal valve. Consequently, a segmental small bowel resection and double-barrel enterostomy were performed. Due to observed necrosis at the stoma ends, the patient was re-explored on postoperative day 1. Necrosis was found in the remaining small bowel, sparing only 40 cm distal to the Treitz ligament and 20 cm proximal to the ileocecal valve. Furthermore, the gallbladder was also found to be ischemic during this exploration. The abdominal aorta, right hepatic artery, superior mesenteric artery, and renal arteries were observed to be full, rhythmic, and patent. Segmental small bowel resection, double-barrel enterostomy, and cholecystectomy were performed. The patient was followed up with a diagnosis of short bowel syndrome. On postoperative day 45, the patient developed respiratory distress, was intubated in the intensive care unit, and subsequently suffered cardiopulmonary arrest. The patient did not respond to CPR and passed away.

Conclusion: In this case, while the vital role of surgical exploration is re-emphasized, the importance of clinical suspicion, the review of imaging by the general surgeon—even when not detailed in the radiology report—and the decisive action for diagnostic laparotomy are highlighted.

Recurrent intestinal perforation and ischemic necrosis in a patient with systemic lupus erythematosus: A case report

Mustafa Can Çağ, Fevziye Duygu Avlar, Can Yahya Boztuğ, Hüseyin Garip, Kemal Aygün

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: This case report describes the management of acute abdominal complications and subsequent surgical interventions in a 39-year-old female with systemic lupus erythematosus (SLE), highlighting the challenges of intestinal involvement.

Material and Methods: A 39-year-old female with SLE presented with abdominal pain and diarrhea. Colonoscopy revealed terminal ileitis, suggesting SLE-related intestinal involvement. Following clinical deterioration with obstructive symptoms, contrast-enhanced CT showed wall thickening in the ascending colon and terminal ileum with mesenteric fat stranding. Emergency diagnostic laparotomy revealed closed perforations in the ileal loops, gato formation, and patchy necrosis.

Results: A wide resection was performed from 130 cm distal to the ligament of Treitz to the proximal third of the transverse colon, followed by end jejunostomy and transversostomy. Despite multiple cytokine filter applications for persistent sepsis, worsening abdominal findings necessitated a second laparotomy on postoperative day 6. A new necrotic and perforated area was identified 20 cm proximal to the jejunostomy. Consequently, further resection was performed from 100 cm distal to Treitz, and a jejunocolic anastomosis was created. On postoperative day 5, fecal discharge from the wound indicated an anastomotic leak, leading to a third operation where the anastomosis was converted to a permanent end jejunostomy. The patient initially responded to IVIG and steroid therapy, with regressing sepsis. However, while being followed for short bowel syndrome, she developed pulmonary thromboembolism despite prophylactic low molecular weight heparin. She progressed to shock and cardiac arrest under heparin infusion and was declared exitus. Pathological examination revealed full-thickness ischemic necrosis, though findings were not specifically diagnostic of SLE-specific vasculitis.

Conclusion: This case underscores the devastating potential of acute abdominal conditions in SLE. While initial findings suggested lupus enteritis, recurrent perforations and full-thickness necrosis indicate a progression based on severe intestinal ischemia rather than simple inflammation. The development of thromboembolism despite prophylaxis suggests an underlying prothrombotic state.The aggressive nature of SLE-related gastrointestinal complications, characterized by recurrence despite surgical intervention, carries high mortality.The failure of multiple laparotomies and the temporary response to immunomodulators reflect significant treatment resistance. This case emphasizes the necessity of a high index of clinical suspicion, rapid evaluation of ischemic causes (vasculitis or thrombosis), and an integrated multidisciplinary approach. Even without specific pathological confirmation of SLE vasculitis, ischemic processes must be prioritized in the management of acute abdominal complaints in SLE patients to improve prognosis.

Small bowel obstruction following gastric balloon placement: A rare complication

Yiğit Ata Öztürk, Fahri Kurucu, Can Yahya Boztuğ

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Endoscopic gastric balloon placement is a commonly used minimally invasive method in the treatment of obesity. It is generally considered safe. In the literature, the reported rate of balloon migration ranges from 0.5% to 1.5%. The incidence of obstruction requiring surgical intervention is below 1%. In this study, a case of mechanical ileus secondary to balloon migration is presented.

Material and Methods: A 24-year-old female patient with no known comorbidities and no history of prior abdominal surgery presented to the emergency department with persistent epigastric and periumbilical pain that had started 2 days earlier, inability to pass gas or stool for 2 days, and three episodes of yellow-colored vomiting. According to the medical history obtained, she had undergone endoscopic gastric balloon placement 3 months prior.

Results: On physical examination, abdominal distension and epigastric and periumbilical tenderness were noted. A preliminary diagnosis of mechanical ileus/internal herniation was considered, and an emergency laparotomy was planned. During laparotomy, free intraperitoneal fluid was observed. A foreign body was identified 150 cm distal to the ligament of Treitz. A 3 cm enterotomy was performed, and the foreign body was removed. Primary repair was carried out, and the repair site was reinforced with Lambert sutures. A Jackson-Pratt drain was placed in the pelvis.

Conclusion: Oral intake was initiated on postoperative day 1, and the patient was advanced to diet 1 on the same day. On postoperative day 2, the diet was progressed to diet 3. During follow-up, no nausea or vomiting developed, and the patient had passage of flatus and stool. The patient was discharged on postoperative day 3 with prescriptions and follow-up recommendations. Balloon migration is a rare (<1%) but serious complication. It should always be considered in patients presenting with ileus who have a history of gastric balloon placement. Early surgical intervention significantly improves the prognosis.

Keywords: Emergency laparotomy, foreign body-related obstruction, ileus

Intestinal tuberculosis: A case undergoing ileocecal resection due to ileus

Dilan Pehlivan[1], Merve Aktaş[2], Bilal Alkaş[1], Adam Rajab Mwinyi[1], Mehmet Uluşahin[1]

[1]*Department of General Surgery, Karadeniz Technical University Faculty of Medicine, Trabzon*

[2]*Clinic of General Surgery, Bayburt State Hospital, Bayburt*

Objective: Intestinal tuberculosis is a rare infectious disease which may clinically and radiologically mimic inflammatory bowel disease and malignancies. The ileocecal region is the most commonly involved site, and surgical intervention may be required due to complications such as obstruction, perforation, or bleeding. In this study, we aimed to present a case of intestinal tuberculosis presenting with ileus and diagnosed after surgical treatment.

Material and Methods: A 42-year-old male patient presented to the emergency department with complaints of nausea and vomiting. In his medical history, chronic hepatitis B infection and newly diagnosed pulmonary tuberculosis were present. Abdominal computed tomography revealed wall thickening up to approximately 11 mm in the ileocecal region, which was interpreted as inflammatory bowel disease or a mass lesion. Dilatation of small bowel loops compatible with ileus was observed. The patient was hospitalized in the general surgery department and followed under anti-tuberculosis treatment with medical management for ileus.

Results: During follow-up, due to the absence of clinical improvement despite medical treatment and progression of ileus findings, surgical treatment was decided. Intraoperatively, mass-like lesions causing luminal obstruction were detected at three different segments approximately 50-60 cm proximal to the terminal ileum and at the level of the cecum (Figure 1 and Figure 2). Ileocecal resection was performed. The postoperative course was uneventful, and the patient was discharged on postoperative day six. Histopathological examination was reported as intestinal tuberculosis.

Conclusion: Intestinal tuberculosis may mimic malignancy and inflammatory bowel disease with findings such as wall thickening and obstruction in the ileocecal region. In patients who do not respond to medical treatment and develop obstruction, surgical treatment may be required both for diagnosis and treatment. Intestinal tuberculosis should be considered in the differential diagnosis in patients presenting with ileocecal mass and ileus findings.

Keywords: Intestinal tuberculosis, ileus

A reliable reconstruction option in hidradenitis suppurativa: Superior gluteal artery perforator flap

Muhammed Alperen Taş[1], Eyyüp Maral[1], Servet Yekta Aydın[2], Ali Cihat Yıldırım[1]

[1]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

[2]*Clinic of Plastic and Reconstructive Surgery, Kütahya City Hospital, Kütahya*

Objective: Hidradenitis suppurativa (HS) is a recurrent, chronic, inflammatory skin disease that occurs in areas with a high concentration of apocrine glands, such as the axilla, inguinal region, perineum, and gluteal region. Its pathophysiology is explained by hyperkeratosis of the follicular epithelium and the resulting obstruction of the follicle, leading to an inflammatory condition. It presents with painful nodules, abscesses, fistulized sinuses, and prominent scarring. Conservative approaches are generally insufficient in these patients. Surgical treatment becomes inevitable to halt the progression of the disease and prevent recurrence. Incisions and drainage provide symptomatic relief during the acute abscess phase but do not eliminate the underlying cause. The gold standard in surgical treatment is extensive local excision based on the principle of radical removal of all inflammatory, hair-containing, and apocrine gland-containing skin and subcutaneous fatty tissue until healthy tissue borders are reached. The inevitable result of this excision is extensive tissue defects that cannot be closed primarily. In such cases, advanced reconstructive surgical techniques are employed.

Material and Methods: In this case, the diagnosis, treatment, and follow-up process of a patient with gluteal HS who underwent SGAP flap surgery at our clinic was evaluated.

Results: A 51-year-old male patient presented to the outpatient clinic with HS in the gluteal region, measuring approximately 12x11 cm, with a history of abscess drainage, fistulized sinuses, and deep scarring. A wide local excision was performed to include all foci of the disease. The wound was closed with a wet dressing. On the 4th postoperative day, a SGAP flap was applied to the right gluteal region by the plastic surgery team. The patient was discharged on the 7th postoperative day. No complications were observed in the flap tissue during postoperative follow-ups.

Conclusion: Pedicle perforator flap techniques represent a modern revolution in reconstruction. Secondary healing, split-thickness skin grafts, and musculocutaneous flaps-traditional reconstruction techniques-have prompted surgeons to seek new approaches due to high contracture risk, prolonged healing times, functional losses, and poor aesthetic outcomes. The fundamental principle of the pedicled perforator flap technique is the elevation of an island of tissue through a single perforator vessel that nourishes the skin and subcutaneous fatty tissue while preserving the underlying major muscle tissue. No recurrence has been reported in perforator flap repairs performed after wide local excision. In HS management, a multidisciplinary approach and correctly applied advanced reconstructive techniques have shown high success rates. However, larger case series and longer follow-up periods are needed for the future.

[P-411]

Managing Chilaiditi syndrome in laparoscopic surgery

Muhammed Salih Süer, Yılmaz Türk, İsmail Oskay Kaya

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Chilaiditi syndrome is a rare anatomical condition characterized by interposition of the colon, most commonly the hepatic flexure, between the liver and the diaphragm. On imaging, it may mimic serious conditions such as pneumoperitoneum and can present with abdominal pain, nausea, or respiratory symptoms due to diaphragmatic compression. Although most cases are asymptomatic and detected incidentally, Chilaiditi syndrome becomes clinically significant when it complicates surgical procedures, particularly laparoscopic operations in the upper abdomen. Altered anatomy may obscure normal landmarks, increase the risk of bowel injury, and necessitate modifications in trocar placement. Therefore, preoperative recognition and surgical planning are essential for safe operative management.

Material and Methods: We present a case of laparoscopic cholecystectomy performed in a patient with preoperatively diagnosed Chilaiditi syndrome. Preoperative imaging findings, intraoperative technical adaptations, and postoperative outcomes were retrospectively evaluated to highlight key surgical considerations.

Results: Preoperative computed tomography revealed interposition of the colon between the liver and diaphragm, consistent with Chilaiditi syndrome. Intraoperatively, reduction of the interposed colon was achieved easily. However, the liver was found to be displaced inferiorly, altering the usual anatomical relationships. Consequently, trocar placement was modified, with ports inserted at lower-than-standard positions to avoid bowel injury. Particular caution was exercised during instrument insertion due to the atypical presence of intestinal loops in the right upper quadrant.The procedure was completed without intraoperative complications. Given the patient's underlying chronic obstructive pulmonary disease and the potential impact of diaphragmatic compression, close postoperative respiratory monitoring was performed. The patient had an uneventful recovery and was discharged on postoperative day three.

Conclusion: Chilaiditi syndrome presents unique technical challenges during laparoscopic cholecystectomy despite the relative ease of colonic reduction. Inferior displacement of the liver and altered anatomical landmarks increase the risk of injury during trocar insertion and instrument manipulation. Careful preoperative imaging review, modification of trocar positioning, and heightened intraoperative vigilance are essential to ensure procedural safety. Additionally, potential respiratory implications related to diaphragmatic compression should be considered, particularly in patients with preexisting pulmonary disease. With appropriate planning and technique adjustments, laparoscopic cholecystectomy can be safely performed in patients with Chilaiditi syndrome.

Non-recurrent laryngeal nerve in thyroid surgery: Impact of intraoperative neuromonitoring and primary nerve repair on surgical outcomes

Narmin Hajizada, Harun Ölmez, Özcan Dere, Önder Özcan, Cem Dönmez

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: The non-recurrent laryngeal nerve (NRLN) is a rare anatomical variation of the RLN and represents one of the highest-risk situations for nerve injury in thyroid surgery. The reported incidence of NRLN is 0.3-1% on the right side and <0.1% on the left. In this variation, the nerve branches from the vagus nerve at a high cervical level and directly enters the larynx without following the tracheoesophageal groove. Failure to recognize the NRLN intraoperatively may result in permanent vocal cord paralysis. In this study, we aimed to evaluate intraoperative neuromonitoring findings, the experience of primary repair in a case with nerve injury, and surgical outcomes in patients with NRLN identified during thyroid surgery, and to compare these findings with the literature.

Material and Methods: Patients who underwent thyroidectomy in our clinic were retrospectively reviewed. Patients in whom a NRLN was identified intraoperatively were included in the study. The evaluated parameters included demographic data, surgical indication, intraoperative neuromonitoring findings, nerve injury and repair status, postoperative vocal cord function, and pathological results.

Results: A total of four NRLN cases were identified. The mean age was 64.3 years (range: 54-70). Surgical indications were hyperthyroidism (n=2), thyrotoxicosis (n=1), and compressive symptoms (n=1). Pathology revealed papillary thyroid carcinoma in one case and benign disease in three cases. During intraoperative neuromonitoring, no signal was obtained from vagus nerve stimulation in one patient; however, a strong response was recorded from a high-located NRLN in the same patient, confirming the presence of NRLN. NRLN injury occurred in one case and was repaired intraoperatively using primary epineural suturing. Postoperative vocal cord assessment showed permanent paralysis in 1 (25%), transient minimal limitation in 1 (25%), and normal function in 2 (50%) patients.

Conclusion: In the presence of a NRLN, failure to identify the nerve in its usual anatomical location complicates dissection and increases injury risk. The 25% permanent paralysis rate in our series supports the elevated surgical risk associated with NRLN. Intraoperative neuromonitoring is a valuable adjunct; absence of response to vagus stimulation with a positive signal at the laryngeal entry level represents a typical neurophysiological pattern for NRLN, also observed in our series. NRLN injury is rare but serious, and primary epineural repair may provide functional recovery. When vagus stimulation is negative, NRLN should be suspected and sought at the laryngeal entry level.

Revisional sleeve gastrectomy in a patient who developed weight gain after plication surgery: A single case report

Fırat Aslan[1], Muzaffer Önder Öner[2], Serhat Binici[1]

[1]*Department of General Surgery, Van Yüzüncü Yıl University Faculty of Medicine, Van*

[2]*Department of General Surgery, İstanbul Nişantaşı Üniversitesi BHT Clinic, İstanbul*

Objective: Various bariatric surgical techniques are used in the treatment of obesity. As a primary surgical procedure, gastric plication aims to achieve weight loss by reducing gastric volume. However, in some patients, insufficient weight loss or weight regain may be observed after plication. In such cases, revisional surgical options are considered to achieve more effective weight loss. Sleeve gastrectomy is one of the commonly preferred methods in revisional surgery. The aim of this study is to evaluate the effectiveness and safety of revisional sleeve gastrectomy in patients who developed weight gain after primary plication surgery.

Material and Methods: A 38-year-old female patient who underwent gastric plication as primary obesity surgery was found to have significant weight gain within one year. Clinical and metabolic evaluations of the patient were performed, and revisional surgery was decided due to insufficient weight loss. Revisional surgery was carried out using the laparoscopic sleeve gastrectomy technique. The patient's weight, metabolic parameters, and quality of life were monitored before and after the operation.

Results: After revisional sleeve gastrectomy, a significant reduction in the patient's weight was observed. During the 6-month follow-up period, approximately 25% of the initial body weight was lost. Improvements were noted in blood glucose levels, lipid profile, and blood pressure values. No postoperative complications developed, and the patient successfully adhered to lifestyle changes after surgery.

Conclusion: Revisional sleeve gastrectomy is an appropriate and safe option for achieving effective weight loss and metabolic improvement in patients who develop weight gain after gastric plication surgery. Patient selection, a multidisciplinary approach, and long-term follow-up are key factors for success. Revisional surgery is an important component of personalized strategies in the treatment of obesity.

A rare benign breast lesion: Hamartoma of the right breast

Güvenç Diner, Boran Cihat Karakuş, Güven Erdoğrul

Department of General Surgery, University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: Breast hamartomas are rare tumors formed by irregular but benign proliferation of normal breast tissue components. Histopathologically, they consist of varying proportions of glandular, fibrous, and fatty tissue. Clinically, they usually present as painless, slow-growing, well-circumscribed, most commonly in middle-aged women. They can be confused with fibroadenoma, lipoma, or fibrocystic changes. Imaging provides important diagnostic clues, but definitive diagnosis is often made by histopathology. Although malignant transformation is rarely reported, correct diagnosis and appropriate surgical management are necessary.

Material and Methods: A 47-year-old woman presented our general surgery clinic with a palpable mass in the right breast. She reported noticing the mass in the for about four months. There was no family history of breast cancer. Physical examination revealed a painless, well-circumscribed mass in the lower quadrant of the right breast. No pathological axillary lymph nodes were detected. Ultrasound showed a 21×11 mm solid lesion at 7-8 o'clock in the right breast, with a hypoechoic periphery, hyperechoic center, defined margins, and macrolobulated; hamartoma was the preliminary diagnosis. MRI also demonstrated a solid mass of 2×1 cm compatible with hamartoma. Tru-cut biopsy was performed and histopathology reported findings consistent with a hamartoma containing fibrous tissue. The lesion was excised through an incision in the lower outer quadrant of the right breast. No complications occurred postoperatively, and the patient was discharged without issues on the second postoperative day. Histopathological specimen confirmed the diagnosis of hamartoma.

Results: Breast hamartomas are rare lesions that require careful diagnosis because they resemble other benign breast lesions clinically. Reported cases in the literature show that these lesions most commonly occur in middle-aged women and present as slow-growing, usually asymptomatic masses. Their well-circumscribed and mobile nature on physical examination often leads to confusion with many benign pathologies, especially fibroadenoma. Therefore, clinical evaluation must be supported by imaging methods. Mammography, ultrasonography, and magnetic resonance imaging are helpful in diagnosis by revealing the heterogeneous content and capsule-like appearance of hamartomas. However, imaging findings are not always specific, so definitive diagnosis is made by histopathological examination. Preoperative tru-cut biopsy assists in the diagnosis. Malignant transformation has been rarely reported in hamartomas. This increases the importance of surgical excision, especially in lesions with rapid growth or atypical radiologic features.

Conclusion: Although breast hamartomas are rare, they must be considered in the differential diagnosis of benign breast lesions. A multidisciplinary approach including clinical examination, imaging, and histopathological evaluation is essential for accurate diagnosis and appropriate treatment.

Keywords: Benign breast lesion, hamartomas, trucut biopsy

Laparoscopic cholecystectomy in a case of hepatized gallbladder: Surgical process and outcomes

Aslan Mert Demirci

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Gallbladders have been reported in various ectopic locations. An intrahepatic gallbladder is defined as a gallbladder located within the liver parenchyma or in a subcapsular position along the anteroinferior surface of the right hepatic lobe.

Material and Methods: In this report, we present the case of a 62-year-old man in whom an intrahepatic gallbladder was not identified preoperatively but who underwent laparoscopic cholecystectomy without intraoperative or postoperative complications.

Results: A 62-year-old male presented to the outpatient clinic with a six-month history of intermittent colicky abdominal pain, predominantly localized to the right hypochondrium and radiating to the right shoulder. His past medical and family histories were unremarkable. General examination was unremarkableand all observations were stable. Abdominal examination revealed no palpable masses ororganomegaly. There was mild tenderness in the right upper quadrant and epigastric region with no rebound tenderness and Murphy's sign was negative. Initial laboratory investigations including full blood count, liver function tests, and serum amylase as well as kidney functiontests were all normal. Based on the history and clinical findings, a provisional diagnosis of gallbladder stones was suspected. Abdominal ultrasonography and computed tomography were planned for further evaluation. Following appropriate preoperative preparation, the patient underwent elective laparoscopic cholecystectomy successfully. No intraoperative complications occurred, and the patient was discharged on postoperative day one without any complications.

Conclusion: Although intrahepatic gallbladder is a rare congenital anomaly, it frequently requires surgical intervention due to an increased incidence of cholelithiasis associated with biliary stasis. Awareness of ectopic gallbladder locations and accurate recognition of this condition are crucial for appropriate intraoperative planning and for minimizing potential surgical complications.

Gastric fistula developing after gynecological oncology surgery: Case report

Bülent Sultanoğlu[1], Kenan Demirbakan[2], Murat Oynak[3]

[1]*Clinic of General Surgery, Gaziantep City Hospital, Gaziantep*

[2]*Clinic of General Surgery, Memorial Antalya Hospital, Antalya*

[3]*Clinic of Interventional Radiology, Memorial Antalya Hospital, Antalya*

Objective: Gastrointestinal complications following gynecological oncology surgery occur in 5-10% of cases. Gastric fistula is a rare but serious condition among these complications. This study presents a case of gastric fistula that developed in a patient operated on for mucinous ovarian cancer and aims to emphasize the importance of a multimodal treatment approach.

Material and Methods: A 28-year-old female patient was operated on by gynecology for mucinous cell ovarian cancer. The patient underwent oophorectomy, total omentectomy due to omental cake, and peritonectomy. On the 45th postoperative day, the patient presented to our emergency department with epigastric abdominal pain. Computed tomography revealed an abscess between the stomach and spleen. The fistula was drained under computed tomography guidance after consultation with interventional radiology, and fistulization to the stomach was detected during drainage. The patient was monitored conservatively with discontinuation of oral intake. During follow-up, the fistula closed spontaneously. A pouch radiograph taken before catheter removal showed that the pouch had opened into the gastric vein. The patient underwent surgery, and wedge resection of the fistula area was performed with a stapler. The postoperative period was uncomplicated, and the patient was discharged in good health.

Results: Common cytoreductive procedures in gynecological oncology surgery, especially omentectomy and peritonectomy, are risk factors for intra-abdominal abscess development. Percutaneous drainage is the first-line treatment in patients with gastric fistulas and has a success rate of 70-90%. 15-25% of fistulas can close spontaneously with conservative treatment. Fistulography is essential for pre-surgical anatomical evaluation. In definitive surgical treatment, wedge resection with a stapler is a safe and effective method.

Conclusion: Gastric fistula developing after gynecological oncology surgery is a rare but serious complication. Early diagnosis, appropriate drainage guided by computed tomography, conservative treatment, and timely surgical intervention can lead to successful outcomes. A multimodal and multidisciplinary approach is the most important factor in patient management and provides results consistent with the literature.

Keywords: Gastric fistula, multimodal treatment, ovarian cancer, percutaneous drainage, postoperative complications

Giant retroperitoneal dedifferentiated liposarcoma: A rare case presentation requiring multivisceral en-bloc resection

Özge Bozdemir Altınışık[1], Emine Mataracı[2], Maksude Esra Kadıoğlu[3], Aydın Aktaş[1], İsmet Çelik[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

[2]*Department of Pathology, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

[3]*Department of Radiology, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

Objective: Retroperitoneal soft tissue sarcomas are rare malignancies, accounting for approximately 10-15% of all sarcomas. Among these, dedifferentiated liposarcomas are characterized by aggressive biological behaviour and a high risk of local recurrence. Due to the expansive nature of the retroperitoneal space, these tumours often remain asymptomatic for prolonged periods, leading to delayed diagnosis and presentation at advanced stages with large tumour volumes. Radiologically, dedifferentiated liposarcomas may mimic peritoneal carcinomatosis or gynaecological malignancies, posing significant diagnostic challenges. This case report describes a patient who was initially suspected of having a gynaecological malignancy but was ultimately diagnosed with a giant retroperitoneal dedifferentiated liposarcoma following surgical and histopathological evaluation.

Material and Methods: A 76-year-old female with a medical history of hypertension and asthma presented with progressive constipation and abdominal distension over several months. Contrast-enhanced abdominal computed tomography demonstrated heterogeneously enhancing mass lesions within the mesenteric fatty tissue, consistent with an omental cake appearance. Serum tumour markers were within normal limits. Tru-cut biopsy findings were suggestive of liposarcoma, and surgical intervention was planned. Intraoperative exploration revealed a giant retroperitoneal mass measuring approximately 50×40×15 cm. With the aim of achieving R0 resection, the tumour was excised en bloc with the left kidney and left adrenal gland. Due to concerns regarding surgical margin safety, splenectomy and total abdominal hysterectomy with bilateral salpingo-oophorectomy were additionally performed. The postoperative course was uneventful, and the patient was discharged on postoperative day seven. Histopathological examination confirmed FNCLCC grade 2 dedifferentiated liposarcoma with negative surgical margins, and immunohistochemical analysis demonstrated strong positivity for MDM2 and CDK4.

Results: Retroperitoneal dedifferentiated liposarcomas typically present with nonspecific symptoms, contributing to delayed diagnosis and advanced disease at presentation. While tumour sizes reported in the literature commonly range between 15 and 30 cm, the approximately 50 cm mass observed in this case represents an exceptional finding. Moreover, the radiological mimicry of gynaecological malignancy and the requirement for extensive multivisceral en bloc resection involving the kidney, adrenal gland, spleen, and gynaecological organs render this case particularly rare. As complete surgical excision with negative margins remains the most critical prognostic factor, aggressive multivisceral resection is justified when clear anatomical planes are absent.

Conclusion: This case highlights the importance of accurate diagnosis and radical surgical management in achieving optimal oncological outcomes.

Keywords: Differential diagnosis (gynaecological malignancy), multivisceral en bloc resection, retroperitoneal dedifferentiated liposarcoma

The impact of histological subtype on clinical course in retroperitoneal adipose tumors: A comparison of dedifferentiated liposarcoma and benign adipose tumor

Mehmet Furkan Avcı, Turgay Şimşek, Mehmet Fatih Özsaray, Abdülaziz Emek, Nuh Zafer Cantürk, Orhan Tatlı

Kocaeli University Faculty of Medicine, Kocaeli

Objective: Retroperitoneal adipose tumors are rare, and preoperative differentiation between benign and malignant lesions is often challenging. Because these tumors can remain asymptomatic for a long time within the wide retroperitoneal space, they are usually diagnosed after reaching a large size. Histological subtype, particularly the presence of dedifferentiated liposarcoma, has a significant impact on clinical course, local recurrence risk, and prognosis. In this study, two retroperitoneal adipose tumors with different biological behaviors were compared to highlight the impact of histological subtype on clinical outcomes.

Material and Methods: This study is a retrospective evaluation of two patients who presented with abdominal pain and were found to have retroperitoneal adipose tumors. The patients were assessed using contrast-enhanced computed tomography (CT), and open surgical resection was performed following a multidisciplinary board decision. Resected specimens were examined histopathologically and immunohistochemically. Postoperatively, the patients were followed up with clinical and radiological evaluations.

Results: In both cases, preoperative contrast-enhanced CT revealed retroperitoneal adipose tumors. In the first case, the mass measured 36×24×13 cm and showed a heterogeneous appearance with thick septations and solid nodular components. En-bloc surgical resection was performed, and histopathology revealed FNCLCC grade 3 dedifferentiated liposarcoma with positive margins. At six months, follow-up CT demonstrated local recurrence involving the left kidney, and the patient underwent reoperation with concomitant nephrectomy. In the second case, a 22×11 cm retroperitoneal mass with homogeneous fat density and thin septations was observed, and complete resection was achieved. Histopathology showed no cellular atypia or mitotic activity, consistent with a benign adipose neoplasm (lipoma), and surgical margins were negative. During one-year follow-up, no local recurrence or complications were detected. When the cases were compared, early local recurrence occurred in the dedifferentiated liposarcoma case, whereas no recurrence occurred in the benign case. Positive margins and aggressive histology adversely affected the clinical course. No perioperative mortality or major complications were observed.

Conclusion: Histological subtype is one of the most important factors determining the clinical course and risk of local recurrence in retroperitoneal adipose tumors. Dedifferentiated liposarcoma exhibits aggressive biological behavior with early local recurrence, whereas benign adipose tumors generally have a favorable postoperative prognosis. In malignant cases, achieving negative surgical margins and close long-term follow-up are critical for disease-free survival. Therefore, a histology-based surgical approach and regular surveillance are recommended in the management of retroperitoneal adipose tumors.

Early gastric cancer originating from a giant pedunculated gastric polyp

Muhammed Çağrı Akköprü

Department of General Surgery, Fırat University Hospital, Elazığ

Objective: Polypoid lesions are defined as mucosal or submucosal projections extending into the gastrointestinal lumen. Although initial diagnosis of a gastric polyp can be made by endoscopic visualization, histopathological examination is essential for accurate classification. In clinical practice, such polypoid lesions are commonly referred to as "polyps." Gastric polyps are encountered in approximately 2-3% of upper gastrointestinal endoscopic examinations.Early gastric cancer is defined as adenocarcinoma confined to the mucosa or submucosa (T1Nx), regardless of regional lymph node involvement. Early gastric cancer has an excellent prognosis, with five-year survival rates exceeding 90%. A 56-year-old female patient presented to our outpatient clinic with complaints of epigastric pain, nausea, and loss of appetite. Her vital signs were as follows: blood pressure 110/70 mmHg, pulse rate 80 beats per minute, and body temperature 36.7 °C. Physical examination revealed epigastric tenderness, with no other pathological findings. Laboratory investigations showed hemoglobin level of 9.8 g/dL, while other parameters were within normal limits.

Material and Methods: Upper gastrointestinal endoscopy was planned for diagnostic and screening purposes and was performed under anesthesia.

Results: Endoscopic examination revealed a giant pedunculated gastric polyp originating from the corpus and extending toward the antrum. Multiple biopsies were obtained from the polyp and sent to the pathology laboratory for histopathological evaluation. Histopathological examination revealed adenocarcinoma. The patient was subsequently referred to the oncology department for further evaluation, including contrast-enhanced thoracic and whole-abdominal computed tomography (CT) and positron emission tomography (PET). Based on imaging findings and multidisciplinary discussion at the general surgery–oncology board, the case was considered consistent with early-stage gastric adenocarcinoma. Endoscopic excision of the polyp was planned, with further treatment to be reassessed according to the histopathological findings. During the procedure, the pedunculated polyp was observed to extend from the gastric corpus through the pylorus into the duodenal bulb. The polyp was retracted from the bulb back into the stomach and resected at its stalk using a snare, completing the polypectomy. Histopathological examination of the resected specimen demonstrated that the adenocarcinoma was confined to the surface of the polyp, with no evidence of malignancy in the stalk or at the mucosal junction.

Conclusion: With the widespread use of endoscopy for the screening and diagnosis of upper gastrointestinal diseases, the detection rate of gastric polyps has increased, leading to a parallel rise in the diagnosis of early-stage gastric cancer. In polyps with a risk of malignant transformation, complete excision by polypectomy—including the stalk and adjacent mucosa—plays a critical role in both diagnosis and treatment.

Deep aggressive angiomyxoma of the vulva: A rare case with an infiltrative growth pattern

Özgür Gangal, Onur Saygın, Mustafa Satman, Yunus Emre Çalışkan, Esra Akça Çalışkan, Metehan Arslan, Emre Bozdağ, Erkan Somuncu

Department of General Surgery, University of Health Sciences Türkiye, Kanuni Sultan Süleyman Training and Research Hospital, İstanbul

Objective: Aggressive angiomyxoma is a rare mesenchymal neoplasm of the pelvic and perineal regions with locally aggressive behavior. Although slow-growing, its infiltrative nature makes complete surgical excision difficult and is associated with a high risk of recurrence. This report presents the clinical, radiological, surgical, and pathological features of a deep aggressive angiomyxoma located in the labium majus.

Material and Methods: Clinical, radiological, surgical, and pathological data of a patient who underwent surgical treatment for a vulvar mass were retrospectively evaluated.

Results: A 25-year-old woman presented with a two-year history of progressively increasing swelling in the left genital region and recently increased pain. Physical examination revealed a soft, mobile, subcutaneous mass measuring approximately 10×5 cm along the left labium majus (Figure 1). No ulceration, discoloration, active bleeding, or bilateral inguinal lymphadenopathy was observed. The patient had no chronic diseases. Her medical history included appendectomy and genital condyloma excision in 2023. Ultrasonography demonstrated a semisolid, heterogeneous subcutaneous mass. Pelvic magnetic resonance imaging revealed a lesion extending from the left labium majus to the left inguinal canal, showing hyperintense signal intensity on T2-weighted images and peripheral-septal contrast enhancement. Imaging findings were interpreted as an infiltrative, low-grade locally aggressive soft tissue tumor (Figure 2). Surgical exploration in the lithotomy position revealed a lesion closely related to surrounding soft tissues, without a distinct capsule and with ill-defined margins. The lesion was excised. Due to the size of the defect and tissue tension, plastic surgery consultation was obtained, and reconstruction was performed using a fasciocutaneous flap (Figure 3). No postoperative complications occurred. Macroscopic examination revealed a bright, homogeneous lesion with myxoid features. Microscopic evaluation showed hypocellular areas with loose myxoid stroma and thin-walled vascular structures. Tumor infiltration into adipose tissue and peripheral nerve structures was observed, adjacent to the surgical margins. Immunohistochemistry demonstrated estrogen and progesterone receptor positivity, focal desmin positivity, and weak smooth muscle actin expression. CD31, S100, SOX10, STAT6, and MUC4 were negative. The Ki-67 proliferation index was 2%. These findings confirmed the diagnosis of deep aggressive angiomyxoma. Due to margin proximity, positron emission tomography revealed a millimetric residual lesion consistent with the surgical field. The patient was enrolled in close clinical and radiological follow-up.

Conclusion: Deep aggressive angiomyxoma has a high recurrence potential due to its infiltrative growth pattern despite benign histology. Vulvar anatomical limitations hinder clear surgical margins and increase residual disease risk, necessitating a multidisciplinary surgical approach and long-term clinical-radiological follow-up.

Keywords: Aggressive angiomyxoma, vulva, labium majus, soft tissue tumors

A rare cause of intra-abdominal mass in an adult patient: Omental cavernous lymphangioma

Abdullah Sami Maden[1], Üsame Yıldız[1], Mehmet Emin Şahin[1], Süleyman Kargın[1], Yusuf Tanrıkulu[2]

[1]*Konya City Hospital, Konya*

[2]*Başkent University, Konya Application and Research Center, Konya*

Objective: Lymphangiomas are benign malformations of the lymphatic system, predominantly diagnosed in children; adult cases are rare. Intra-abdominal involvement represents a small fraction of all lymphangiomas and is even less frequent in adults. These lesions most commonly arise from the mesentery or omentum, while primary omental localization in adults has been only rarely reported. Although the exact pathogenesis remains unclear, progressive cystic dilatation due to congenital lymphatic drainage abnormalities during embryologic development is the most accepted mechanism. Histologically, lymphangiomas are classified as simple, cavernous, or cystic types. The cavernous subtype consists of dilated endothelial-lined lymphatic channels within a fibrous stroma. Clinical presentation is usually non-specific and may include abdominal pain, distension, nausea, or constipation. Imaging typically reveals multiloculated cystic lesions with thin septations; however, proximity to adjacent organs may complicate differentiation from malignancy. Definitive diagnosis is generally established after surgical resection and histopathological evaluation.

Material and Methods: This study represents a retrospective single-center case report. Clinical findings, radiologic imaging, intraoperative observations, and histopathological results were reviewed from medical records.

Results: A 43-year-old woman presented with longstanding abdominal pain and constipation. Physical examination suggested a mass in the left lower quadrant. Laboratory findings were normal. Contrast-enhanced abdominal computed tomography demonstrated a cystic lesion surrounding the left colon and extending toward the left adnexa, with loculated fluid in the pararectal area. Malignancy could not be excluded radiologically. Colonoscopy revealed no significant intraluminal pathology except for a small rectal polyp. Following multidisciplinary assessment, surgical exploration was performed. Intraoperatively, the omentum encased the left segment of the transverse colon, producing a marked mass effect. Given the close relationship with the colon and the inability to exclude malignancy preoperatively, a left hemicolectomy was undertaken according to oncologic principles. Histopathology confirmed cavernous lymphangioma of the omentum without evidence of colonic malignancy. The postoperative course was uneventful, and no recurrence was observed during three years of follow-up.

Conclusion: Cavernous omental lymphangioma in adults is an exceptionally rare benign condition. Its non-specific clinical and radiologic features may mimic malignant disease, making preoperative diagnosis difficult. Complete surgical excision is curative, with low recurrence rates after total resection. Lymphangioma should be considered in the differential diagnosis of intra-abdominal cystic masses in adults to guide appropriate management and potentially avoid unnecessary extensive resections.

Keywords: Cavernous lymphangioma, intra-abdominal mass

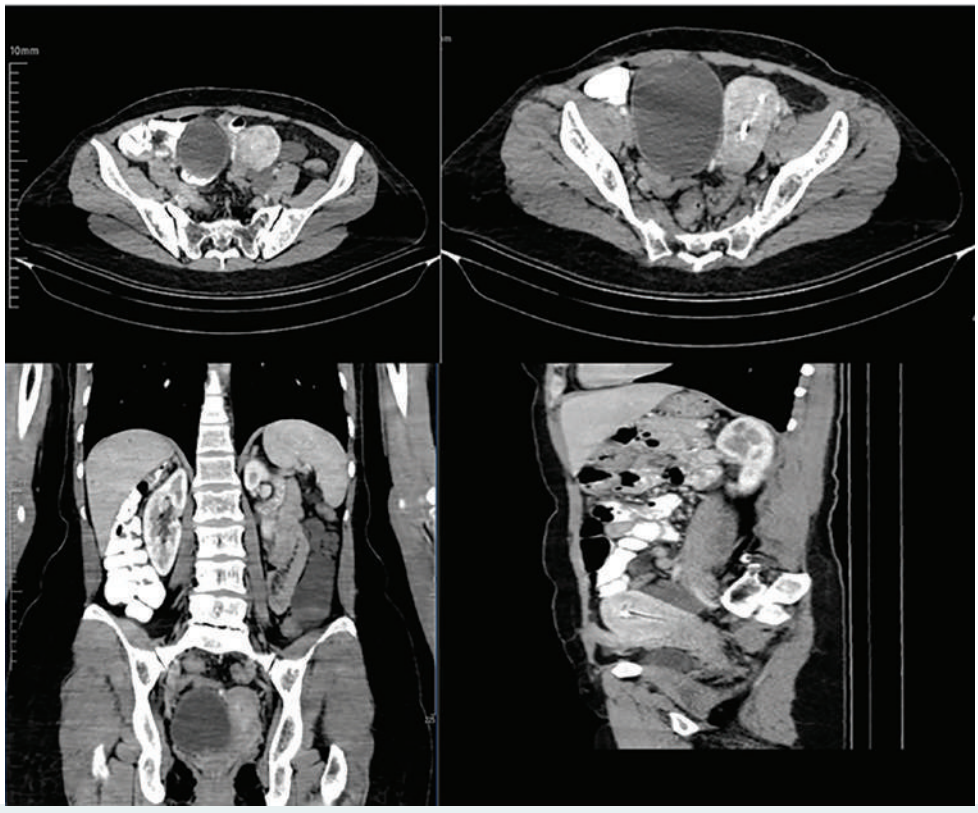

Figure 1. Imaging findings.

Primary squamous cell carcinoma presenting with an obstructive mass in the cecum: A rare colon tumor

Özgür Gangal, Onur Saygın, Serdar Kaan Küçük, Harun Avcuoğlu, Beyhan Kılıç, Yasin Kara, Emre Bozdağ, Erkan Somuncu

Department of General Surgery, University of Health Sciences Türkiye, Kanuni Sultan Süleyman Training and Research Hospital, İstanbul

Objective: The vast majority of colorectal cancers are adenocarcinomas, whereas primary squamous cell carcinoma of the colon is extremely rare. Definitive diagnosis is established by histopathological and immunohistochemical evaluation of resection material. This report presents a case of primary squamous cell carcinoma detected in a patient after surgery for an obstructing cecal mass.

Material and Methods: Clinical, radiological, endoscopic, surgical, and pathological data of a patient who underwent surgical treatment for an obstructive cecal mass were retrospectively reviewed. Histopathological and immunohistochemical analyses of the resection specimen were performed.

Results: A 62-year-old woman presented to the emergency department with a four-day history of abdominal pain, constipation, and nausea. She was hemodynamically stable. Her medical history included cholecystectomy, appendectomy, bilateral total thyroidectomy, and incisional hernia repair, with no chronic diseases. Abdominal computed tomography demonstrated irregular wall thickening in the proximal colon with distal dilated bowel loops and air-fluid levels consistent with ileus. The patient was hospitalized, and after decompression, colonoscopy on the second day revealed a near-complete obstructing cecal mass preventing luminal passage. Biopsies were obtained; however, emergency surgery was performed on the same day due to obstruction without awaiting biopsy results. Surgical exploration revealed an approximately 6 cm obstructing cecal mass and dense adhesions between small bowel loops. No macroscopic metastasis or peritoneal carcinomatosis was observed; ascites was present. Right hemicolectomy with ileocolic anastomosis and adhesiolysis were performed. The postoperative course was uneventful, and the patient was discharged on day 8. No additional findings were noted during follow-up. Colonoscopic biopsy was reported as poorly differentiated carcinoma. Pathological examination of the resection specimen revealed an ulcerative tumor measuring 5.5×4×4 cm. Histopathology demonstrated moderately differentiated squamous cell carcinoma with subserosal invasion. Angiolymphatic invasion was present, while venous and perineural invasion were absent. All 31 lymph nodes were reactive, and surgical margins were negative. Immunohistochemical examination showed cytokeratin 5/6 positivity with widespread cytoplasmic staining and nuclear p63 positivity. Chromogranin and synaptophysin were negative. The Ki-67 proliferation index was 40%. Tumor-infiltrating lymphocytes were prominent. Mismatch repair analysis revealed loss of MLH1 and PMS2 and preserved MSH2 and MSH6 expression. Anal canal involvement, an adenocarcinoma component, and another primary squamous cell carcinoma focus were excluded, establishing the diagnosis of primary colonic squamous cell carcinoma.

Conclusion: Primary squamous cell carcinoma of the cecum is a rare histological subtype. Accurate diagnosis requires detailed histopathological and immunohistochemical evaluation of resection material and is essential for appropriate clinical management and follow-up.

Keywords: Squamous cell carcinoma, colorectal tumors, immunohistochemistry

Incidental giant ileal GIST: A case report

Emin Yılmaz[1], Felat Akıncı[2], Zeyneddin Ali Muhammed[1], Erol Pişkin[2]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

[2]*Clinic of Gastroenterology Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, Ankara*

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal system and are usually located in the stomach and small intestine. These tumors, which often present with non-specific symptoms, can be detected incidentally, especially when they are small in size.

Material and Methods: Our hospital has accessed the preoperative and postoperative information of the patient operated on in gastroenterology surgery through the system.

Results: A 53-year-old male patient presented with a hard mass in the right lower quadrant of his abdomen. Imaging findings revealed a 16 cm mass originating in the ileum, showing no invasion into surrounding tissues. The patient underwent segmental small bowel resection. The pathology result was consistent with high-risk GIST, and R0 resection was achieved. The patient recovered without complications in the postoperative period, and adjuvant imatinib therapy was initiated. No recurrence or metastasis was observed during the twelve-month follow-up.

Conclusion: This case demonstrates that large-sized ileal GISTs with an asymptomatic course can be detected incidentally. Early surgical resection and appropriate adjuvant therapy are fundamental approaches that increase long-term survival.

Keywords: GIST, ileum, imatinib

A rare retroperitoneal tumor detected synchronously with colorectal adenocarcinoma: PEComa

Hikmet Kadakal, Oğuzhan Büyükgebiz

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Perivascular epithelioid cell tumors (PEComa) are rare mesenchymal neoplasms composed of distinctive perivascular epithelioid cells that co-express melanocytic (HMB-45, Melan-A) and muscle (SMA, Desmin) markers. While commonly found in the uterus and gastrointestinal system, retroperitoneal localization is exceptionally rare, and synchronous presentation with another malignancy is infrequently reported in the literature. This study aims to present a case of retroperitoneal PEComa incidentally detected during surgery for colorectal adenocarcinoma.

Material and Methods: A 73-year-old female patient presented with abdominal pain and constipation. Abdominal CT revealed wall thickening and lymphadenopathy at the sigmoid-descending colon level, but no retroperitoneal mass was reported. Following a colonoscopy that showed an ulcerovegetative mass at 30 cm, an anterior resection was planned. During surgical exploration, a yellow, 1.5 cm retroperitoneal mass, independent of the rectal tumor, was noticed in the superomedial aspect of the left kidney and was totally excised in addition to the rectal surgery.

Results: Pathological examination of the rectal specimen revealed "Moderately differentiated Adenocarcinoma (pT3N0Mx)". The retroperitoneal mass showed a mesenchymal tumor composed of epithelioid cells with clear and eosinophilic cytoplasm. Immunohistochemical analysis demonstrated that the tumor cells were positive for HMB-45, Melan-A, and SMA, while negative for S-100, CD117 (c-kit), and DOG-1. With a Ki-67 index of 2% and no necrosis, the lesion was diagnosed as "PEComa" based on its immune profile and morphology. The patient was discharged on the 10th postoperative day, and adjuvant therapy was planned for the rectal cancer.

Conclusion: Cases of retroperitoneal PEComa concurrent with colorectal malignancies are extremely limited in the literature. These tumors, which lack specific radiological findings, can be confused with Gastrointestinal Stromal Tumors (GIST) or metastases. Definitive diagnosis is established via immunohistochemical examination showing HMB-45 and SMA positivity with CD117 negativity. Surgical excision and close follow-up remain the primary treatment approach for these tumors, which may have uncertain malignant potential.

Keywords: PEComa, rectal cancer, retroperitoneal tumor

Neostigmine use in the treatment of postoperative gastroparesis developing in a patient with Parkinson's disease: A case report

Canyar Eşref Beyatlı, Mehmet Ali Koç

Department of General Surgery, Ankara University Faculty of Medicine, Ankara

Objective: Postoperative gastroparesis is a gastrointestinal motility disorder that can develop after abdominal surgery and is more common in patients who are elderly, have diabetes mellitus, or have neurological disease. Clinically, it presents with nausea, vomiting, gastric dilatation, and oral intake intolerance, which may prolong the hospital stay. Standard treatment includes nasogastric decompression, fluid-electrolyte balance, and prokinetic agents; however, resistance to treatment may develop in some cases. Although neostigmine, an acetylcholinesterase inhibitor, is known to increase intestinal motility, its role in the treatment of postoperative gastroparesis is limited. This study presents the successful treatment of refractory gastroparesis with neostigmine following extended right hemicolectomy.

Material and Methods: A 78-year-old male patient with a history of Parkinson's disease, hypertension, diabetes mellitus, and hypothyroidism underwent an extended laparoscopic right hemicolectomy due to a mucinous adenocarcinoma located in the hepatic flexure. During the operation, the stomach was skeletonized along the greater curvature, including the pylorus. Due to postoperative nausea, vomiting, and abdominal distension, nasogastric drainage was applied. Since metoclopramide was contraindicated due to Parkinson's disease, domperidone 3×10 mg intravenous and neostigmine 2.5 mg intravenous infusion therapy were initiated after a neurology consultation.

Results: On postoperative day 5, nausea-vomiting and abdominal distension developed after oral intake. Imaging revealed marked gastric dilatation. Daily drainage of 1300-1500 mL of bile-containing fluid was observed via nasogastric tube, and bowel sounds were hypoactive. Despite intravenous domperidone treatment, no clinical improvement was observed within three days. After neostigmine treatment: A decrease in nasogastric drainage volume, an increase in bowel sounds, gas and stool passage were observed, and an improvement in oral intake tolerance was noted. No extrapyramidal symptoms were observed during the treatment. The nasogastric tube was removed on the third day of treatment. Following the discontinuation of treatment, mild symptoms developed, and neostigmine was restarted, resulting in complete clinical improvement. Nine days after the start of treatment, the patient was able to tolerate a diet 3 regimen. No recurrence was observed during clinical follow-up.

Conclusion: Postoperative gastroparesis is a challenging clinical condition to manage, particularly in patients at high risk for autonomic dysfunction. This case demonstrates that the use of neostigmine in postoperative gastroparesis resistant to standard prokinetic therapy may improve clinical outcomes by increasing gastrointestinal motility. With appropriate patient selection and close monitoring, neostigmine may be an alternative treatment option in selected cases. However, larger clinical studies are needed to determine the optimal dose and duration of treatment.

A rare colon tumor causing intussusception in an adult

Turgut Anuk[1], Ahmet Başak[2]

[1]*Department of General Surgery, Yalova University Faculty of Medicine, Yalova*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Erzurum City Hospital, Erzurum*

Objective: Intussusception is defined as the telescoping of a proximal segment of the intestine into the lumen of an adjacent distal segment. It most commonly occurs in the ileocecal region, followed by ileocolic and colocolic types. In childhood, intussusception is usually caused by benign conditions and often resolves with medical treatment. In adults, however, it is rare and most often associated with an underlying malignant pathology, requiring surgical intervention. In this case report, we present a rare adult case of a tumor in the transverse colon causing intussusception

Material and Methods: A 42-year-old male patient presented with abdominal pain, nausea, constipation, vomiting, and abdominal distension. His medical history revealed no prior abdominal surgery, and there was no family history of malignancy. Physical examination showed abdominal distension without additional pathological findings. Contrast-enhanced abdominal computed tomography revealed an intussusception at the midline level of the transverse colon, measuring approximately 15×6 cm, containing areas of fat density. A lesion protruding into the lumen, inflammatory changes in the adjacent mesentery, and millimetric lymph nodes were also observed. Subsequent colonoscopy demonstrated a pedunculated tumoral mass corresponding to this region, which obstructed passage of the colonoscope. Histopathological evaluation of the biopsy specimen revealed ulceration, hemorrhage, and congestion. Total excision of the mass was recommended for definitive diagnosis. The patient subsequently unde

Results: Intussusception in adults is a rare but clinically significant condition. Benign causes include leiomyomas and lipomas of the ileocecal wall, while malignant causes include tumors such as adenocarcinoma and lymphoma

Conclusion: In adult patients with clinical and physical examination findings suggestive of intussusception, the possibility of underlying malignancy should always be considered, even though it is rare

Keywords: Intussusception, colon, malignancy

Primary squamous cell carcinoma of the breast: A rare and aggressive malignancy

Hikmet Kadakal, Mahmut Burak Kılcı, Nihat Zafer Utkan

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Primary squamous cell carcinoma (SCC) of the breast is an exceptionally rare and aggressive malignancy, accounting for less than 0.1% of all invasive breast cancers. Diagnostic criteria strictly require that the tumor consists of >90% squamous cells and does not originate from the overlying skin, nipple, or distant sites. These tumors typically present with a triple-negative phenotype and high proliferative indices, associating them with a prognosis comparable to or worse than poorly differentiated ductal carcinomas.

Material and Methods: A 42-year-old postmenopausal woman presented with a painful mass in the left breast axillary tail. Imaging revealed a diagnostic discrepancy: mammography showed a well-circumscribed mass (BI-RADS 0), whereas ultrasonography demonstrated an irregular, hypoechoic lesion (BI-RADS 3). Following an inconclusive core needle biopsy showing only inflammatory changes, an excisional biopsy was performed. Metastatic disease from extramammary sites was rigorously excluded via PET-CT and clinical work-up.

Results: Immunohistochemical analysis confirmed a poorly differentiated, triple-negative (ER-, PR-, HER2-) SCC with positive p63 and CK5/6 expression and a Ki-67 index of 30%. The patient underwent left subcutaneous mastectomy with axillary lymph node dissection. Remarkably, while four sentinel lymph nodes were negative, one non-sentinel node exhibited carcinoma macrometastasis, illustrating the phenomenon of "skip metastasis". Adjuvant therapy included six cycles of paclitaxel, cyclophosphamide, and adriamycin followed by radiotherapy.

Conclusion: Primary breast SCC often exhibits a "pseudocystic" appearance, mimicking abscesses, which poses significant diagnostic challenges. Unlike invasive ductal carcinoma, these tumors show a lower rate of nodal involvement (10-30%), yet the phenomenon of "skip metastasis" necessitates careful surgical consideration. Therapeutically, due to potential resistance to standard anthracyclines, platinum-based regimens (cisplatin/carboplatin) and targeted therapies addressing frequent EGFR overexpression (approx. 40%) should be strongly considered to improve outcomes in these aggressive tumors.

Keywords: Breast cancer, primary squamous cell carcinoma, rare tumor, triple-negative

Palpation thyroiditis and massive multinodular goiter: A case of mechanically-induced hyperthyroidism necessitating total thyroidectomy

Yalçın Ural Turhan Akbulut, Sarp Tunalı, Yiğit Türk, Murat Özdemir, Recep Gökhan İçöz

Endocrine Surgery Unit, Department of General Surgery, Ege University Faculty of Medicine Hospital, İzmir

Objective: This case report presents the unusual co-occurrence of severe hyperthyroidism developing on the basis of palpation thyroiditis, combined with a massive multinodular goiter (MNG).

Material and Methods: The physical examination, biochemical investigations (thyroid function tests), and radiological imaging of the patient, who presented with weight loss and dysphagia, were evaluated. Following unresponsiveness to medical treatment and a diagnostic palpation test, a definitive diagnosis was established. The case was analyzed through the total thyroidectomy procedure, specimen weight, and histopathological results.

Results: A 65-year-old female patient presented with complaints of weight loss, hand tremor, and dysphagia. Her history included diagnosis of juvenile goiter at the age of 16 and history of radioactive iodine therapy. Physical examination revealed a bilateral, firm, fixed, massive MNG. Laboratory investigations confirmed hyperthyroidism. Imaging revealed a significant increase in gland size, numerous nodules, and reduced parenchymal activity. Medical therapy initiated under the presumptive diagnosis of Graves' disease failed to achieve a response. An increase in hormone levels following thyroid palpation, and a subsequent drop upon restriction, supported the diagnosis of palpation thyroiditis. Due to the massive MNG and uncontrolled symptoms, the patient underwent total thyroidectomy. The resected specimen weighed 737 grams. Pathological examination confirmed MNG, with no evidence of malignancy. No surgical complications occurred in the postoperative period, and the patient was discharged.

Conclusion: The increase in hormone levels subsequent to palpation serves as a critical diagnostic clue for palpation thyroiditis. While surgical intervention is rarely required, it became necessary in this case due to the co-occurrence of massive MNG and the inability to control the patient's symptoms.

A rare anatomical variation in thyroid surgery: A case of right non-recurrent laryngeal nerve confirmed by intraoperative nerve monitoring

Beyza İzem Erdem[1], Burcu Çanakçı[1], Dilan Alıcı Pehlivan[1], Bestenur Bahçekapılı[2], Muhammed Selim Bodur[1]

[1]*Department of General Surgery, Karadeniz Technical University Faculty of Medicine, Trabzon*

[2]*Department of Radiology, Karadeniz Technical University Faculty of Medicine, Trabzon*

Objective: Non-recurrent laryngeal nerve (NRLN) is a rare but clinically critical anatomical variation in thyroid surgery. In normal anatomy, the recurrent laryngeal nerve (RLN) loops around the subclavian artery on the right and the aortic arch on the left before reaching the tracheoesophageal groove. However, due to embryological developmental differences, the nerve may directly enter the larynx without looping around these structures. The incidence of NRLN is reported between 0.5-1% in literature, predominantly on the right side; left-sided occurrence is extremely rare. When NRLN is present, failure to locate the nerve in its expected position may lead surgeons toward more aggressive dissection, increasing iatrogenic injury risk. This case presents a right NRLN confirmed by intraoperative nerve monitoring (IONM) and discusses its contribution in managing this anatomical variation.

Material and Methods: A 75-year-old female patient was evaluated for a 17x12 mm nodule in the lower pole of the left thyroid lobe. Fine needle aspiration biopsy revealed suspicious cytology for malignancy, and bilateral total thyroidectomy with IONM was planned. Surgery was initiated with left lobectomy; the left vagus nerve, left superior laryngeal nerve, and left RLN were identified through dissection and confirmed with IONM.

Results: During right lobectomy, the right vagus nerve was identified. When typical RLN course was not observed in the tracheoesophageal groove, dissection strategy was redirected in a controlled manner. The nerve was found entering the larynx with a transverse course, confirming right NRLN. The nerve was verified and preserved using IONM. According to Toniato classification, the transverse course above the inferior thyroid artery trunk was compatible with type IIa pattern. Thoracic computed tomography demonstrated findings consistent with aberrant right subclavian artery; systematic reviews report this vascular anomaly in 97% of right NRLN cases. No postoperative dysphonia or dysphagia was observed; serum calcium and parathyroid hormone levels were normal. The patient was discharged uneventfully on postoperative day two. Pathological examination revealed benign hyperplastic nodule in the left lobe and unifocal 1 mm papillary thyroid carcinoma in the right lobe.

Conclusion: NRLN, although rare, is an important anatomical variation that may predispose to major complications. Recent meta-analyses have demonstrated that IONM reduces temporary unilateral RLN injury by 38% and permanent injury by 51%. NRLN possibility should be considered in patients with aberrant right subclavian artery on preoperative imaging. IONM provides valuable contribution for evaluating nerve response via vagus stimulation and functional confirmation when the nerve is not observed in its typical anatomical course.

Late-onset thyroid metastasis with tracheal invasion of clear cell renal cell carcinoma: A case report

Faruk Aksoy, Banu Karapolat, Yunus Emre Topkaya, Burcu Kemal Okatan

Clinic of Medical Pathology, Kanuni Training and Research Hospital, Trabzon

Objective: Renal cell carcinoma (RCC) is the most common malignant tumor of the kidney and is characterized by a high metastatic potential. The most frequent metastatic sites include the lungs, liver, bones, and brain; however, thyroid gland metastasis is rare. RCC accounts for approximately 12% of all tumors metastasizing to the thyroid gland. Thyroid metastases may develop many years after nephrectomy and may occasionally present as the first sign of recurrence. Therefore, metastatic RCC should be considered in euthyroid patients presenting with rapidly enlarging thyroid nodules.

Material and Methods: A 75-year-old female patient presented in August 2024 with progressive neck swelling and dyspnea. Physical examination revealed a prominent cervical mass with tracheal deviation to the left. Her medical history was notable for right nephrectomy performed in 2012 due to clear cell renal cell carcinoma. Neck ultrasonography demonstrated a heterogeneous cystic-solid nodule measuring 61×31 mm occupying nearly the entire right thyroid lobe, along with additional nodules of varying sizes. The patient was biochemically euthyroid. Due to the nodule reaching 6 cm in diameter and causing significant tracheal compression, total thyroidectomy was performed. Histopathological examination revealed a capsulated tumor with extensive hemorrhagic and cystic areas. Immunohistochemical staining showed positivity for RCC, PAX8, CD10, and Vimentin, while TTF-1 and thyroglobulin were negative, confirming the diagnosis of metastatic clear cell renal cell carcinoma.In the postoperative period, the patient developed persistent cough and reported expectoration of mass-like material. Imaging studies and bronchoscopic evaluation revealed a tracheal mass. Consequently, tracheal resection and cervical dissection were performed in October 2024. Pathological examination again confirmed RCC metastasis. The patient is currently being followed by the medical oncology department, and systemic therapy planning is ongoing.

Results: Despite its rich vascular supply, the thyroid gland is an uncommon site for metastatic disease. RCC is among the most frequent primary tumors metastasizing to the thyroid. Previous studies have reported a mean interval of 9-10 years between nephrectomy and thyroid metastasis; in the present case, metastasis occurred 12 years later, consistent with the literature. Tracheal invasion by metastatic RCC is exceedingly rare and has been infrequently reported.

Conclusion: Metastatic RCC should be considered in patients with a history of nephrectomy who present years later with rapidly enlarging thyroid nodules and compressive symptoms. Surgical resection remains an important diagnostic and therapeutic option in selected cases, and a multidisciplinary approach is essential for optimal patient management.

Axillary lymph node metastasis in papillary thyroid carcinoma at early perioperative period: Report of a case and review of the literature

Cumhur Arıcı[1], Hasan Çalış[1], Kenan Demirbakan[2], Zeki Demirok[1]

[1]*Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya*

[2]*Clinic of General Surgery, Antalya Memorial Hospital, Antalya*

Objective: Papillary thyroid carcinoma is a common thyroid cancer that usually grows slowly and has a good prognosis. Despite frequent lymph node metastases, mortality rates are low. However, metastasis to unusual regions such as the axilla can rarely occur.

Material and Methods: A 36-years-old woman with a history of neck swelling was diagnosed with papillary thyroid carcinoma. Cervical lymph node metastasis was detected in the patient.

Results: Total thyroidectomy and lateral-central neck dissection were performed. During postoperative radioactive iodine treatment and whole-body scanning, axillary lymph node metastasis was detected, and the diagnosis of metastasis was confirmed by biopsy.

Conclusion: Risk factors for poor prognosis in papillary thyroid carcinoma include large tumors, extracapsular spread, older age, specific variants, and distant metastasis. Surgical resection is the primary treatment method, aiming to eliminate local and regional spread. However, metastasis to atypical regions such as the axilla is rare and not well understood due to limited data. Such metastases are thought to develop through retrograde spread from the neck or abnormal lymphatic flow caused by surgery. Axillary metastasis is usually detected during or after surgery and may indicate systemic disease. Imaging techniques are important for diagnosis. Although it is generally a sign of poor prognosis, isolated cases without distant metastasis have also been reported. Therefore, the possibility of distant metastasis should be considered in aggressive thyroid cancer treatment.

Keywords: Axillary metastasis, thyroid cancer

Schwannoma of ansa-cervicalis: A rare location for schwannoma

Muharrem Oner, Kadir Can Şahin, Ahmet Mert Özhasırcı, Necla Reyhanlı, İrfan Efe Boztepe

Department of General Surgery, University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Schwannomas are rare neoplasms that originate from the nervous system. We describe a case of schwannoma of the ansa-cervicalis in a patient where preoperative imaging is suggestive of glomus caroticum tumor.

Material and Methods: A 44-year-old man presented to the surgical oncology department with a recurrent anterior triangle neck swelling. Magnatic resonance ımaging (MRI) demonstrated right enhancing soft tissue mass at the carotid bifurcation consistent with glomus tumor. Intraoperatively, the lesion was found abuting the bifurcatuion and arising from the right ansa-cervicalis. Histopathology evaluation revealed schwannoma.

Results: Schwannoma of the ansa-cervicalis is extremely rare. Very few cases have been reported in the literature. Making the preoperative diagnosis is difficult. Preoperative imaging is necessary to rule out other causes of neck masses such as thyroid lesions, lymphadenopathy, and carotid body tumor. Verocay bodies were noted on histology.

Conclusion: Schwannoma of cervical region can have origin from any nerve. Any Neurologic post-operative deficit depends on the nerve of origin and the precision of the surgery performed.

Keywords: Ansa-cervicalis, schwannoma, verocay body

A rare variation in the gallbladder wall: Ectopic liver tissue and case presentation

Fırat Başçı, Tufan Gümüş, Alper Uğuz

Department of General Surgery, Ege University Faculty of Medicine Hospital, İzmir

Objective: Ectopic liver tissue (ELT) is a rare developmental anomaly that is not connected to liver tissue but has normal liver histology. It results from the abnormal migration of the hepatic diverticulum during embryological development. It was first reported by Corsy and colleagues in 1922. Types that are located in the gallbladder serosa are usually asymptomatic and are incidentally detected in 0.24-0.47% of cholecystectomy specimens. In this case presentation, accessory liver tissue detected in a patient operated on for symptomatic cholelithiasis is discussed in the context of the literature.

Material and Methods: This study presents the surgical management and histopathological findings of a case in which ectopic liver tissue was incidentally detected in the gallbladder serosa during laparoscopic cholecystectomy planned for symptomatic cholelithiasis.

Results: A 42-year-old female patient with no known comorbidities presented with recurrent right upper quadrant pain. Preoperative ultrasonography revealed multiple stones within the gallbladder, the largest measuring 16 mm. Biochemical analysis, including liver function tests and complete blood count, was within normal limits (AST: 9 U/L, ALT: 11 U/L, ALP: 131 U/L, GGT: 31 U/L, T. Bil: 0,27 mg/dL, WBC: 8800/mm³, Htc: 44%, Plt: 368,000/mm³). During laparoscopic cholecystectomy, an accessory tissue approximately 1.5 cm in size, macroscopically identical to liver parenchyma, was identified on the serosa near the fundus-body junction of the gallbladder. The gallbladder was resected en-bloc with this tissue (Figures 1 and 2). Histopathological examination confirmed chronic cholecystitis, focal gastric metaplasia, and histologically normal liver tissue located on the gallbladder serosa. The patient was discharged with no postoperative complications.

Conclusion: Ectopic liver tissue (ELT) is a rare anatomical anomaly that arises as a result of the abnormal migration or accessory budding of the hepatic diverticulum during the embryonic development stage. Although most frequently reported in the gallbladder serosa (45-47%), it can also be detected in the pancreas, spleen, omentum, and retroperitoneal area. ELT is usually an incidental finding during surgery. Although often asymptomatic, it has the potential to cause pathologies such as hepatitis, cirrhosis, bleeding, and torsion. Due to inadequate ductal drainage, they carry a risk of malignant transformation, and the risk of hepatocellular carcinoma is higher than in normal liver tissue. Therefore, en bloc resection and definitive histopathological evaluation of suspicious tissue nodules detected on the gallbladder is recommended.

Keywords: Ectopic liver tissue, gallbladder, laparoscopic cholecystectomy

Case report: Unexpected lymph node metastasis and surgical management in early-stage ampullary adenocarcinoma

Firdevs Melike Onuktav, Oğuzhan Aydın, Yusuf Yunus Korkmaz, Özgür Bostancı, Erdem Kınacı

Department of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Investigating the etiology of chronic pancreatitis in patients undergoing evaluation for pancreatitis attacks following cholecystectomy can be challenging, as the inflammatory state may mask underlying malignancies. In this report, we present the management of a 52-year-old female patient who presented with a "double-duct" sign and was diagnosed with pT1a adenocarcinoma following a papillectomy.

Material and Methods: Ampullary carcinomas are rare neoplasms originating from the ampulla of Vater. Although they often present early due to biliary obstruction, their biological behavior can be aggressive. The radiologically detected "double-duct" sign is a classic finding for periampullary malignancies. Surgical resection remains the only curative option, with lymph node involvement being the most critical prognostic factor. In our case, the pathology of the papillectomy performed via ERCP (endoscopic retrograde cholangiopancreatography) was reported as "invasive adenocarcinoma (pT1a) arising from a high-grade intraampullary papillary-tubular neoplasm". Due to the proximity of the *in situ* carcinoma to the basal margin, a pylorus-preserving Whipple procedure was performed.

Results: Preoperative computed tomography (CT) revealed a common bile duct width of 12 mm and a Wirsung duct width of 5.5 mm. Preoperative tumor markers were within normal limits (CEA: 0.77 µg/L, CA 15-3: 27.4 U/mL, CA 19-9: 14.9 U/mL). During the Pylorus-Preserving Whipple procedure, the pancreas was noted to be of medium consistency with a 4 mm Wirsung duct. Reconstruction was completed via duct-to-mucosa pancreaticojejunostomy, hepaticojejunostomy, and duodenojejunostomy. Although no residual primary tumor was found in the final pathology specimen, metastasis was detected in 3 out of 26 lymph nodes (3/26). Immunohistochemical analysis showed: CK20(+), CDX-2(+), CK19(+), and CK7(-). The tumor was classified as microsatellite stable (MSS/pMMR).

Conclusion: The most striking aspect of this case is the discrepancy between the T and N stages. While the literature suggests a low risk of lymph node metastasis for pT1a lesions (the earliest stage of invasion), this case demonstrated an 11.5% nodal involvement rate. This highlights the necessity of radical surgery and the significance of nodal spread potential even in early-stage ampullary lesions. Furthermore, the immunohistochemical profile (CK20+, CDX-2+) indicating intestinal-type differentiation is crucial for understanding the biological character of the tumor. Stable tumor markers during the 15-month follow-up support the success of adjuvant therapy and achieving negative surgical margins

Keywords: Adenocarcinoma, ampulla of vater

[P-474]

Case report: Mechanical ileus presenting with segmental ileal ischemia in an elderly patient with no history of previous abdominal surgery

Utku Öztürk, Yiğit Kağan Zeren, Betül Kübra Aydın Mucuk, Mesut Yavaş

Department of General Surgery, Gazi University Faculty of Medicine, Ankara

Objective: In elderly patients, mechanical ileus, especially if accompanied by signs of systemic inflammatory response, should be carefully evaluated for bowel ischemia. Although segmental small bowel ischemia is rare in cases without a history of adhesions, it has high morbidity and mortality. This study presents a case of a patient who presented with ileus and was found to have intraoperative segmental ileal ischemia.

Material an Methods: An 80-year-old male patient with two days of absent stool and gas was evaluated with a preliminary diagnosis of ileus. His medical history included benign prostatic hyperplasia, coronary artery disease, and a history of coronary bypass surgery. Due to clinical deterioration and altered consciousness, laboratory tests and contrast-enhanced abdominal computed tomography (CT) scans were performed. The presence of systemic inflammation and a radiological transition zone led to the patient undergoing emergency surgery.

Results: Laboratory tests revealed a leukocyte count of 33,920/mm³ (neutrophils 92%), CRP of 167 mg/L, and procalcitonin of 2.3 ng/mL. Lactate was 2.7 mmol/L. CT scan showed extensive dilation of the small bowel loops, ileal passage zone at the umbilicus level, wall thickening, and mesenteric fatty plane contamination. No purulent fluid was detected on exploration. A segmental ischemic area approximately 15 cm long with lost peristalsis was observed 20-35 cm proximal to the cecum. The ischemic segment was resected with a 2 cm safe margin from the demarcation line and a side-to-side anastomosis was performed with a stapler.

Conclusion: Segmental bowel ischemia should be considered in patients with advanced age and cardiovascular comorbidities, as well as in the presence of significant inflammatory parameters and mesenteric contamination on CT scans. Early surgical intervention is crucial for prognosis in cases of ileus that develop clinically worsening.

A silent emergency after vaginal birth: Obstetric anal sphincter injury

Büşra Öztürk Taş[1], Muhammed Alperen Taş[2], Ali Cihat Yıldırım[2], Sezgin Zeren[2]

[1]*Clinic of Gynecology and Obstetrics, Kütahya City Hospital, Kütahya*

[2]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

Objective: Obstetric anal sphincter injury (OASIS) is the most severe form of perineal trauma, involving perineal damage extending to the anal sphincter complex after vaginal delivery. Its incidence varies due to differences in diagnosis and reporting methods. OASIS affects 5-7% of women having their first vaginal delivery. However, this rate rises to 26% in evaluations performed with ultrasonography. The most important risk factors include forceps delivery, shoulder dystocia, advanced gestational age, induction of labor, and episiotomy. These injuries occurring after vaginal delivery lead to long-term morbidities in women that seriously reduce their quality of life. In this case, we present the management of a successful obstetric anal sphincter injury following early intervention.

Material and Methods: In this case, the diagnosis, treatment and follow-up process of a patient who experienced anal sphincter injury after vaginal delivery at our clinic was evaluated.

Results: A 23-year-old gravida 1, parite 0 female patient was admitted to our clinic for vaginal delivery due to term pregnancy. Labor progressed spontaneously. A mediolateral episiotomy was performed at 7 o'clock during the second stage of labor. The fetal presentation was cephalic and the newborn's birth weight was measured as 3000 gr.During the postpartum perineal and rectovaginal examination, a tear was observed at the 3-9 o'clock position, with a full-thickness tear in the external anal sphincter and a tear of >50% in the internal anal sphincter. No injury was observed in the anorectal mucosa. A general surgeon was consulted for the case. The anal sphincter complex was repaired using the overlapping sphincteroplasty technique with 3.0 PDS.The patient was discharged on the 4th postoperative day. No significant anal sphincter loss was observed on endoanal ultrasound performed at 8 weeks postoperatively. No anal incontinence or other complications were observed during postoperative follow-up.

Conclusion: Early and accurate diagnosis is critical for better functional outcomes.Early diagnosis can be made through systematic perineal examination and rectal examination after vaginal delivery. However, diagnosis is missed in 80% of cases. Endoanal ultrasonography is the gold standard for assessing the location and extent of sphincter damage, while anal manometry is the gold standard for assessing sphincter function. Primary surgical repair performed immediately after diagnosis is the primary treatment method. End-to-end or overlap techniques are the main techniques frequently used in repairs. OASIS can lead to morbidities such as perineal pain, sexual dysfunction, wound dehiscence, abscess, rectovaginal fistula, and anal incontinence; therefore, early and accurate diagnosis is of vital importance. Repair of these injuries by experienced clinicians is important for successful outcomes.

Ileocecal mesenteric duplication cyst in an adult patient: A rare case presenting with mimicry of acute appendicitis

Tahir Mehmet Güler, Yılmaz Türk

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Gastrointestinal duplication cysts are rare congenital lesions associated with embryological developmental anomalies and are mostly diagnosed in childhood. Symptomatic cases in adults are rarer and may mimic acute abdominal conditions, particularly acute appendicitis. This case presentation describes the clinical, imaging, surgical, and histopathological findings of a mesenteric duplication cyst in the ileocecal region in an adult patient presenting with right lower quadrant pain and vomiting.

Material and Methods: Clinical data were extracted from institutional records. Contrast-enhanced abdominal CT was reviewed, followed by laparoscopic exploration and ileocecal segmental resection with primary anastomosis. The specimen underwent gross and histopathological evaluation, and postoperative course with short-term follow-up was recorded.

Results: A 37-year-old woman presented with a 2-day history of right lower quadrant pain with nausea and vomiting. Exam showed minimal tenderness without guarding or rebound. Laboratory tests were not suggestive of infection/inflammation (normal leukocytes and lactate, low CRP). Abdominal CT showed a ~25×25 mm cystic lesion on the mesenteric surface of the ileocecal region, suggestive of a duplication cyst; the appendix was normal with no radiological evidence of acute appendicitis. Gynaecological assessment found no acute pathology. Laparoscopy identified a cyst adjacent to the ileum; ileocecal segmental resection with primary anastomosis was performed. No perioperative complications occurred. Oral intake was resumed on postoperative day 3 and the patient was discharged on day 5. No recurrence or re-admission occurred on short-term follow-up. Gross pathology showed a 2.5×2×1.5 cm ileal cyst with a smooth inner surface and serous content. Histopathology confirmed an ileocecal duplication cyst with mucosal ischaemia; seven lymph nodes were reactive, the vermiform appendix was normal, and no malignancy or ectopic (gastric/pancreatic) mucosa was detected.

Conclusion: Adult duplication cysts are rare yet may mimic acute appendicitis with right lower quadrant pain. Here, low inflammatory markers and a normal-appearing appendix on imaging supported alternative aetiologies. Symptoms may arise from compression, torsion/stretching, raised intraluminal pressure and resulting mucosal ischaemia, presenting as pain and vomiting in adults. Given their close relationship to the bowel wall and vascular supply, segmental resection is a safe, curative option. Accordingly, ileocecal duplication cyst should remain a rare but clinically relevant differential diagnosis in adults with right lower quadrant pain, especially when typical appendicitis laboratory and imaging findings are absent. This case highlights mucosal ischaemia as a likely mechanism and suggests that early diagnosis and timely resection minimise morbidity and support favourable outcomes.

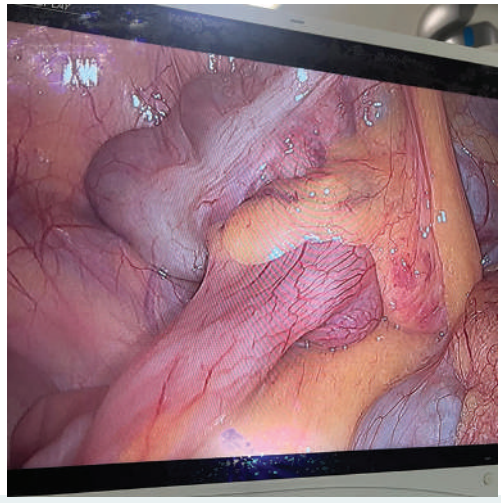

Figure 2. Duplication cyst.

Table 1. Summary of the clinical, imaging, surgical, and pathological characteristics of the case

Parameter	Findings
Age/gender	37 years old/female
Presentation	Emergency department
Duration of symptoms	2 days
Complaint	Right lower quadrant pain, nausea-vomiting
Physical examination	Minimal tenderness in the right lower quadrant, no guarding/rebound
ASA score	II
Laboratory	Leukocytes: normal (6.8), CRP low (~1.5), lactate normal (1.42), Hb normal
Radiological findings (CT)	Approximately 25×25 mm mesenteric cystic lesion in the ileocecal region; appendix normal; minimal free fluid
Preliminary diagnosis	Mesenteric duplication cyst

Table 1. Continued

Parameter	Findings
Surgical approach and procedure performed	Laparoscopic exploration followed by ileocecal segmental resection + primary anastomosis
Operation duration	150 minutes
Intraoperative Complication	None
Postoperative Complications	None
Oral intake	Postoperative day 3
Length of hospital stay	5 days
Macroscopic pathology	2.5×2×1.5 cm cystic lesion; serous content; smooth inner surface; wall thickness 0.2 cm
Histopathological diagnosis	Ileocecal duplication cyst
Additional histological findings	Mucosal ischaemia
Lymph nodes	7 reactive
Appendix	Normal
Ectopic mucosa	None
Malignancy	None
Follow-up period	1 month
Recurrence/mortality	None

Management of a case of gallstone ileus mimicking intussusception and literature review

Miray Maden, Sumru Beril Çetintaş Atak

Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli

Objective: Gallstone ileus is a pathology that occurs when gallstones create an obstruction in the intestines via a bilioenteric fistula. It is especially common in elderly patients and is difficult to diagnose. Gallstone ileus has high mortality and morbidity rates due to its common occurrence in the elderly and the difficulty in diagnosing it. Treatment requires surgical removal of the stone. Fistula repair can be performed in the same session, but in high-risk patients, passage surgery should be performed and fistula repair should be postponed to a second session. The literature indicates that a two-stage treatment approach is more appropriate and that early intervention reduces mortality.

Material and Methods: We present a patient who was hospitalized in the intensive care unit, was consulted to our department due to ileus, and was operated on with a suspicion of intussusception, in whom gallstone ileus was identified intraoperatively.

Results: A 70-year-old female patient with a known diagnosis of Alzheimer's disease, immobilized due to stroke, and being monitored in the intensive care unit for pneumonia with a PEG catheter, underwent abdominal CT scanning due to bile-stained fluid coming from the PEG tube and the cessation of gas and stool passage for the past 5 days. Due to a suspicious appearance of intussusception in approximately 3.5 cm of the small intestine on the CT scan, we decided to perform surgery on the patient (Figure 1). During expulsion, obstruction and edema due to gallstones were observed in the small intestine approximately 140 cm from the ileocecal valve. There was dilation in the proximal bowel loops. The approximately 3.5 cm stone was removed via enterotomy, and the operation was completed (Figure 2). The patient experienced no complications during intensive care monitoring and was started on PEG feeding on the 3rd day after surgery.

Conclusion: In our case, where there was no known diagnosis of cholelithiasis, the presence of Alzheimer's disease and immobility in the patient led to the cholecystitis attacks being overlooked. The presence of intestinal edema due to stone and a target sign on the CT scan raised suspicion of involution in the 3.5 cm segment. It is important to remember that in the rare condition of gallstone ileus, early intervention is life-saving and that in emergency situations, enterolithotomy alone is sufficient. In intensive care, gallstone ileus should be considered in elderly patients diagnosed with ileus, even without a history of independent cholelithiasis.

Transverse colon volvulus: A rare cause of colonic mechanical obstruction

Ali Çınar, Aykut Özkılıç, Sarp Tunalı, Bora Sonay, Kamil Erözkan, Osman Bozbıyık

Department of General Surgery, Ege University Faculty of Medicine, İzmir

Objective: Volvulus is a critical clinical condition requiring emergency surgical intervention, characterized by lumen obstruction and vascular occlusion leading to ischemia or necrosis of the colonic wall as a result of a hollow organ twisting around its own axis. Among colon volvuluses, the sigmoid colon (75-80%) and cecum (15-20%) are the most frequently affected regions. Transverse colon volvulus (TCV) accounts for only 1-4% of all cases. Etiological factors include an abnormally long transverse colon, a narrow or hypermobile mesentery, chronic constipation, distal obstructions, and adhesions resulting from previous abdominal surgeries.

Material and Methods: In this case, a 34-year-old patient who underwent surgery due to TCV is presented.

Results: Thirty-four-year-old male patient presented to our emergency department with complaints of abdominal pain, nausea, and vomiting persisting for approximately one day. The patient's history included intermittent abdominal pain for the past two years and a mesenteric detorsion operation one year ago for intermittent midgut volvulus due to intestinal malrotation. Laboratory tests at the time of admission showed no significant pathology. On physical examination, abdominal distension was present, but there was no defense or rebound tenderness. A contrast-enhanced abdominal CT scan revealed a sudden change in calibration at the level of the descending colon, the pathognomonic "whirl sign" in mesenteric structures, and significant colonic dilatation reaching 9 cm proximally. During a therapeutic colonoscopy, a volvulus area was identified at the splenic flexure. Since no signs of ischemia were found, colonoscopic detorsion and decompression were achieved. However, on the third day of follow-up, the cessation of gas and stool passage, abdominal distension, and the detection of the typical "coffee bean sign" on direct abdominal X-ray led to a repeat colonoscopic decompression. Following decompression, the patient was taken to surgery. During the operation, it was confirmed that the transverse colon mesentery was considerably long, the transverse colon had twisted around its own axis at the splenic flexure,and the proximal segments were dilated. A left hemicolectomy was performed on the patient. The postoperative course was uneventful, and the patient was discharged with full recovery on the 9th day.

Conclusion: TCV is a difficult condition to diagnose due to its rarity and non-specific clinical symptoms. High rates of morbidity and mortality have been reported in delayed cases. TCV should be considered not only in the elderly population but also in young patients and individuals with chronic obstruction attacks, as seen in our case. Abdominal CT and the "whirl sign" are of critical importance in diagnosis. To minimize the risk of recurrence, resection of the affected segment and primary anastomosis is the most reliable method rather than detorsion alone. Volvulus should be considered in the differential diagnosis of every patient presenting with mechanical large bowel obstruction; it must be remembered that early intervention.

Keywords: Transvers colon volvulus, whirl sign, intestinal obstruction

Sigmoid colon duplication: A rare case report

Alper Varman, Murat Çakır, Ömer Kişi, Arslan Hasan Kocamaz, Ahmet Avcu

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: Colonic duplications are rare congenital anomalies of the gastrointestinal tract and are exceptionally uncommon in adults. Clinical manifestations are often non-specific and may mimic diverticulitis, perforation, or obstruction. We present a rare case of sigmoid colon duplication identified intraoperatively in a patient operated on for suspected diverticulitis.

Material and Methods: A 38-year-old male patient was hospitalized with complaints of abdominal pain and constipation. Abdominal computed tomography demonstrated findings consistent with diverticulitis, along with suspected disruption of wall integrity at the level of the sigmoid colon. Based on clinical and radiological evaluation, the patient was scheduled for surgery.

Results: Intraoperative exploration revealed duplication of the sigmoid colon. Multiple diverticula were observed in the proximal colon segments. Due to the presence of extensive diverticular disease, total colectomy with ileorectal anastomosis was performed. The postoperative course was uneventful, and the patient was discharged in good condition on postoperative day seven.

Conclusion: Colonic duplication is an extremely rare condition in adults, and preoperative diagnosis remains challenging. Its association with diverticular disease has been rarely reported. Colonic duplication should be considered in the differential diagnosis in the presence of atypical clinical and radiological findings. Intraoperative findings play a decisive role in determining the surgical strategy.

Keywords: Colonic duplication, diverticulitis, total colectomy

Temporary peripheral facial nerve paralysis after facial mask hyperventilation: A case report

Kubilay Kenan Özlük[1], Şevket Barış Morkavuk[1], İbrahim Burak Bahçecioğlu[1], Mert Demirci[2], Hakan Saydam[2], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Facial paralysis can be primary or secondary. Secondary peripheral facial paralysis most often results from various factors such as trauma, viral infections, post-surgical complications, and tumor compression. In this case, we aimed to present a case of peripheral facial paralysis that developed after mask ventilation, along with a review of the literature.

Material and Methods: Facial paralysis due to mechanical trauma after mask ventilation is a previously defined, rare complication. Pressure behind the mandible during face mask use, use of an inappropriately sized laryngeal mask/endotracheal tube, or difficult intubation can increase the risk of nerve injury.

Results: A 37-year-old female patient presented to our clinic with a palpable mass in her left breast. Investigations revealed a diagnosis of invasive ductal breast cancer. A racket mammoplasty + SLNB operation was planned. Following surgery, during tracheal extubation, the patient developed laryngospasm, prompting hyperventilation via mask by the anesthesiologist. With an oxygen saturation above 95%, the patient was admitted to the ward. During follow-up, the patient reported numbness on the left side of her lip and surrounding area. Neurological examination revealed findings consistent with peripheral facial paralysis. Following a neurology consultation, brain computed tomography and diffusion magnetic resonance imaging scans were performed. No pathological findings were detected, and neurology diagnosed peripheral facial paralysis secondary to mechanical compression during positional or mask ventilation. The patient was treated with 100 mg prednisolone and 40 mg pantoprazol intravenously. The patient, whose symptoms improved after the procedure, was discharged from the hospital.

Conclusion: The incidence of peripheral nerve injuries after general anesthesia is less than 1%. Perioperative nerve damage is a rare but known complication. During anesthesia, ventilation with a face mask and the jaw thrust maneuver can cause damage to the branches of the facial nerve. Cases of facial nerve and its branches (mental and buccal nerves) damage due to face mask compression exist in the literature. Treatment involves steroids and neurotropic B vitamins such as thiamine (B1), pyridoxine (B6), and cobalamin (B12).

Keywords: Facial nerve paralysis, facial mask, temporary

Synchronous small bowel GIST with unique exophytic hyaline degeneration in a patient with advanced gastric adenocarcinoma: Case report

Mehmet Sercan Candan[1], Cengiz Tavusbay[1], Mehmet Sefa Uludağ[1], Aslı Kahraman[2], Fevzi Cengiz[1]

[1]*Department of General Surgery, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

[2]*Department of Pathology, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the digestive system. The frequency of synchronous (simultaneous) occurrence of GISTs with other primary gastrointestinal (GI) malignancies, especially gastric cancer, has been significantly reported in the literature. However, it is rare for these tumors to contain macroscopically "pearl-like" cystic and hyaline degeneration areas, and for this structure to be located on the serosal surface, which is a visually misleading presentation.

Material and Methods: A 75-year-old female patient presented with recent vomiting and excessive weight loss. An upper GI endoscopy revealed edematous and polypoid lesions constricting the gastric corpus from the fundus to the antrum. Biopsy results indicated poorly differentiated adenocarcinoma. Due to severe gastric obstruction, the patient underwent palliative surgery.

Results: During laparotomy, locally advanced gastric cancer was detected that completely involved the stomach, had penetrated the serosa, and was adherent to the colonic mesentery to a degree that made dissection impossible. The patient was assessed as inoperable and unresectable. A jejunostomy was planned for palliative feeding. During preparation for jejunostomy, a second synchronous mass was detected approximately 50 cm from the ligament of Treitz. It originated from the intestinal wall, showed exophytic growth, contained areas with a distinct creamy-white colour resembling a cap at the apex, and was partially cystic in structure. This mass was resected. Histopathological and histochemical examinations revealed a 4x3 cm cystic area filled with serous fluid on the outer surface of the 5x4x4 cm mass removed from the small intestine. Brown hemorrhagic foci were noted in the remaining solid areas. Pathological diagnosis: GIST of the small intestine. Immunohistochemistry: DOG1 (+) and CD117 (+) (diffuse and strongly positive). Intraoperative view of a well-defined, exophytic GIST located approximately 50 cm from the ligament of Treitz. At the apex of the tumor, a bright white, homogeneous, and glassy "pearl-like" appearance is noted, consistent with histopathologically significant hyaline and cystic degeneration.

Conclusion: This case is notable for its exophytic serosal hyalinization, which is the pathological counterpart of the pearl-like bright structure observed in the surgical photograph. The "marked hyalinization on free surfaces" mentioned in the pathology report refers to the tumor's stroma becoming homogeneous and glassy. This finding, combined with a low mitotic rate and low-risk of progression, supports a biologically indolent tumor profile. Furthermore, the synchronous detection of a GIST in a patient with advanced gastric cancer once again highlights the importance of surgical exploration. This case presentation demonstrates that GISTs can present with intense hyaline and cystic degeneration, deviating from their usual solid appearance. We believe that recognising such degenerative changes, especially in the presence of synchronous tumors, may be valuable in determining the surgical strategy.

Keywords: Gastrointestinal stromal tumor (GIST), hyaline degeneration, synchronous tumors

[P-487]

Giant Nuck canal cyst: A case report

İbrahim Halil Öcal[1], Abdulkadir Akbaş[2]

[1]*Clinic of General Surgery, Adıyaman Training and Research Hospital, Adıyaman*

[2]*Department of General Surgery, Dicle University Faculty of Medicine, Diyarbakır*

Objective: Nuck's canal cyst is a congenital pathology that is rare in women and develops as a result of the peritoneal extension failing to close. While most cases are small in size, cysts reaching enormous proportions are quite rare. This article presents a case of an enormous Nuck's cyst extending from the middle section of the labium majus to the uterus.

Material and Methods: A 28-year-old female patient presented to the outpatient clinic complaining of increasing pain and swelling in the right groin area over the past few weeks. Her systemic examination was normal. Physical examination revealed a mobile, smooth-surfaced, fluctuant, painless mass palpable in the middle section of the right labium majus. No redness or fistula opening was detected on the skin. Superficial ultrasonography revealed a thin-walled, fluid-filled cystic lesion extending from the level of the labium majus along the right inguinal canal, communicating with the peritoneal cavity. The findings were considered consistent with a Nuck's canal cyst. Surgical exploration revealed that the cyst originated in the middle portion of the labium majus and extended to the uterine level of the peritoneal opening. The cyst was completely excised by dissection up to the intact portion of the peritoneum. The peritoneal defect was primarily closed, and a probing mesh support was applied to prevent possible hernia formation. No complications were observed during postoperative follow-up, and the patient was discharged one day after surgery. The excised cyst measured 12×3 cm macroscopically. Histopathological examination reported a cystic structure lined with a single layer of squamous and cuboidal epithelium and surrounded by a fibrous capsule; the findings were consistent with a Nuck canal cyst. A smooth-walled, translucent cystic structure associated with the hernia sac is observed during inguinal exploration.

Results: Embryologically, the peritoneal extension continues from the inguinal canal to the labium majus, and normally undergoes obliteration shortly after birth. If this canal fails to close, peritoneal fluid may leak into the labium majus, forming a cystic structure. Clinically, patients typically present with a painless swelling in the groin. The most common differential diagnoses are indirect inguinal hernia, lymphangioma, lipoma, Bartholin's cyst, and epidermoid cyst. Ultrasonography is usually sufficient for diagnosis. The preferred method of treatment is surgical excision.

Conclusion: Nuck's canal cyst, although rare, should be considered in the differential diagnosis of inguinal masses in women. Cases reaching enormous sizes are very rare. Excellent prognosis is achieved with surgical excision and appropriate peritoneal repair. This case is noteworthy as one of the largest Nuck's cysts in the literature due to its size.

Keywords: Inguinal canal, labium majus, Nuck channel, peritoneal cyst

Interparietal Spiegel hernia: Case report

Sümeyra Güler[1], Şevket Barış Morkavuk[1], İlyas Huseyinzade[2], Asgar Huseyinov[2], İbrahim Burak Bahçecioğlu[1], Müjdat Turan[2], Mehmet Ali Gülçelik[1]

[1]*Department of of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Spiegel's hernia was first described in 1645 by the Belgian anatomist Adriaan van den Spiegel, and later Klinkosch reported the first case of a Spigelian hernia in 1764. It constitutes 1-2% of all abdominal hernias. The junction of the semilunar and arcuate lines is the weakest part of the Spigelian fascia and is responsible for most Spigelian hernias. Interparietal hernias, also known as interstitial hernias, are defined by the formation of a hernia sac located between the layers of the anterior abdominal wall.

Material and Methods: In this case report, we aimed to present a case of interparietal Spiegel hernia along with a review of the literature.

Results: A 62-year-old female patient presented to our clinic with abdominal pain in the left quadrant below the umbilicus. Physical examination revealed no palpable lesions or hernia sacs. Laboratory findings showed no pathological evidence, so an abdominal ultrasound was planned. The ultrasound revealed bowel loops between the muscle planes in the left lateral quadrant of the abdomen. With a preliminary diagnosis of Spiegel hernia, a computed tomography (CT) scan of the abdomen was performed. The CT scan showed a Spiegel hernia between the muscle planes in the semilunar line. The patient was diagnosed with an interparietal Spiegel hernia, and surgery was planned. The external oblique muscle fascia was opened approximately 2 cm medially. It was observed that the internal oblique fascia had lost its integrity in an area of approximately 1 cm, and that preperitoneal fat tissue and bowel loops had herniated through this area. The hernia sac was freed from the surrounding tissues and sent back into the abdominal cavity. The internal oblique muscle fascia was repaired with prolene and a prolene mesh was placed over it.The operation was completed by closing the external oblique muscle fascia with prolene.

Conclusion: Spigelian hernia occurs through the Spigelian aponeurosis, which is the aponeurosis of the transversus abdominis muscle bounded laterally by the semilunar line and medially by the lateral border of rectus abdominis. The exact cause of Spigelian hernia is not known, but its development is related to many factors such as collagen disorders, aging, obesity, rapid weight loss, multiple pregnancies, chronic lung disease, trauma, history of surgery, and reproductive diseases. The CT is the method of choice in the differential diagnosis, which can exclude the presence of an obstructing tumor. However, it is reported that both CT and herniography are not successful in differentiating the different types of inguinal hernia.

Pseudoperitoneum formation due to misplacement of dual mesh: A case evaluated with suspicion of recurrent hernia

Beyza Altıntaş, Kübra Bilge Polat, Umut Keskin, Muhittin Sonışık

University of Health Sciences Türkiye, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital,Ankara

Objective: The use of prosthetic mesh in incisional hernia repair reduces recurrence rates; however, rare complications related to mesh malposition may cause diagnostic difficulties. Improper anatomical placement of dual mesh can lead to pseudoperitoneum and chronic seroma formation, which may mimic recurrent hernia on radiological imaging.

Material and Methods: A 70-year-old female patient with a history of multiple incisional hernia surgeries presented with abdominal pain and swelling. Computed tomography demonstrated findings suggestive of recurrent incisional hernia and ileus. As no clinical signs of ileus were present, the patient was evaluated electively and scheduled for surgical exploration.

Results: Surgical exploration revealed no true hernia defect. Instead, an epithelialized pseudoperitoneal layer with a large associated seroma sac was identified between the previously placed dual mesh and the subcutaneous tissue. Seroma drainage was performed, the epithelialized surface was mechanically disrupted, and sterile talc was applied to promote adhesion. No postoperative complications were observed.

Conclusion: Malposition of dual mesh may result in pseudoperitoneum and seroma formation, leading to radiological findings that can be misinterpreted as recurrent incisional hernia. In patients with a history of repeated hernia repairs, clinical-radiological correlation is essential to avoid misdiagnosis and unnecessary surgical intervention.

Keywords: Incisional hernia, dual mesh, seroma, pseudoperitoneum

[P-492]

A case of peritoneal mouse (peritoneal loose body) found incidental in a patient operated on for incisional hernia

İbrahim Halil Öcal[1], Abdulkadir Akbaş[2]

[1]*Clinic of General Surgery, Adıyaman Training and Research Hospital, Adıyaman*

[2]*Department of General Surgery, Dicle University Faculty of Medicine, Diyarbakır*

Objective: Peritoneal loose bodies (PLBs) are defined as benign structures, usually calcified, found freely within the abdominal cavity. They most commonly arise from torsion, infarction, and rupture of epiploic appendages. The detached fragment gradually becomes surrounded by a fibrous capsule and dystrophic calcification, acquiring a typical "egg-like" structure. PLBs are usually small (<2 cm) and are detected incidentally; however, larger ones are termed "giant PLBs" and are rarely noticed during surgery. In this article, we aim to present a case of a multifocal PLB incidentally detected in a patient who had undergone resection after ischaemia and had portal vein thrombosis.

Material and Methods: A 72-year-old male patient underwent small bowel resection and anastomosis three years ago due to mesenteric ischaemia. He was operated on in the general surgery clinic due to an incisional hernia in his current presentation. Portal vein thrombosis was detected in the patient's recent angiography-abdominal CT scan. During the abdominal exploration performed during the operation, free-floating, approximately 5 cm in diameter, white-grey, oval, smooth-surfaced masses were detected. In addition, necrotic areas in the omentum and 0.5-1 cm masses associated with the omentum were observed. The lesions were excised and sent for pathology. Macroscopically, well-defined, firm, white-grey calcified nodules were observed. Microscopic examination revealed necrotic adipose tissue in the centre, surrounded by a dense fibrotic capsule and areas of dystrophic calcification. No tumour proliferation was observed. The findings were reported as "PLB (peritoneal mouse)".

Results: PLB is a formation that is usually detected incidentally and has a clinically silent course. Most cases are detected during laparotomy, laparoscopy or imaging. Etiologically, besides epiploic appendage torsion, omental or peritoneal fat necrosis may also be a source. In our case, circulatory disorders such as previous ischaemic bowel resection and portal vein thrombosis may have predisposed the omental fat tissue to ischaemic necrosis. Therefore, the formation of PLB was likely considered a sequela of ischaemic fat necrosis. Giant PLB cases are rare in the literature; most are between 2 and 4 cm in size. The presence of multifocal lesions measuring approximately 5 cm in our case makes it interesting.

Conclusion: PLBs are generally benign and asymptomatic. However, they may be more common in patients who have previously undergone abdominal surgery or experienced ischaemic events. When detected incidentally during surgery, their characteristic macroscopic and pathological features should be known to avoid confusion with malignancy.

Keywords: Calcification, intra-abdominal mass, necrotic adipose tissue, omental body, peritoneal loose body

A rare case: Primery thyroid amyloidosis

Ahmet Fırat Bozdoğan[1], Alparslan Ertenlice[2]

[1]*Clinic of General Surgery, Isparta City Hospital, Isparta*

[2]*Department of General Surgery, Ankara Yıldırım Beyazıt University, Ankara*

Objective: Amyloid goiter results from the accumulation of amyloid proteins in the thyroid gland. Amyloid deposition can cause compressive symptoms along with enlargement of the thyroid gland. Treatment is surgical, especially if there is a compressive symptom. Here, we present a rare case of primary thyroid amyloidosis diagnosed by histopathological examination after surgery.

Material and Methods: Immunohistochemical staining shows a positive result with amyloid A.

Results: A 36-year-old female patient with no underlying medical conditions was referred from the endocrinology clinic to the general surgery outpatient clinic in January 2026 with complaints of throat swelling and difficulty breathing. Examination revealed swelling in the neck. Thyroid ultrasound showed a multinodular goiter. Thoracic and abdominal computed tomography scans showed no signs of systemic amyloidosis. Surgery was planned due to compression symptoms. The patient underwent bilateral total thyroidectomy. She was discharged on the 3rd postoperative day after recovery. Pathology revealed positive staining for amyloid A, confirming thyroid amyloidosis.

Conclusion: Amyloid goiter is an extremely rare pathological condition caused by amyloid infiltration of the thyroid tissue. It occurs in association with primary or secondary amyloidosis, more frequently seen in secondary amyloidosis. Preoperatively, it simulates a multinodular goiter. Surgical intervention is necessary to diagnose the condition and alleviate the compressive symptoms.

Keywords: Bilateral total thyroidectomy, multinodular goiter, thyroid amyloidosis

[P-495]

Adult patient with an undescended testis within an inguinal hernia sac: A rare case

Eda Nural[1], Hakan Ataş[2], Nazmiye Sena Arıkan[2], Selma Nil Ayan Uğurcan[2]

[1]*Kahramanmaraş State Hospital, Kahramanmaraş*

[2]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

Objective: Inguinal hernia is the most common abdominal wall hernia in adults and represents a frequent reason for admission to surgical clinics. Although it usually presents with groin swelling and pain, it may occasionally be associated with congenital anomalies. Cryptorchidism, defined as the absence of the testis from the scrotum, is commonly diagnosed in childhood but is rare in the adult population. While the coexistence of inguinal hernia and cryptorchidism is frequently observed in children, it has been reported only rarely in adults. Adult cases of cryptorchidism are most often detected incidentally during surgical procedures performed for inguinal hernia. Testes that remain outside the scrotum for a prolonged period are associated with an increased risk of atrophy and malignant transformation, making appropriate surgical management essential. In this case report, we present an adult patient in whom an undescended testis was identified within the inguinal hernia sac and managed surgically in the same session, along with a brief review of the relevant literature.

Material and Methods: A 25-year-old male patient presented to the hospital with complaints of pain and swelling in the right groin region. He had no known comorbidities and no history of previous surgical procedures. Physical examination revealed both direct and indirect inguinal hernias palpable in the right inguinal area.

Results: Superficial ultrasonography demonstrated herniation of intra-abdominal fatty tissue and bowel loops into the inguinal canal through a 16-mm defect in the right lower quadrant during the Valsalva maneuver, with the hernia sac being reducible. No additional pathology or mass was detected. The patient underwent elective surgery, during which an indirect inguinal hernia was identified. Opening of the hernia sac revealed an atrophic undescended testis (Figure 1). Urology was consulted intraoperatively, and orchiectomy was performed. The postoperative course was uneventful, and the patient was discharged on postoperative day 2. Histopathological examination confirmed an atrophic testis.

Conclusion: Although inguinal hernia is common in adult males, the presence of an undescended testis within the hernia sac is extremely rare and is usually diagnosed intraoperatively. Adult cases of cryptorchidism are generally detected incidentally during inguinal hernia repair, and prolonged extra-scrotal location of the testis is associated with an increased risk of atrophy and malignant transformation; therefore, orchiectomy is recommended in adult patients. This case emphasizes that, although rare, cryptorchidism should be considered during inguinal hernia surgery in adult male patients and demonstrates that a multidisciplinary approach is safe and effective.

Keywords: Inguinal hernia, undescended testis, congenital anomaly, atrophic testis

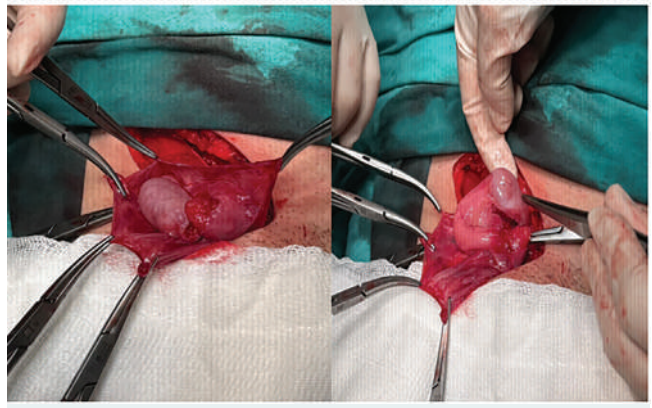

Figure 1. Intraoperative appearance of peritoneal loose bodies. During abdominal exploration, white-grey, smooth-surfaced PLBs found free around the omentum (view from the surgical field).

[P-498]

Canal of Nuck cyst detected during laparoscopic TAPP repair for presumed inguinal hernia in a female patient: A case report

Kamran Mahmudzada

Elmadağ Dr. Hulusi Alataş State Hospital, Ankara

Objective: A canal of Nuck cyst is a rare condition in adult women that results from incomplete obliteration of the processus vaginalis. It may present with clinical findings similar to those of an inguinal hernia and therefore is frequently misdiagnosed or underdiagnosed. Preoperative imaging modalities are not always diagnostic, and the diagnosis is most often established based on intraoperative findings and histopathological examination.

Material and Methods: A 49-year-old female patient presented with right groin pain. Physical examination revealed tenderness in the right inguinal region. Based on the clinical findings, ultrasonographic evaluation was performed. On subsequent ultrasonography, findings consistent with a right indirect inguinal hernia were observed, while no cystic lesion or additional pathology was detected. Accordingly, the patient was scheduled for laparoscopic surgery with a prediagnosis of inguinal hernia, and a transabdominal preperitoneal (TAPP) repair of the right inguinal hernia was planned.

Results: During laparoscopic exploration, a cystic lesion containing serous fluid without bowel or omental involvement was identified in the right inguinal region. The lesion was considered intraoperatively to be consistent with a canal of Nuck cyst and was totally excised. Subsequently, the existing inguinal defect was repaired using the TAPP technique. Histopathological examination of the excised specimen revealed a cystic structure lined by flattened single-layer epithelium. Immunohistochemical analysis demonstrated positive staining for calretinin, while ERG, CD31, and p53 were negative. These findings were reported as consistent with a mesothelial cyst (canal of Nuck cyst). The postoperative course was uneventful, and the patient was discharged without complications.

Conclusion: Even in female patients in whom an inguinal hernia is identified on preoperative ultrasonography and no cystic lesion is detected, a canal of Nuck cyst may be encountered during surgical exploration. Therefore, the laparoscopic approach offers significant advantages in terms of both accurate diagnosis and simultaneous treatment.

[P-499]

A rare but aggressive appendix tumor: goblet cell carcinoma

Elif Jarin Akkoç, Muratcan Fırat, Bedii Berat Apaydın

Department of General Surgery, İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul

Objective: Goblet cell carcinoma is a rare primary tumor of the appendix, occurring in the sixth decade of life, with equal incidence in men and women, usually spreading to peritoneal surfaces without hematogenous metastasis. Like other primary appendix tumors, it may present with acute appendicitis and diagnosed incidentally, due to its aggressive spread, it may also be detected in the late stages. It contains both epithelial and neuroendocrine components and is classified into three subtypes based on histopathological features. It is reported that the subtype with signet ring cell differentiation has the worst survival rate. We aim to contribute to the literature with a case of goblet cell carcinoma that recurred with signet ring cell carcinoma differentiation one and a half years after diagnosis.

Material and Methods: A 45-year-old female patient with no comorbidities other than known hypertension presented in August 2023 with changes in bowel habits and right lower quadrant pain that had been present for three months. Contrast-enhanced CT scan revealed minimal dilation in the small bowel loops and no other pathological findings. Colonoscopy was reported as "Ileocaecal valve stenosis, ulcerovegetative appearance extending to the appendix," and biopsy revealed "Diffuse atypical cellular infiltration characterized by widespread intracellular mucin." Surgery was planned. Right hemicolectomy was performed in September 2023.

Results: The patient was referred to oncology after postoperative pathology report concluded "Appendix goblet cell carcinoma, T4bN2," and received 8 cycles of adjuvant oxaliplatin and capecitabine. No disease recurrence was observed for a year and a half of follow-up. In April 2025, the patient presented with abdominal swelling, imaging revealed widespread intra-abdominal ascites and peritoneal carcinomatosis (Figure 1). The patient was evaluated by our gastrointestinal oncology council, cytoreductive surgery and HIPEC were decided upon. In August 2025, our team performed anastomosis revision, omentectomy, peritonectomy, total abdominal hysterectomy and bilateral salpingo-oophorectomy, cholecystectomy, and administered 15 mg of mitomycin at a dose of 1.5 LT/m^2, prepared at 42 degrees Celsius, HIPEC infusion. Postoperative pathology report revealed "signet ring cell carcinoma metastasis and infiltration" in the anastomosis line serosa, both ovaries, uterus, cervix, gallbladder, peritoneal and omental specimens.

Conclusion: Biological behavior and clinical evaluation of goblet cell adenocarcinomas are controversial. There are cases treated with HIPEC and cytoreductive surgery in the literature, a high recurrence rate has been observed in follow-ups, intraperitoneal recurrence is the most common one. Due to its highly aggressive nature, it requires meticulous and multidisciplinary management, and sharing of clinical experiences is necessary.

Keywords: Appendix, HIPEC, goblet cell carcinoma

Efficiency of nivolumab in PD-L1 positive metastatic gastric cancer: Case presentation

Kahraman Dinler[1], Şevket Barış Morkavuk[1], Halil Çınar[2], Kemal Coşkun Çakmak[2], Cansu Hıdır[2], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Immunotherapy has recently become a new focus in the treatment of malignant tumors following surgery, chemotherapy, radiotherapy, and molecularly targeted therapy. Nivolumab, a human monoclonal antibody, is the first programmed cell death protein-1 (PD-1) inhibitor that can block the interaction of its ligand (PD-L1) restore the immune response of T-cells, and enhance the recognition of tumor cells by the immune system.

Material and Methods: PD-1 is expressed in cytotoxic T-cells and T-regulatory cells that are activated in response to inflammation or infection in peripheral tissues. Binding of programmed PD-L1 to PD-1 limits the response of T-cells to stimuli and causes immune suppression. Anti-PD-1 therapies disrupt this pathway and allow activated cytotoxic T-cells to attack cancer cells. In this case report, we aim to present a case of gastric cancer with multiple liver metastases that regressed almost completely after PD-L1 treatment, along with a review of the literature.

Results: A 68-year-old male patient with gastric cancer and multiple liver metastases was referred to our clinic from an external center. Abdominal CT scan revealed a lesion consistent with multiple metastases in the liver, the largest measuring 43×38 mm, and a mass in the gastric antrum showing local invasion of the liver. Pathology blocks showed a PD-L1 expression percentage of 70%. The patient was started on docetaxel, cisplatin, 5Fu, and nivolumab. Post-treatment follow-up showed regression of the liver lesions. The patient, who was given one course of Folfiri treatment, refused the treatment and discontinued it. Four years later, the patient presented to our clinic again with complaints of upper gastrointestinal bleeding. It was learned that the patient had received frequent blood transfusions for the past 5 months and had undergone gastric coil embolization once at an external center. A control CT scan showed that the multiple lesions in the liver responded almost completely to treatment, with only a single lesion in segment 7 showing activation. Due to the persistence of systemic disease and uncontrollable bleeding, palliative gastrectomy was performed.

Conclusion: PD-1 is expressed in activated T and B-cells in peripheral tissues in response to inflammation or infection. Binding of PD-L1 to PD-1 inactivates T-cells and limits the immune response to stimuli, leading to immunosuppression. Cancer cells enhance the immunosuppressive effect of this pathway by triggering PD-1 expression, allowing cancer to “hide” from the natural immune attack. Anti-PD-1 therapies disrupt this pathway by preventing the PD-1 ligand from binding to its receptor; thus, active cytotoxic T-cells become able to attack cancer cells.

Keywords: Immunotherapy, PD-L1, programmed cell death

High-risk small intestinal gastrointestinal stromal tumor with spontaneous peritoneal dissemination in the absence of tumor rupture: A rare case report

Nadir Samet Koçsoy, Zeynep Nur Yurdakul, İbrahim Kılınç, Behzat Fatih Demirci

University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: Gastrointestinal stromal tümörler (GIST), gastrointestinal sistemin en sık görülen mezenkimal tümörleri olup biyolojik davranışları heterojendir. GIST’lerde intraabdominal yayılım çoğunlukla tümör rüptürü sonrası gelişen serbest peritoneal ekim şeklinde görülmekte ve kötü prognostik bir bulgu olarak kabul edilmektedir. Ancak rüptür bulgusu olmaksızın peritoneal ekim görülmesi nadirdir. Bu çalışmada, rüptür bulgusu olmaksızın, spontan ekim ve implantasyon gösteren yüksek riskli bir ince barsak GIST olgusunun sunulması amaçlanmıştır.

Material and Methods: Karın ağrısı şikayeti ile dış merkeze başvuran ve batın içi kitle saptanması üzerine kliniğimize refere edilen 76 yaşındaki erkek hastanın klinik, radyolojik, intraoperatif ve patolojik verileri retrospektif olarak değerlendirildi. Preoperatif kontrastlı batın bilgisayarlı tomografi görüntüleri incelendi. Cerrahi eksplorasyon sırasında elde edilen intraoperatif bulgular analiz edildi. Rezeksiyon materyallerinin histopatolojik ve immünhistokimyasal incelemeleri yapıldı.

Results: Hastanın özgeçmişinde 10 yıl önce geçirilmiş gastrointestinal sistem kanaması mevcuttu. Preoperatif görüntülemede, pelvisi ve sağ alt kadranı dolduran, yaklaşık 15 cm çapında batın içi kitle saptandı; peritoneal implant veya tümör rüptürü lehine bulgu izlenmedi. Cerrahi eksplorasyonda Treitz ligamanından 200. Cm’den köken alan, kapsülü intakt primer tümör saptandı ve kitle, köken aldığı ince barsak ansı ile birlikte en-blok rezeksiyon ile çıkarıldı. Nodüler implantların, çekum serozası, çekum mezosu ve Treitz ligamanından yaklaşık 150. cm distalinden itibaren ileoçekal bölgeye kadar uzanan ince barsak mezenterinde görüldü. Treitz ligamanının 150. cm proksimalinde implant saptanmadı. İmplantlar milimetrik boyuttan en büyüğü yaklaşık 3 cm çapa ulaşan polipoid lezyonlar şeklindeydi ve intraoperatif görüntülerle belgelendi. Primer tümörün kaynaklandığı düşünülen ince barsak ansının mezosu bölünürken mezenterik vasküler yapıda 10 yıl önce geçirilmiş GİS kanama nedenli yerleştirilen coil materyali görüldü. Postoperatif patolojide; batın içi kitle ve ince barsak mezosundan eksize edilen lezyonlar yüksek riskli GIST ile uyumlu bulundu. İmmünohistokimyasal incelemede CD117, DOG-1 ve CD34 yaygın ve güçlü pozitif, SMA, desmin, S100 ve myogenin negatif saptandı. Ki-67 proliferasyon indeksi en yoğun alanda %45-50 olarak değerlendirildi.

Conclusion: Bu olgu, GIST’lerde intraabdominal implantasyonun her zaman rüptür ve serbest peritoneal ekim ile ilişkili olmadığını göstermektedir. GİST’lerde üptür bulgusu olmaksızın intraabdominal ekim ve implantasyon görülmesi farklı yayılım mekanizmalarının varlığına işaret etmektedir. GIST olgularında, rüptür öyküsü bulunmasa dahi atipik ve lokalize intraabdominal implantasyon olasılığı göz önünde bulundurulmalıdır.

Keywords: GIST, spontaneous peritoneal implantation

Perforated Amyand hernia in a 95-year-old male patient operated with the preoperative diagnosis of incarcerated inguinal hernia: A rare case report

Mert Şahin Öztürk, Zeynep Göçerler, Firuzabonu Pulatova, Volkan Doğru

Akdeniz University Hospital, Antalya

Objective: Amyand's hernia is defined as the presence of the vermiform appendix within an inguinal hernia sac and is observed in approximately 0.5-1% of all inguinal hernias. The occurrence of acute appendicitis within the hernia sac is even rarer, reported in approximately 0.07-0.13% of cases. Amyand's hernias containing perforated appendicitis are exceedingly uncommon in the literature, with an incidence of less than 0.01%. Preoperative diagnosis is often difficult, and patients are typically operated on with a preliminary diagnosis of incarcerated inguinal hernia. The surgical approach should be planned according to intraoperative findings and evaluated using the Losanoff–Basson classification.

Material and Methods: A 95-year-old male patient hospitalized in the hematology ward for myelodysplastic syndrome (MDS) was referred to our clinic with a painful swelling in the right inguinal region. He had undergone surgery for a right inguinal hernia approximately 20 years earlier. The patient reported progressive swelling in the right inguinal area for one week and severe pain during the last two days, and the previously reducible swelling had become irreducible. Laboratory investigations revealed pancytopenia (Hb: 7.7 g/dL, platelets: 23,000/mm³, leukocytes: 1,600/mm³). Physical examination demonstrated a firm, tender, irreducible mass in the right inguinal region with mild skin hyperemia. Ultrasonography showed herniated mesenteric fat and bowel loops passing through a fascial defect measuring approximately 2.5 cm. Reduction could not be achieved with probe compression, and weak vascular signals at low PRF suggested strangulation. Emergency surgery was planned, and preoperative hematologic optimization was performed with erythrocyte suspension transfusion and platelet replacement. After hemoglobin and platelet levels reached acceptable surgical ranges, the patient underwent surgery.

Results: During exploration, dense purulent fluid confined within the hernia sac and surrounded by omentum without surrounding spread was observed. The appendix was identified within the sac, and perforation was detected in its distal segment. These findings were consistent with Amyand's hernia containing perforated appendicitis (Losanoff–Basson Type 3). An appendectomy was performed, and due to contamination, mesh was avoided and primary tissue repair using the Bassini technique was preferred.

Conclusion: Although Amyand's hernia is rare, it should be considered in the differential diagnosis, particularly in patients presenting with incarcerated inguinal hernia. Preoperative imaging is often not definitive, and diagnosis is frequently established intraoperatively. In the presence of perforation, mesh repair is contraindicated because of infection risk, and primary tissue repair should be preferred. Furthermore, appropriate preoperative hematologic optimization is crucial in high-risk patients with hematologic comorbidities to reduce perioperative complications. The diagram illustrates the four types of Amyand's hernia according to the Losanoff-Basson classification. Type 1 involves a normal appendix within the hernia sac and may be managed with hernia repair with or without appendectomy. Type 2 consists of acute appendicitis within the sac and requires appendectomy with primary tissue repair. Type 3 is characterized by perforated appendicitis with peritonitis or sepsis and should be treated with appendectomy and primary repair without mesh. Type 4 describes Amyand's hernias associated with additional intra-abdominal pathology. The lower panel shows a resected perforated appendix specimen.

Keywords: Amyand's hernia, incarcerated inguinal hernia, perforated appendicitis

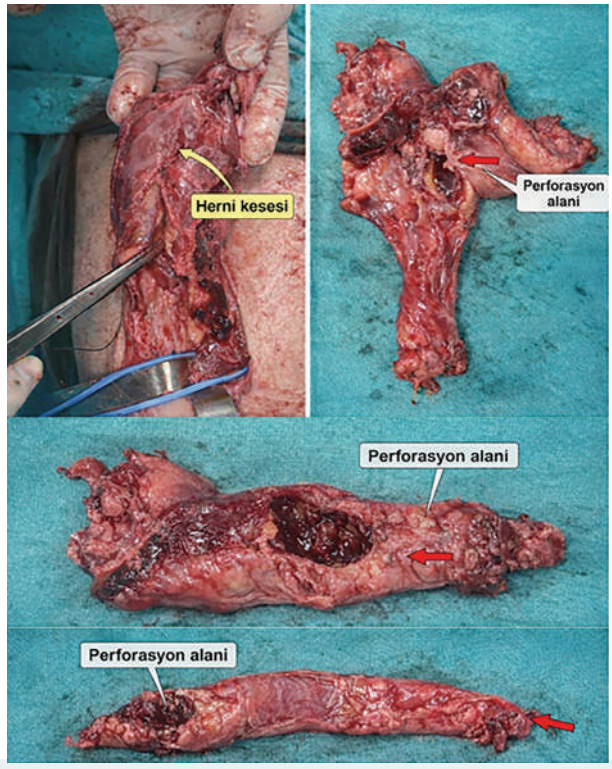

Figure 1. Intraoperative and macroscopic views of Amyand's hernia specimen. (A) Intraoperative view of the appendix located within the hernia sac; the yellow arrow indicates the hernia sac. (B) Resected specimen showing the perforation site marked with a red arrow. (C) Gross specimen demonstrating a perforation localized to the distal segment of the appendix.

Unexpected diagnosis of gastric AA-type secondary amyloidosis in a patient undergoing distal gastrectomy for suspected gastric cancer: A case report

Gizem Polat Özcan, Doğuşhan Sevgen, Engin Erdoğan, Hikmet Pehlevan Özel

University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: A portion of gastric tumors occur not as primary adenocarcinomas but as secondary manifestations of systemic diseases or metastases from distant neoplasms. These cases may closely resemble primary gastric malignancies on endoscopic and radiologic evaluation, making histopathological and immunohistochemical confirmation essential. Among patients presenting with upper gastrointestinal bleeding, common causes include peptic ulcer disease, gastric cancer, and varices; rarely, gastric amyloidosis caused by amyloid deposition in the gastric wall may be responsible. Secondary (AA-type) amyloidosis develops in the context of chronic inflammatory or infectious diseases and can cause ulceration and bleeding due to amorphous protein deposits in the mucosa and submucosa. Reports of gastric amyloidosis mimicking gastric carcinoma are rare.

Material and Methods: This study presents a single case. The diagnostic workup included upper gastrointestinal endoscopy with biopsy and colonoscopy, followed by contrast-enhanced abdominal CT to assess gastric involvement. Because of uncontrolled bleeding and hemodynamic instability, emergency open distal gastrectomy with Billroth II reconstruction and D2 lymph node dissection was performed. The specimen underwent hematoxylin-eosin, crystal violet, and Congo red staining, and the amyloid type was determined immunohistochemically.

Results: A male patient in his seventies with a history of chronic kidney disease and chronic cardiac disease presented with melena. Upper gastrointestinal endoscopy revealed an ulcerovegetative mass in the gastric antrum, and biopsies were reported as gastritis. Colonoscopy showed no pathological findings. Computed tomography demonstrated irregular transmural wall thickening in the gastric antrum, which was interpreted in favor of primary gastric cancer. Histopathological examination of the gastrectomy specimen revealed dense eosinophilic amorphous deposits in the gastric mucosa and submucosa, with focal extension into the muscularis propria and vascular walls. Amyloid deposition was confirmed by crystal violet and Congo red staining. Immunohistochemical analysis demonstrated amyloid A positivity, establishing the diagnosis of AA-type secondary gastric amyloidosis. Postoperatively, further evaluation for the underlying etiology was planned; however, the patient died on postoperative day five due to cardiac causes, and comprehensive systemic evaluation could not be performed.

Conclusion: Gastric AA-type amyloidosis is a rare condition that may present with upper gastrointestinal bleeding and mimic gastric cancer clinically and radiologically. Awareness of this entity is crucial, as insufficient preoperative biopsy sampling may result in unnecessary extensive surgery. Careful histopathological evaluation and systemic assessment are essential when amyloid deposition is suspected.

Keywords: Gastric mass, amyloidosis, gastrointestinal bleeding

Delayed Meckel's diverticulum perforation and drug-induced toxic hepatitis following acute perforated appendicitis: A case report of a complication chain

Vedat Kaplan[1], Baran Yüksekyayla[2]

[1]*Şanlıurfa Training and Research Hospital, Şanlıurfa*

[2]*Harran University Faculty of Medicine, Şanlıurfa*

Objective: To present a case of delayed Meckel's diverticulum perforation and subsequent toxic hepatitis developing during follow-up after surgery for acute appendicitis, and to emphasize the importance of complication management.

Material and Methods: The demographic data, laboratory findings, imaging results, intraoperative findings, and postoperative clinical course of the patient who presented to the Emergency Department of Şanlıurfa Training and Research Hospital with abdominal pain and was operated on with a diagnosis of acute appendicitis based on clinical, laboratory, and radiological evaluations were retrospectively reviewed through the hospital information management system. Details of the surgical interventions, developed complications, and applied treatment approaches were recorded. The obtained data were evaluated in the context of the literature and organized in the format of a case report.

Results: A 21-year-old male patient presented with abdominal pain persisting for four days. Laboratory findings revealed leukocytosis (27,550/mm³) and markedly elevated CRP (>429 mg/L). The patient was operated on with a preliminary diagnosis of perforated appendicitis. Diffuse purulent content was observed intraoperatively, and an appendectomy was performed. A Meckel's diverticulum was identified approximately 100 cm proximal to the ileocecal valve; as it appeared macroscopically intact, no resection was performed. Although initial clinical improvement was observed in the postoperative period, a marked increase in acute phase reactants and right lower quadrant pain developed on postoperative day six. Computed tomography demonstrated a loculated collection with air-fluid levels suggestive of perforation. At reoperation, perforation was identified at the mid-segment of the Meckel's diverticulum with formation of a localized abscess. Segmental small bowel resection including the diverticulum with primary anastomosis and abscess drainage was performed. The patient showed clinical improvement. After discharge, the patient presented with right upper quadrant pain and marked elevation of transaminases (AST 895 U/L, ALT 612 U/L). Imaging findings were normal. Antibiotic and analgesic treatments were discontinued, and supportive therapy was initiated. Liver enzyme levels rapidly decreased, and the condition was interpreted as toxic hepatitis. Despite these complications, the patient was discharged in good health.

Conclusion: This case highlights the importance of intraoperative evaluation of concomitant Meckel's diverticulum in complicated appendicitis and the multidisciplinary management of postoperative surgical and medical complications.

Application of FAST in a patient with foot ulcers due to Buerger's disease

Batuhan Karaköse, Ela Atmaca, Yusufcan Ekinci, Edip Gönüllü, Bayram Çolak

İzmir Bakırçay University Çiğli Training and Research Hospital, İzmir

Objective: Buerger's disease, also known as thromboangiitis obliterans, is a segmental, non-atherosclerotic, occlusive vasculitis affecting small and medium-sized arteries and veins of the extremities, particularly prevalent in young adults. The most significant risk factor for Buerger's disease is smoking. Treatment for Buerger's disease requires a multidisciplinary approach. In cases unsuitable for revascularization and presenting with severe pain due to critical limb ischemia, neuromodulation techniques such as spinal cord stimulation have been reported to provide promising results for pain control and limb preservation.

Material and Methods: A forty-seven-year-old male patient presented with discoloration and pain in the third toe of his right foot. Approximately three years prior, he had undergone traumatic amputation of his right fourth toe, followed by the development of ulcerative lesions and persistent pain in the third toe during the post-amputation period. He reported pain with a visual analog scale (VAS) score of 9-10. Computerized tomography angiography revealed occluded bilateral tibialis anterior and posterior arteries. In accordance with these findings, medical treatment was initiated for circulatory palliation and pain control, and interventional angio procedures were performed. After failing to benefit from medical treatment and interventional angio procedures, the patient was consulted to the algology clinic. A lumbar sympathetic block was performed for pain palliation and to enhance circulation. Although a temporary reduction in pain was achieved after the procedure, the pain recurred within two days. Subsequently, it was decided to apply spinal cord stimulation (SCS) for the patient. The patient's VAS scores were assessed before permanent implantation and 15 minutes after electrode placement. The implants used were narrow-spaced (31 mm) 8-contact and wide-spaced (52 mm) 8-contact electrode systems. During electrode placement, paresthesia was achieved to cover the patient's painful areas. Following paresthesia optimization, the fast-acting sub-perception therapy (FAST) program was activated, and the perception threshold was reduced by approximately 70% (pulse width: 280–320 µs, frequency: 90 Hz).

Results: The patient, who showed a significant reduction in VAS scores during the procedure, continued to use the FAST program. At 24 hours postoperatively, the VAS score was recorded as 2. In our four-month follow-up, the VAS score remained at 0-1, and an increase in wound healing rate was observed.

Conclusion: Despite many treatment methods, the FAST program is one of the effective and current methods that can be preferred for pain palliation and wound healing support, alongside interventional and medical treatment, in Buerger's disease patients with severe pain that cannot be controlled.

Keywords: Buerger's disease, spinal cord stimulation, fast-acting sub-perception therapy (FAST)

Morgagni hernia in adulthood: Case report

Veysel Oğuzhan Yıldırım, Aydın Dinçer, Erdal Karagülle, Hasan Özkan

University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Morgagni hernia is a rare congenital defect located in the anterior-retrosternal portion of the diaphragm and is infrequently diagnosed in adulthood. Due to its nonspecific clinical presentation, diagnosis may be delayed. In this case report, we aimed to present the diagnostic process and laparoscopic surgical management of Morgagni hernia in an adult patient presenting with long-standing respiratory symptoms.

Material and Methods: Clinical, radiological, and surgical data of a 52-year-old male patient who presented with dyspnea and chest pain were retrospectively evaluated. Posterior-anterior chest radiography and thoracic computed tomography findings were reviewed. The surgical approach, intraoperative findings, and postoperative follow-up outcomes were analyzed.

Results: Laboratory findings were within normal limits. Posterior-anterior chest radiography revealed a suspicious mass or consolidation in the right lower lung zone. Thoracic computed tomography demonstrated herniation of a colonic segment into the thoracic cavity through a wide defect in the right diaphragm. Preoperative respiratory exercises and medical treatment were administered. The patient underwent laparoscopic surgery. Intraoperatively, a diaphragmatic defect measuring approximately 6×7 cm was identified on the right side, containing herniated omentum and colon. The herniated organs were reduced into the abdominal cavity. The defect was repaired primarily and reinforced with a dual mesh to reduce the risk of recurrence. No postoperative complications were observed. The patient was discharged on the fourth postoperative day. At the 12th-day and one-month follow-up visits, the patient's respiratory symptoms had completely resolved.

Conclusion: Although Morgagni hernia is rare in adults, it should be considered in the differential diagnosis of patients presenting with long-standing and unexplained respiratory symptoms. Computed tomography is the main diagnostic modality. Laparoscopic repair is a safe and effective treatment option with low morbidity, short hospital stay, and improved patient comfort.

Keywords: Adult, diaphragmatic hernia, Morgagni's hernia

Nuck canal cyst in women: A multicenter approach to the diagnostic and surgical management of a rare pathology

Emir Yetkin[1], Şükran Çavdar[2], Faruk Yazıcı[3], Serkan Demir[4], M. Salih Süer[4], Şener Balas[4]

[1]*Polatlı Duatepe State Hospital, Ankara*

[2]*Payas State Hospital, Hatay*

[3]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[4]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Nuck canal cyst is a rare congenital anomaly resulting from incomplete obliteration of the processus vaginalis during embryologic development in women. Clinically, it presents as painful or painless inguinal swelling and is frequently misdiagnosed as indirect inguinal hernia, lymphadenopathy, lipoma, or round ligament endometriosis. This study aimed to retrospectively evaluate adult female patients diagnosed and surgically treated at three centers, focusing on diagnostic challenges, radiologic features, and surgical outcomes of Nuck's canal cysts.

Material and Methods: Five adult female patients diagnosed with Nuck's canal cyst and treated surgically in three general surgery centers between 2023 and 2025 were retrospectively analyzed. The mean age was 41.6 years (range: 36-51). Four patients had right-sided and one had left-sided involvement. All patients presented with a palpable inguinal mass. Ultrasonography was used as the initial imaging modality in all cases, while magnetic resonance imaging was performed in one patient to better define anatomical extension. All patients underwent complete cyst excision via open surgery, with simultaneous inguinal reinforcement using Lichtenstein or mesh plug repair.

Results: Radiologic evaluation revealed well-circumscribed, thin-walled, anechoic cystic lesions measuring 3-6 cm in diameter in the inguinal region. Histopathological examination confirmed the diagnosis of Nuck's canal cyst in all cases. No early or late postoperative complications, seroma formation, or recurrence were observed during a mean follow-up period of 8 months. The demographic characteristics, side predominance, radiologic findings, and surgical management were consistent with the largest adult case series reported in the literature, particularly those by Prodromidou et al. and Kohlhauser and Pirsch. All cases involved adult women, with right-sided involvement in three and left-sided involvement in one. The most common reason for presentation was painless swelling in the groin area. All patients were treated with open surgery, and no postoperative complications or recurrence were observed.

Conclusion: Although rare, Nuck's canal cyst should be considered in the differential diagnosis of inguinal masses in adult female patients. Ultrasonography is a practical and accessible first-line diagnostic tool, while MRI provides additional value in assessing lesion extent and identifying associated hernia components. Surgical excision is a safe and definitive treatment with excellent outcomes. This multicenter experience contributes to the limited literature on adult cases and highlights the importance of clinician awareness to ensure accurate diagnosis, appropriate surgical planning, and avoidance of unnecessary extensive procedures.

Intraductal carcinoma arising from the epithelial component of a fibroadenoma as a rare breast tumor

Hanife Köle[1], İsmail Zihni[1], Veli Vural[1], Cumhur Arıcı[1], Gülgün Erdoğan[2]

[1]*Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya*
[2]*Department of Pathology, Akdeniz University Faculty of Medicine, Antalya*

Objective: Fibroadenomas are the most common benign solid tumors of the breast and are usually observed in younger age groups. These lesions consist of epithelial and stromal components, and epithelial atypia or malignant transformation within a fibroadenoma is extremely rare. The development of ductal carcinoma *in situ* (DCIS) within a fibroadenoma has been reported in less than 1% of cases in the literature. In this case report, we present a rare case of DCIS arising from the epithelial component of a fibroadenoma.

Material and Methods: Clinical and pathological data of a patient who underwent surgery at our center were retrospectively evaluated.

Results: A 27-year-old woman with a family history of breast cancer presented with a progressively enlarging painless mass in the right breast. Following physical examination and imaging studies, the lesion was classified as BI-RADS 4A, and a tru-cut biopsy was performed (Figure 1). Ultrasonographic image of the right breast showing an isoechoic solid lesion measuring 15×7×18 mm, located 3 cm from the nipple at the 11 o'clock position, with its long axis parallel to the skin, focal contour irregularities, microlobulations, and no vascular signal on color Doppler imaging. Due to the detection of epithelial atypia on pathological examination, an excisional biopsy was performed. The surgical specimen was evaluated histopathologically and immunohistochemically. Histopathological examination revealed low-grade, solid-type DCIS arising in a background of fibroadenoma. Immunohistochemical analysis demonstrated diffuse estrogen receptorpositivity and loss of CK5/6 staining, while myoepithelial cells were preserved with calponin and p63 staining (Figure 2). Surgical margins were negative. Following discussion at the multidisciplinary oncology council, adjuvant radiotherapy and tamoxifen therapy for five years were planned. No residual or recurrent disease was detected during follow-up.

Conclusion: Since fibroadenomas are typically observed in younger patients, the possibility of malignancy should always be considered in older patients presenting with presumed fibroadenomas. Given the impracticality of examining every fibroadenoma and the potential associated morbidity, this issue raises important questions regarding breast cancer surveillance in women with multiple fibroadenomas. Tru-cut biopsies often fail to sample the entire lesion, and the increasing reliance on core needle biopsy for the diagnosis of fibroadenomas should raise awareness of the risk of overlooking epithelial atypia. Patients with microcalcifications on imaging, a positive family history, BI-RADS 4 lesions, and atypia on biopsy—as in our case—should be considered high risk, and excisional biopsy should be recommended rather than relying solely on tru-cut biopsy.

Keywords: Fibroadenoma, Ductal carcinoma *in situ*, tru-cut biopsy

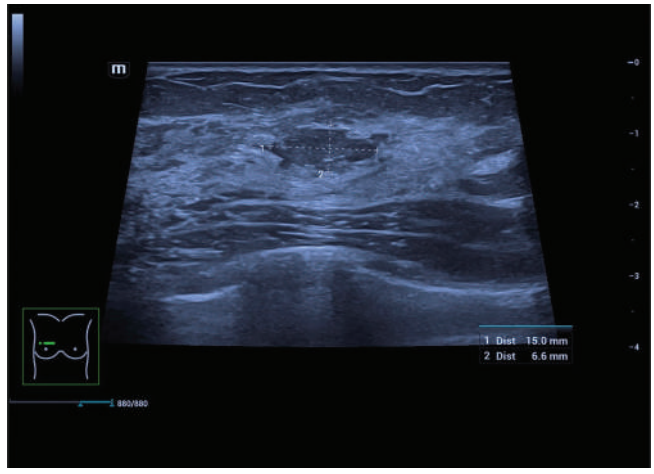

Figure 1. Ultrasonographic image of the right breast showing an isoechoic solid lesion measuring 15×7×18 mm, located 3 cm from the nipple at the 11 o'clock position, with its long axis parallel to the skin, focal contour irregularities, microlobulations, and no vascular signal on color Doppler imaging.

Isolated colonic metastasis developing five years after primary cutaneous malignant melanoma

Berat Ünal, Turgay Sayın, Bahattin Bayar, Hamza Hattab, Gıyasettin Başakıncı, Özge Kaya Korkmaz, Ebru Çılbır, Ahmet Oğuz Hasdemir

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Malignant melanoma is an aggressive malignancy that can metastasize to regional lymph nodes in the early period and exhibits an unpredictable metastatic pattern in advanced stages. Gastrointestinal system metastases are clinically detected rarely, and colonic involvement is reported to be extremely uncommon. In this study, a rare case of isolated colonic metastasis developing approximately five years after the diagnosis of primary cutaneous malignant melanoma is presented. Although lymph nodes, lungs, liver and brain are the most common metastatic sites, the gastrointestinal tract is an important and often overlooked target, with postmortem involvement reported in 50-60% of advanced cases, while clinically symptomatic disease is uncommon. Gastrointestinal involvement most frequently affects the small intestine, whereas colonic metastases are rare and usually present with obstruction, bleeding or anemia, leading to diagnosis at advanced stages. Rarely, isolated asymptomatic colonic metastases are detected incidentally. This case report highlights the diagnostic and clinical features of colonic metastases of melanoma.

Material and Methods: Five years after wide excision with grafting and axillary dissection for stage III malignant melanoma of the volar right wrist (Figure 1), a 56-year-old man receiving adjuvant dabrafenib + trametinib showed increased metabolic activity in the appendix, cecum and ascending colon on follow-up ^{18}F-FDG PET/CT (Figure 2). Colonoscopy revealed two polypoid masses at 130 cm in the hepatic flexure and a polyp in the transverse colon (Figure 3), and biopsies demonstrated colonic mucosa infiltrated by malignant melanoma. The patient was diagnosed with isolated colonic metastasis and underwent right hemicolectomy. Pathology showed ulcerated polypoid malignant melanoma with biphenotypic morphology, melanoma infiltration of the appendix, and 0/15 tumor-free regional lymph nodes (Figure 4). The tumor was present as three polypoid foci limited to the mucosa and submucosa, with sparing of the muscularis propria, subserosa and serosa. No postoperative complications occurred, and follow-up ^{18}F-FDG PET/CT confirmed removal of all metabolically active lesions.

Results: Gastrointestinal metastases of malignant melanoma reflect the aggressive nature of the disease, and colonic metastases are diagnostically challenging because of their rarity and often asymptomatic or nonspecific presentation. In patients with a history of melanoma, late-detected colonic lesions should raise suspicion for metastasis. Although CT, PET-CT and colonoscopy are useful, definitive diagnosis is based on histopathological and immunohistochemical evaluation. In isolated organ metastasis, surgical treatment may provide a survival benefit, while immunotherapy requires careful patient selection because of gastrointestinal adverse effects.

Conclusion: In conclusion, metastatic disease should be considered in atypical colonic lesions in melanoma patients, and a multidisciplinary approach is essential.

Keywords: Malignant melanoma, colonic metastasis

A breath-restricting mass: Mesenteric desmoid tumor

Ali Can Dağlıoğlu, Mustafa Örmeci, Ali Haldun Özcan, Ufuk Filikçi, Hüseyin Sağıroğlu

Department of General Surgery, Bandırma Onyedi Eylül University Faculty of Medicine, Balıkesir

Objective: Desmoid tumors (aggressive fibromatosis) are rare fibroblastic/myofibroblastic neoplasms characterized by the absence of metastatic potential but a tendency for locally invasive behavior. Their annual incidence is approximately 2-4 per million, accounting for nearly 3% of all soft tissue tumors.Intra-abdominal lesions most commonly originate from the mesentery and are more frequently observed in young women. Imaging findings are non-specific and may mimic mesenteric cysts, gastrointestinal stromal tumors, or other benign lesions

Material and Methods: A 19-year-old female presented with left-sided thoracic pain and difficulty during inspiration. Thoracic CT revealed mild pleural effusion. As symptoms persisted despite drainage, abdominal CT and ultrasonography were performed. Due to progressive pain, the patient underwent surgery. The mesenteric mass was completely excised with negative surgical margins (R0 resection). The diagnosis was confirmed by histopathological and immunohistochemical examination.

Results: Abdominal CT demonstrated a well-circumscribed cystic lesion in the left upper quadrant. Ultrasonography revealed a heterogeneous, mildly vascularized solid mesenteric mass measuring approximately 7 cm. Histopathological analysis confirmed a desmoid tumor (aggressive fibromatosis) with nuclear β-catenin positivity. Postoperatively, the patient's symptoms resolved. Following multidisciplinary evaluation, active surveillance was recommended. No recurrence was detected during follow-up.

Conclusion: Although desmoid tumors exhibit benign histology, they demonstrate locally aggressive behavior, with reported local recurrence rates ranging from 20% to 40%. Mutations in β-catenin (CTNNB1) play a significant role in their pathogenesis. Current guidelines recommend an initial active surveillance strategy for asymptomatic or stable patients. However, surgery remains an appropriate treatment option in symptomatic, progressive, or organ-compressing cases. Achieving negative surgical margins reduces recurrence risk, although the prognostic impact of microscopically positive margins remains controversial. In the present case, atypical thoracic onset symptoms and the initial cystic appearance on imaging were potential factors that could delay diagnosis. Due to symptomatic mesenteric involvement and progressive pain, surgical intervention was preferred. Following R0 resection, no adjuvant treatment was required. This approach is consistent with current literature. Desmoid tumors should be considered in the differential diagnosis of chronic abdominal pain and abdominal mass in young women. Imaging findings may be misleading; definitive diagnosis relies on histopathological examination. In symptomatic mesenteric cases, R0 resection represents an effective treatment option.

Keywords: Desmoid tumor,mesenteric mass, surgical resection

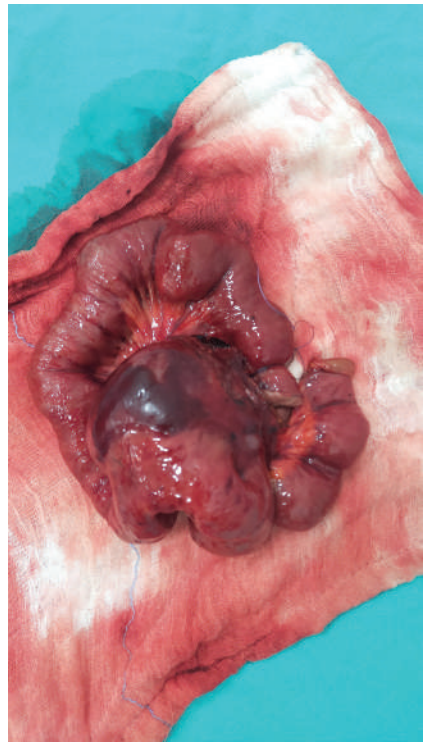

Figure 1. Desmoid tumor; A 10 cm mass was identified, filling the mesentery of an approximately 50 cm intestinal segment beginning 10 cm distal to the ligament of Treitz, with focal invasion of the small bowel serosa.

Surgical approach in an alkali cement burn with delayed presentation: A case report

Derya Özcan, Burcu Yalanız, Ömer Cennet

Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara

Objective: This study aimed to present a case of chemical burn caused by exposure to wet cement that required surgical treatment due to delayed presentation, and to discuss the clinical characteristics of cement burns. Although chemical burns are less common than thermal burns, they represent an important clinical problem because their alkaline nature can lead to deep and progressive tissue damage. Wet cement forms a highly alkaline environment as a result of the hydration of the calcium oxides it contains, causing liquefaction necrosis and allowing the injury to progress for hours or even days.

Material and Methods: The presented case was a 54-year-old male who initially received conservative treatment at an outside medical center for wounds that developed after both lower extremities remained in wet cement for approximately one hour during construction work. However, due to the lack of healing over a period of about 40 days, he was referred to our burn unit. Upon evaluation, the total burn surface area was calculated as 8% and was consistent with deep dermal burns.

Results: Following hospitalization, nutritional support was provided, and regular wound cleansing along with autolytic debridement was performed. Due to the presence of chronic inflammation in the wound bed and insufficient epithelialization, tangential excision and skin grafting were carried out on the 9th day of admission. The postoperative course was uneventful, with satisfactory graft take observed, and the patient was discharged with recommendations for appropriate wound care and moisturizing therapy. No additional complications developed during follow-up.

Conclusion: Cement burns are often recognized late because they typically present with a painless onset, and in many cases this leads to the need for surgical intervention. Early recognition of exposure, prompt irrigation with copious amounts of water, removal of contaminated clothing, and appropriate wound management are the key factors determining prognosis. This case highlights the importance of increasing awareness among individuals at occupational risk and demonstrates the critical role of timely treatment in reducing morbidity.

Keywords: Alkali burn, chemical burn, tangential excision and skin grafting

Figure 1. Burn areas at hospital presentation; the burn areas at the patient's presentation to our unit are shown in the attached image.

Figure 2. Postoperative burn areas; the burn areas on postoperative day 7 are shown in the attached image.

[P-527]

Radiation-induced partial liver injury following right breast radiotherapy: A rare case presenting as hepatic metastasis

Caner Curacı[1], Ali Toprak[1], Burak Dinçer[2], Elifcan Haberal[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara*

[2]*Department of Surgical Oncology, University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara*

Objective: Breast cancer is the most common malignancy among women worldwide and requires a multidisciplinary treatment approach including surgery, systemic therapy, and radiotherapy. While radiotherapy-related toxicities most commonly affect the skin and soft tissues, adjacent organs may also be exposed to unintended radiation. Although the liver is generally considered a low-risk organ in right breast radiotherapy, especially in lower quadrant tumors and tangential field techniques, liver segments IV-VIII may receive low-to-moderate radiation doses. Partial radiation-induced liver disease (RILD) is a rare but clinically misleading condition that may mimic hepatic metastasis.

Material and Methods: Case report.

Results: A 50-year-old premenopausal woman with pT1cN0, ER (+), PR (+), HER2 (–), Ki-67 60% pleomorphic invasive lobular carcinoma underwent: •Oncoplastic breast-conserving surgery •Sentinel lymph node biopsy •4 cycles of TC chemotherapy •Adjuvant radiotherapy: 50 Gy/25 fractions to the right breast •16 Gy boost to the tumor bedTwo weeks after completion of radiotherapy, the patient presented with right upper quadrant pain. Imaging and laboratory findingsct scan: a newly developed 68×18 mm hypodense lesion adjacent to liver segments IV-VIII (suspicious for metastasis). PET-CT: SUV_{max}: 3.73 (mild-to-moderate FDG uptake). Liver biopsy: •Inflammatory cell infiltration •Young fibrous tissue •No evidence of malignancy. Notably, liver function tests (AST, ALT, ALP, bilirubin) remained within normal limits throughout the entire course.

Conclusion: Radiation-induced liver injury is primarily dose-volume dependent and may present as: •Segmental hypodense lesions •Mild FDG uptake on PET •Early onset (2 weeks to 4 months post-RT) •Clinical symptoms without significant laboratory abnormalitiesIn this case: ✔Lesion localized adjacent to the radiotherapy field ✔ Onset at the 2nd week post-RT ✔Mild SUV uptake ✔Normal liver enzymes ✔Negative biopsy for malignancy. These findings strongly support radiation-induced partial liver injury rather than metastatic disease. Importantly, the absence of elevated liver enzymes differentiates this case from classic RILD and highlights the diagnostic difficulty. Newly detected hepatic lesions after right breast radiotherapy should not be immediately considered metastatic. Radiation-induced partial liver injury must be included in the differential diagnosis, particularly when: •The lesion is adjacent to the radiation field •Symptoms develop early after RT •FDG uptake is mild •Liver enzymes are normal. Awareness of this entity may prevent unnecessary systemic treatment and invasive interventions.

Keywords: Breast cancer, radiotherapy, liver injury following radiotherapy

[P-547]

Isolated colonic metastasis developing five years after primary cutaneous malignant melanoma

Berat Ünal

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Malignant melanoma is an aggressive malignancy that can metastasize to regional lymph nodes in the early period and exhibits an unpredictable metastatic pattern in advanced stages. Gastrointestinal system metastases are clinically detected rarely, and colonic involvement is reported to be extremely uncommon. In this study, a rare case of isolated colonic metastasis developing approximately five years after the diagnosis of primary cutaneous malignant melanoma is presented. Although lymph nodes, lungs, liver and brain are the most common metastatic sites, the gastrointestinal tract is an important and often overlooked target, with postmortem involvement reported in 50-60% of advanced cases, while clinically symptomatic disease is uncommon. Gastrointestinal involvement most frequently affects the small intestine, whereas colonic metastases are rare and usually present with obstruction, bleeding or anemia, leading to diagnosis at advanced stages. Rarely, isolated asymptomatic colonic metastases are detected incidentally. This case report highlights the diagnostic and clinical features of colonic metastases of melanoma.

Material and Methods: Five years after wide excision with grafting and axillary dissection for stage III malignant melanoma of the volar right wrist, a 56-year-old man receiving adjuvant dabrafenib + trametinib showed increased metabolic activity in the appendix, cecum and ascending colon on follow-up 18F-FDG PET/CT. Colonoscopy revealed two polypoid masses at 130 cm in the hepatic flexure and a polyp in the transverse colon, and biopsies demonstrated colonic mucosa infiltrated by malignant melanoma. The patient was diagnosed with isolated colonic metastasis and underwent right hemicolectomy. Pathology showed ulcerated polypoid malignant melanoma with biphenotypic morphology, melanoma infiltration of the appendix, and 0/15 tumor-free regional lymph nodes. The tumor was present as three polypoid foci limited to the mucosa and submucosa, with sparing of the muscularis propria, subserosa and serosa. No postoperative complications occurred, and follow-up 18F-FDG PET/CT confirmed removal of all metabolically active lesions.

Results: Gastrointestinal metastases of malignant melanoma reflect the aggressive nature of the disease, and colonic metastases are diagnostically challenging because of their rarity and often asymptomatic or nonspecific presentation. In patients with a history of melanoma, late-detected colonic lesions should raise suspicion for metastasis.Although CT, PET-CT and colonoscopy are useful, definitive diagnosis is based on histopathological and immunohistochemical evaluation. In isolated organ metastasis, surgical treatment may provide a survival benefit, while immunotherapy requires careful patient selection because of gastrointestinal adverse effects.

Conclusion: In conclusion, metastatic disease should be considered in atypical colonic lesions in melanoma patients, and a multidisciplinary approach is essential.

Keywords: Malignant melanoma, colonic metastasis

Two cystic teratomas mimicking mesenteric cysts

Üsame Yıldız, Abdullah Sami Maden, İsmail Hasırcı, Abdülhalim Serden Ay, Mehmet Ali Eryılmaz

University of Health Sciences Türkiye, Konya City Hospital, Konya

Objective: Intraabdominal and abdominopelvic masses are common in general surgical practice; however, when they reach large dimensions, they may create diagnostic uncertainty. Although cross-sectional imaging supports evaluation, the precise origin of large cystic lesions cannot always be clearly defined preoperatively. In some cases, cysts of gynecologic origin may not be recognized as ovarian and may be referred to surgical clinics with a preliminary diagnosis of mesenteric cyst. Mature cystic teratomas can similarly mimic mesenteric masses. We present two cases initially suspected to be mesenteric cysts but ultimately diagnosed as ovarian mature cystic teratomas after surgical exploration and histopathological assessment, and we outline the diagnostic and surgical management process.

Material and Methods: This retrospective single-center case series included two patients operated on for presumed intraabdominal masses and subsequently diagnosed histopathologically with mature cystic teratoma. Clinical, radiological, laboratory, and operative findings were reviewed.

Results: The first patient, a 49-year-old woman, was initially asymptomatic and presented with a large cystic mass extending to the left upper quadrant. Computed tomography showed an approximately 15 cm lesion containing fat and calcifications; CA 19-9 was elevated, whereas other tumor markers were normal. The second patient, aged 38 years, presented with abdominal pain. Imaging studies reported a 16 cm lesion interpreted as a mesenteric mass. In both cases, the exact origin of the lesion could not be definitively established preoperatively. After multidisciplinary evaluation, laparotomy was performed to obtain diagnostic clarity and exclude malignancy. Intraoperative exploration demonstrated a large cystic mass arising from the left ovary and extending from the pelvis toward the upper abdomen. Due to the potential risk of gynecologic malignancy, the gynecologic oncology team was invited intraoperatively, and the procedure continued in a multidisciplinary setting. To reduce the risk of cyst rupture and chemical peritonitis, aspiration was avoided, and the mass was removed with preservation of capsular integrity. Left salpingo-oophorectomy was performed in both patients. Frozen-section analysis indicated a benign lesion, and final histopathology confirmed mature cystic teratoma without malignant or immature components. Postoperative recovery was uneventful.

Conclusion: Giant mature cystic teratomas, despite their benign nature, may mimic mesenteric cysts when presenting as intraabdominal masses and complicate preoperative diagnosis. Multidisciplinary assessment, careful surgical planning, and intact resection are essential for safe management. Ovarian mature cystic teratoma should be considered in the differential diagnosis of large intraabdominal cystic masses in general surgical practice.

Retroperitoneally located epidermoid cyst: A rare case report

Erdi Aydın[1], Surat Khalıqzade[2], Muhammed Emin Birgün[2], Müjdat Turan[2], Şevket Barış Morkavuk[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Primary cystic lesions arising in the retroperitoneal space independent of retroperitoneal organs are extremely rare and have been reported in limited numbers in the literature. Most of these cysts originate from congenital ectodermal remnants and are classified as epidermoid cysts. The incidence of retroperitoneal epidermoid cysts is reported to be less than 1 in 40,000, and they are most commonly located in the presacral region. Localization behind the pancreatic neck or at the root of the mesenteric vessels is considerably rarer. These lesions are usually asymptomatic; however, when symptoms occur, they are generally non-specific and related to the size, location, or complications such as hemorrhage, infection, or rupture. Radiologically, they may be confused with other retroperitoneal cystic lesions, pancreatic cystic tumors, or gynecological masses. Definitive diagnosis is established by histopathological examination.

Material and Methods: A 55-year-old female patient presented with intermittent nausea and abdominal pain for approximately 4-5 months. There were no specific aggravating or relieving factors. She had no known comorbidities, previous abdominal surgery, trauma, or history of pancreatitis. Physical examination revealed minimal tenderness in the left upper quadrant and epigastric region. Abdominal ultrasonography demonstrated a 9×5 cm multiloculated cystic mass located in the retroperitoneum. Contrast-enhanced computed tomography revealed a 57×43 mm cystic lesion extending from the pancreatic tail region toward the posterior aspect of the aorta, along with an adjacent 50×35 mm bilobulated cystic lesion. Endoscopic ultrasonography (EUS) showed a 6 cm cystic lesion adjacent to the pancreas without any solid component. The pancreatic duct was not dilated, and the pancreatic parenchyma appeared normal. Surgical excision was planned with a preliminary diagnosis of a retroperitoneal cyst.

Results: Total excision of the cyst was achieved using blunt and sharp dissection techniques. No invasive relationship with the pancreas or major vascular structures was observed intraoperatively. The postoperative course was uneventful, and the patient was discharged on postoperative day six without complications. Histopathological examination revealed a cyst wall lined by stratified squamous epithelium, with the lumen filled with keratinized material and cellular debris, accompanied by chronic inflammatory findings. These features were consistent with an epidermoid cyst.

Conclusion: Retroperitoneal epidermoid cysts are rare benign lesions that may be confused with other retroperitoneal cystic masses in the preoperative period. Imaging modalities have limited specificity. Definitive diagnosis relies on histopathological evaluation. Total surgical excision remains the most appropriate approach for both diagnosis and treatment.

Keywords: Retroperitoneal epidermoid cyst, retroperitoneal cystic mass, surgical excision

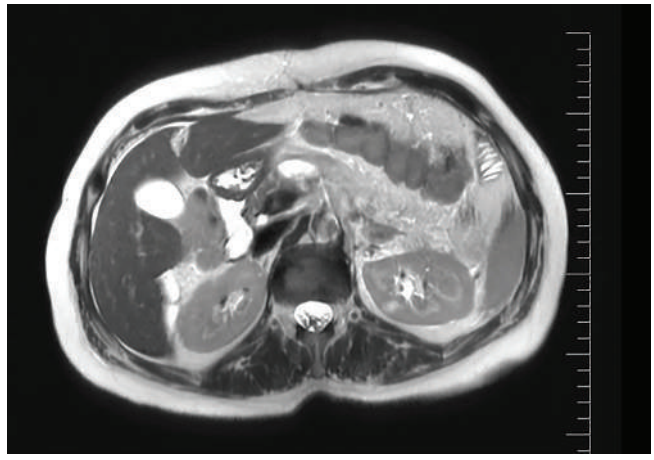

Figure 1. Magnetic resonance imaging sections. A 24×8 mm fluid-density area is present anterior to the head of the pancreas. In the tail region, a 5×3 cm fluid collection, considered secondary to prior surgery, is observed.

Management of a secondary perirectal abscess associated with rectal adenocarcinoma prior to neoadjuvant therapy: A transrectal internal drainage strategy

İdil İlke Aslan, Sarp Tunalı, Kamil Erözkan, Osman Bozbıyık

Department of General Surgery, Ege University Faculty of Medicine, İzmir

Objective: Tumor-associated perirectal abscess formation in rectal cancer represents a rare but clinically significant complication that may delay neoadjuvant chemoradiotherapy (nCRT) and substantially increase the risk of sepsis. In such cases, opting for transrectal internal drainage rather than conventional external drainage is a crucial strategy, as it preserves oncological principles while minimizing the risk of chronic malignant fistula formation within the radiotherapy field.

Material and Methods: This case manages the clinical management of a 45-year-old female patient with rectal cancer who developed a peritumoral abscess secondary to the rectal tumor.

Results: A 45-year-old female patient presented with diarrhea and abdominal pain. Colonoscopic evaluation revealed a circumferential rectal adenocarcinoma extending from 1-1.5 cm above the anal verge to 8 cm proximally. Staging positron emission tomography-computed tomography (PET-CT) demonstrated a 47×40 mm hypermetabolic, necrotic perirectal collection adjacent to the tumor on the right lateral aspect of the rectum. As total neoadjuvant therapy (TNT) was planned, surgical intervention was undertaken to eradicate the infectious focus prior to oncological treatment. Under lithotomy position, examination using an anal retractor identified a fluctuant area at the 9 o'clock position, approximately 5 cm proximal to the anal verge, corresponding to the tumor level. A cruciate intraluminal rectal incision was performed to achieve internal drainage, resulting in evacuation of approximately 50 cc of purulent material. The abscess cavity was thoroughly irrigated with normal saline, and a drain was placed into the rectal lumen. Postoperatively, the patient was closely monitored. On postoperative day 3, a marked reduction in inflammatory markers (CRP and WBC) was observed, allowing safe drain removal and discharge. Following successful control of the infection, the patient proceeded to the planned nCRT regimen.

Conclusion: Transrectal internal drainage for tumor-associated perirectal abscesses offers high clinical efficacy by enabling rapid infection control, early normalization of inflammatory parameters, and timely initiation of TNT. By avoiding the creation of an external cutaneous opening, this approach eliminates the risks of radiation-induced dermatitis and chronic malignant fistula formation during radiotherapy, thereby serving as a safe and effective bridge to nCRT. In conclusion, transrectal internal drainage of perirectal abscesses adjacent to low rectal tumors represents a reliable surgical option with low morbidity that prevents delays in oncological management.

Colon fistulization as a complication of ventriculo-peritoneal shunt: A rare case report and literature review

Zeynep Nur Yurdakul[1], Sabiha Nur Özmen[2], Mehmet Sefa Çamöz[1], Gözde İğdeci Tut[1], Behzat Fatih Demirci[1], Hüseyin Fahri Martlı[1]

[1]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

[2]*Amasya University Sabuncuoğlu Şerefeddin Training and Research Hospital, Amasya*

Objective: Ventriculoperitoneal (V-P) shunting is considered one of the gold standard surgical methods in the treatment of hydrocephalus. Although complications such as infection, mechanical obstruction, and dysfunction are frequently reported in the literature, migration of the catheter into the gastrointestinal system and subsequent colon perforation are among the extremely rare but serious complications. In this report, we present a case where a V-P shunt fistulized into the rectal lumen following a sigmoid colon perforation.

Material and Methods: A 19-year-old male patient with a known history of meningomyelocele and spina bifida had previously undergone V-P shunt placement for hydrocephalus. His first shunt revision was performed in 2022 due to dysfunction. In 2024, the patient presented with the complaint of a foreign object emerging from the rectal area during defecation. Physical examination and laboratory parameters revealed no signs of acute abdomen. Computed tomography (CT) imaging identified that the shunt catheter had penetrated the sigmoid colon wall and terminated within the rectal lumen.

Results: During emergency surgical exploration, the shunt, which was found free on the anterior surface of the rectum and posterior to the bladder, was removed. In a concurrent evaluation with the neurosurgery team, the shunt identified under the fascia was tracked; it was confirmed to be fistulized to the sigmoid colon and was exteriorized via blunt dissection. The perforation site was repaired with primary sutures and covered with a small bowel mesenteric flap. The existing shunt system was converted to an external ventricular drain. Postoperatively, the patient remained clinically stable and followed a complication-free course under appropriate antibiotic therapy with cerebrospinal fluid penetration.

Conclusion: Complications of V-P shunts associated with colon perforation are exceedingly rare, accounting for 0.01-0.07% of all V-P shunt complications. The literature indicates that these complications typically manifest in the late period and may remain asymptomatic in some cases; therefore, early diagnosis is of critical importance. Successful outcomes can be achieved through surgical repair and appropriate antibiotic therapy. This case report highlights a rare but clinically significant dimension of V-P shunt complications.

Ileocecal intussusception secondary to appendiceal mucocele: A minimally invasive surgical approach

Meliha Ülkü Güzel, Eylem İlayda Doğan, Necla Reyhanlı, Erdal Karagülle

University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Intussusception is a rare clinical entity in adults, accounting for approximately 5% of all cases. Unlike pediatric cases, adult intussusception is usually secondary to an underlying organic pathology, most commonly neoplasms. Ileocecal intussusception caused by appendiceal mucocele is particularly uncommon. In this report, we present the laparoscopic management of ileocecal intussusception secondary to an appendiceal mucocele.

Material and Methods: Laparoscopic exploration revealed a mass lesion of the appendix causing ileocecal intussusception. Given the extension of the lesion to the appendiceal base and suspicion of malignancy, a laparoscopic right hemicolectomy with total mesocolic excision was performed to avoid the risk of reoperation. The ileocolic side-to-side anastomosis was constructed extracorporeally. The postoperative course was uneventful, and the patient was discharged on postoperative day five. Final histopathological examination confirmed appendiceal mucocele without evidence of malignancy. In the literature, this rare condition is most commonly managed by open surgical approaches.

Results: A 36-year-old female presented with a 2-3-day history of right lower quadrant abdominal pain, nausea, and loss of appetite. She had no vomiting and maintained active bowel movements and flatus passage. Physical examination revealed tenderness in the right lower quadrant. Laboratory findings showed no leukocytosis, while C-reactive protein was mildly elevated. Contrast-enhanced abdominal computed tomography demonstrated an approximately 6 cm invaginated segment in the ileocecal region. As there were no signs of peritonitis at admission, initial conservative observation was undertaken. However, due to the development of rebound tenderness, an increase in acute phase reactants, and persistent intussusception on follow-up imaging, surgical intervention was indicated.

Conclusion: Although rare, ileocecal intussusception in adults is frequently associated with an underlying organic lesion. Appendiceal mucocele should be considered in the differential diagnosis. In selected patients, laparoscopic management is a safe and effective alternative, providing the advantages of minimally invasive surgery.

Keywords: Intussusception, appendiceal mucocele, minimally invasive surgery

Rapidly growing inverted follicular keratosis in the anal region: A rare localization - case report

Vedat Kaplan[1], İsmail Bengisu[2]

[1]*Şanlıurfa Training and Research Hospital, Şanlıurfa*

[2]*Harran University Faculty of Medicine Hospital, Şanlıurfa*

Objective: Anal region lesions are most commonly benign in nature, and pathologies such as hemorrhoids, fibroepithelial polyps, and condyloma are usually considered in the differential diagnosis. However, lesions demonstrating rapid growth and atypical exophytic macroscopic features may raise suspicion for malignant or premalignant processes. Inverted follicular keratosis (IFK) is a benign epidermal proliferation showing squamous differentiation, typically observed on the face and scalp. Anal localization is extremely rare and may clinically mimic squamous cell carcinoma.

Material and Methods: A detailed medical history and physical examination were performed in a patient presenting with a rapidly growing anal lesion. There was no history of suspicious sexual contact. No family history of dermatological disease was reported. Due to the rapid growth and atypical appearance of the lesion, total excision under local anesthesia was planned. The lesion was excised with clear surgical margins and sent for histopathological examination.

Results: A 34-year-old male patient presented with an anal mass that had been present for approximately one month and had shown significant growth in recent weeks. Physical examination revealed an exophytic lesion approximately 1 cm in diameter, located adjacent to the anal verge, with a grape-like appearance. Macroscopic examination described a 2×1.5×0.5 cm polypoid excision specimen covered with mucosa. Microscopic evaluation demonstrated parakeratosis on the surface and an endophytic growth pattern of squamous cell proliferation extending from the epidermis into the dermis. The lesion was noted to extend to the surgical base margin. Immunohistochemical analysis showed focal weak p16 positivity and basal cell staining with Ki-67. The findings were reported as consistent with IFK.

Conclusion: Although malignancy is often suspected in rapidly growing exophytic anal lesions, rare benign entities should also be considered in the differential diagnosis. Anal localization of IFK is extremely uncommon and may clinically mimic malignant lesions. Therefore, excisional biopsy provides both diagnostic and therapeutic benefit. In our case, due to involvement at the surgical base margin, close clinical follow-up was recommended.

Keywords: Inverted follicular keratosis, anal lesion, excisional biopsy

What can we do if we cannot repair peritoneal defects? Case presentation: A patient who underwent bilateral TEP and laparoscopic cholecystectomy

Ramazan Onuş, Gizem Nur Sucu, Engin Ölçücüoğlu

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: In TEP and TAPP inguinal hernia repairs, peritoneal opening is common. When using standard prolene mesh, the defect must be closed to prevent mesh-bowel contact. Various closure methods have been described depending on defect size and surgeon preference (energy sealing, suturing, clipping). In recurrent hernias, the peritoneal defect may be large and standard techniques may be insufficient. This study presents a patient undergoing elective surgery for bilateral inguinal hernia (right recurrence) and symptomatic gallstones.

Material and Methods: The patient's data was reviewed from digital records and surgical images were used.

Results: The patient had no abdominal surgery other than a previous open right inguinal hernia repair. A subumbilical incision was made, and the preperitoneal space was created for TEP. Before dissection, a large rightsided peritoneal defect caused by adhesions was identified. The direct and indirect hernia sacs were reduced. Closure of the defect was evaluated but deemed unfeasible due to its size and tissue fragility, so intraperitoneal assessment was performed. Leftsided hernia sacs were dissected, and a prolene patch was placed. The subumbilical port was advanced intraperitoneally. Because the peritoneal opening could not be closed with standard techniques, it was left open, and a composite mesh was positioned in the preperitoneal space. The patient was placed in reverse Trendelenburg, and laparoscopic cholecystectomy was completed without complications. Mesh position was confirmed, pneumoperitoneum was ended, and the 120 minutes procedure concluded uneventfully. At one year followup, the patient had no complaints or recurrence.

Conclusion: We were unable to close the uncontrolled peritoneal defect using the described techniques, forcing us to seek an alternative approach. We opted for repair using a composite patch, known not to cause problems when in contact with intra-abdominal organs. The fact that the affected side had previously undergone repair using an open surgical technique influenced our decision. On the other hand, the patient's second surgery had not yet been performed. We concluded the case in this manner due to the absence of acute cholecystitis and the lack of complicated gallbladder surgery. In the event of complicated gallbladder surgery, we might have reconsidered our decision during the operation due to the risk of infection of the patch. Such challenging situations may arise due to patient- or operator-related reasons. To determine whether this approach can be safely used when it is not possible to close the peritoneal defect, multiple case series are required.

Keywords: Inguinal hernia, minimally invasive surgery

Use of a probe (PTeye) in minimally invasive parathyroidectomy: A case report

Celallet Bedirhan Özçağdavul, Sunguralp Farsak, Serdar Ünlü, İlker Kızıloğlu, Bayram Çolak

Department of General Surgery, İzmir Bakırçay University Faculty of Medicine, İzmir

Objective: Hyperparathyroidism is a condition characterized by excessive secretion of parathyroid hormone (PTH) by the parathyroid glands. The most common cause is primary hyperparathyroidism, and approximately 80-85% of these cases are due to a parathyroid adenoma. Surgery remains the gold standard treatment. Parathyroid detectors refer to devices and techniques used intraoperatively during thyroid and parathyroid surgery to identify and preserve parathyroid glands or to localize parathyroid adenomas when present. Rather than a single device, various systems based on different technologies are currently available for this purpose.In this study, we aimed to present a case in which PTeye autofluorescence technology was used during minimally invasive parathyroidectomy, representing a novel application method that, to our knowledge, has not yet been reported in the literature.

Material and Methods: A 50-year-old male patient with no known comorbidities presented with a three-month history of muscle pain and fatigue. Laboratory investigations revealed elevated serum calcium (10.9 mg/dL) and PTH levels (150 pg/mL). Neck ultrasonography and parathyroid scintigraphy demonstrated a lesion consistent with a parathyroid adenoma located adjacent to the inferior pole of the right thyroid lobe. The patient was informed about the procedure, and written informed consent was obtained.

Results: Preoperatively, the planned skin incision of approximately 1.5 cm was marked under ultrasonographic guidance corresponding to the adenoma localization. Reference measurements were obtained using PTeye before reaching the parathyroid tissue. With the assistance of PTeye, the parathyroid adenoma located at the right inferior pole was identified. Measurements confirmed the tissue to be parathyroid in origin, and parathyroidectomy was performed. The operative time was approximately 35 minutes. Intraoperative rapid PTH (quick PTH) measurement showed a decrease to 87.6 pg/mL, confirming successful excision of the adenoma.

Conclusion: Minimally invasive techniques are increasingly preferred in parathyroid surgery. The PTeye system, a next-generation parathyroid detector, may facilitate minimally invasive parathyroidectomy by enabling quicker and more reliable identification of parathyroid tissue while also providing superior cosmetic outcomes.

Keywords: Minimally invasive surgery, parathyroid adenoma, PTeye

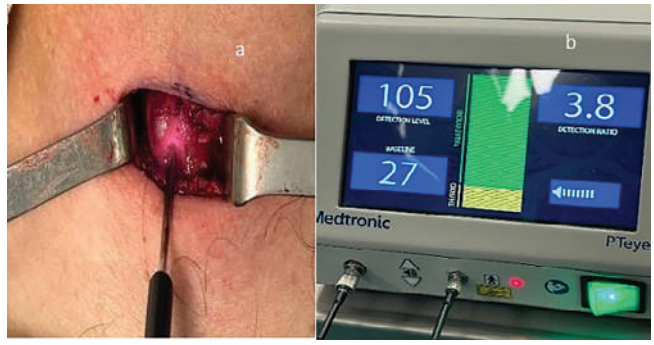

Figure 1. Intraoperative use of PTeye. Use in PTeye and real-time monitoring of adenoma detection.

[P-557]

A silent neuroendocrine tumor: A case of pancreatic somatostatinoma detected at an early stage

Muhammed Metin Yüksel, Mehmet Hanifi Çanakçı, Deniz Kütük, Serkan Demir, Muhammed Salih Süer, Mustafa Özsoy

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Somatostatinoma is a rare pancreatic neuroendocrine tumor (NET) that often presents with non-specific clinical symptoms, frequently leading to delayed diagnosis. Although a classic triad of diabetes mellitus, steatorrhea, and cholelithiasis has been described in functional cases, these findings may not coexist in every patient. This report aims to present the clinical course, preoperative evaluation, surgical treatment, and pathological findings of a histopathologically confirmed somatostatinoma located in the pancreatic head, treated at the Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital.

Material and Methods: The case of a patient diagnosed with somatostatinoma and operated on at University of Health Sciences Türkiye, Ankara Etlik City Hospital was evaluated retrospectively. Demographic data, presenting symptoms, functional findings, laboratory values, imaging modalities, preoperative localization success, surgical approach, operative time, postoperative complications, length of stay, and histopathological parameters (tumor diameter, localization, WHO NET grade, Ki-67 proliferation index, surgical margin status, and presence of metastasis) were examined.

Results: A 47-year-old female (BMI: 21 kg/m^2, ASA 2) presented with abdominal pain for six months. Functional evaluation revealed achlorhydria without steatorrhea, diabetes, or cholelithiasis. Fasting glucose was 121 mg/dL, and serum somatostatin was 233 pg/mL. Contrast-enhanced CT and MRI localized an 11 mm tumor in the pancreatic head without distant metastasis. The patient underwent robotic pancreaticoduodenectomy (operative time: 360 min). No postoperative complications or fistulas occurred (Clavien-Dindo 1); the hospital stay was 10 days with complete symptomatic resolution. Histopathology confirmed a WHO Grade G1 NET (Ki-67: 2%) with R0 resection. No recurrence or mortality was noted at 1 month follow-up.

Conclusion: Somatostatinoma is prone to diagnostic delay due to its rarity and non-specific presentation, with many cases reaching advanced stages and limiting curative options. This case highlights that early-stage (11 mm) pancreatic somatostatinomas carry curative potential when surgically resected. While the surgical approach depends on tumor location (e.g., pancreaticoduodenectomy for head lesions, distal pancreatectomy for distal ones), the primary goals are accurate staging to exclude metastasis and achieving R0 resection. In this case, the combination of low-grade histology (G1), low Ki-67 (2%), absence of metastasis, and R0 status provides strong pathological indicators for a favorable prognosis. In conclusion, somatostatinoma should be considered in the differential diagnosis; early diagnosis and appropriate surgical strategies can yield successful oncological outcomes in selected cases.

Emergency spleen-preserving distal pancreatectomy for traumatic distal pancreatic transection after blunt abdominal trauma: A case report

Metin Yalçın, Murad Ahmadzada, Kadir Serkan Türel, Mehmet Aksoy, Kemal Eyvaz, Arif Aslaner

Department of General Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Pancreatic injuries, although rare in blunt abdominal trauma due to their retroperitoneal location, are high-morbidity clinical conditions presenting significant challenges in diagnosis and treatment. Surgical treatment is often unavoidable, particularly in distal pancreatic injuries affecting the main pancreatic duct. However, with appropriate patient selection, spleen-sparing surgical approaches are important for preserving immune function in young patients. This case report presents a patient who underwent emergency spleen-sparing distal pancreatectomy due to distal pancreatic detachment following a heavy fall.

Material and Methods: Case report: A 24-year-old male patient was referred to our emergency department from an external center after a heavy block fell on him at a construction site.

Results: The patient was conscious and had stable vital signs upon admission. Physical examination revealed tenderness and rebound tenderness in the right quadrant of the abdomen. Laboratory investigations showed significantly elevated amylase and lipase levels. Contrast-enhanced abdominal computed tomography scans performed at other centers and our hospital showed free fluid in the pelvis, but pancreatic injury was not initially reported. Due to continued clinical suspicion, the images were re-evaluated by a radiology specialist, revealing a near-complete laceration in the distal pancreas. The patient underwent emergency laparotomy, and exploration revealed approximately three-quarters separation of the distal pancreas. Splenic-sparing distal pancreatectomy and Wirsung duct repair were performed, preserving the splenic vessels and spleen. In the postoperative period, the patient required intensive care monitoring, developed a pancreatic collection, underwent drainage by interventional radiology, and performed endoscopic retrograde cholangiopancreatography due to ongoing pancreatitis. The patient was discharged after clinical improvement and underwent elective surgery for incisional hernia during long-term follow-up.

Conclusion: In pancreatic injuries due to blunt abdominal trauma, diagnosis may be delayed, and computed tomography may not always be sufficient. With high clinical suspicion, early surgical decision, and appropriate patient selection, spleen-sparing distal pancreatectomy can be a safe and effective treatment option for distal pancreatic injuries.

Keywords: Pancreatic trauma, distal pancreatectomy, spleen-sparing surgery, blunt abdominal trauma

An unusual adhesion-related ileus at the right inferolateral border of the liver: A case report

Hasan Kumru, Gültekin Hoş, Süleyman Ümit Emanet, Aylin Acar, Tolga Canbak

Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul

Objective: Adhesive small bowel obstruction (SBO) accounts for approximately 60-70% of all mechanical SBOs and is most commonly caused by pelvic or mesenteric adhesions. Perihepatic adhesions leading to mechanical ileus are extremely rare, with a reported incidence of less than 1%. Mechanical obstruction caused by fibrotic bands originating from the inferolateral surface of the liver has been described only in a limited number of cases in the literature. This case report aims to present a rare cause of SBO resulting from a fibrotic band arising from the right inferolateral border of the liver.

Material and Methods: A patient presenting with acute ileus was retrospectively evaluated in terms of clinical presentation, laboratory findings, radiological imaging, intraoperative findings, and postoperative course. Diagnostic evaluation included contrast-enhanced computed tomography (CT) and serial upright abdominal radiographs. Following failure of conservative management, surgical exploration was performed. Operative findings and clinical outcomes were analyzed.

Results: A 34-year-old female patient with no known comorbidities had previously undergone emergency laparotomy for acute abdomen following cesarean section in 2023, during which right hemicolectomy with ileocolic anastomosis was performed due to severe colonic dilatation and torsion at the hepatic flexure. Six-teen months later, she was admitted with abdominal distension and tenderness consistent with mechanical ileus. Laboratory parameters showed no evidence of bowel ischemia. Contrast-enhanced CT demonstrated marked dilatation of proximal small bowel loops with normal-caliber distal segments, supporting the diagnosis of mechanical obstruction. Serial upright abdominal radiographs revealed multiple air-fluid levels. As conservative management failed, surgical intervention was undertaken. During median laparotomy, dense intra-abdominal adhesions were dissected. Exploration revealed a thin, fibrotic band approximately 1 cm in length originating from the right inferolateral border of the liver and extending to the small bowel mesentery, causing mechanical obstruction approximately 100 cm distal to the ligament of Treitz. Proximal bowel loops were dilated, distal segments were normal, and bowel viability was preserved. The fibrotic band was divided, and bridotomy was performed without the need for bowel resection.

Conclusion: Mechanical SBO caused by fibrotic bands originating from the right inferolateral border of the liver is an exceptionally rare entity and may be difficult to diagnose preoperatively. Atypical perihepatic adhesions may not produce a clear transition zone on imaging studies. Therefore, perihepatic bands should be considered in patients with SBO who fail conservative treatment. Surgical bridotomy is a safe and effective approach that can result in rapid clinical recovery, as demonstrated in this case.

Keywords: Perihepatic adhesion, bridotomy, mechanical small bowel obstruction, explorative laparotomy, adhesion

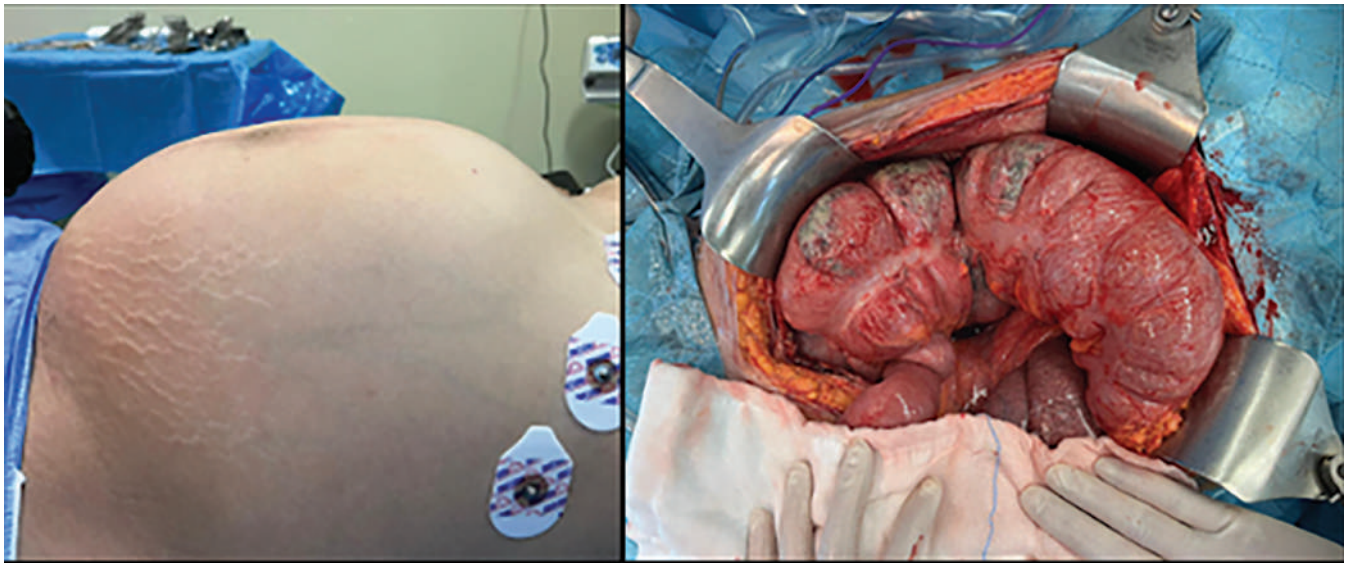

Figure 1. Abdomen before and after emergency laparotomy.

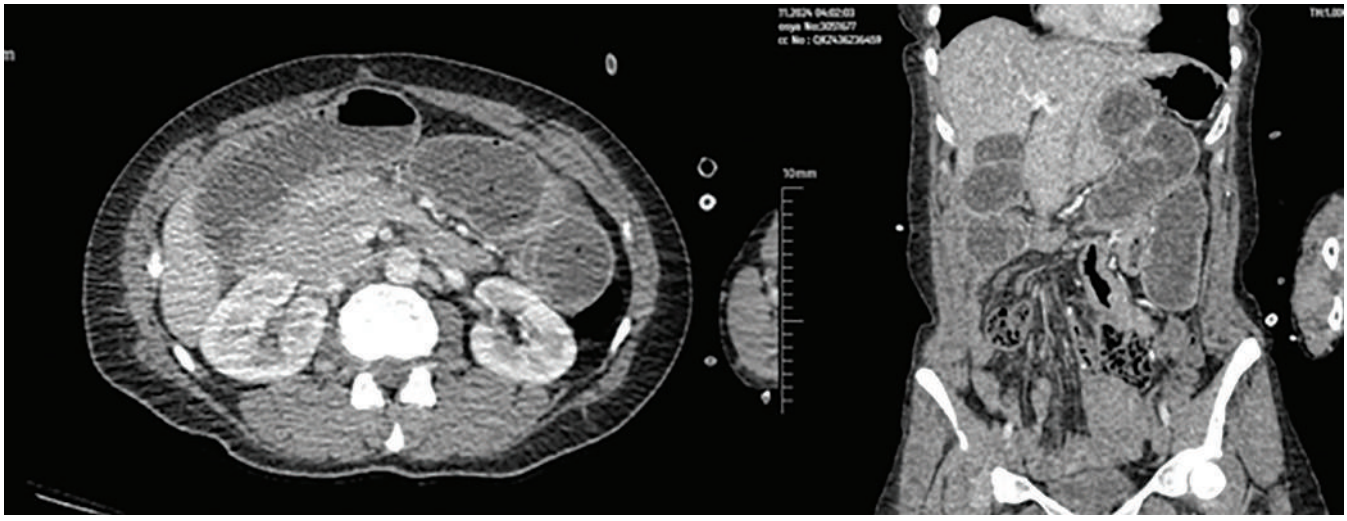

Figure 2. Preoperative contrast-enhanced CT image.

Marked dilatation of the proximal small bowel loops was observed, while the distal segments were of normal caliber, favoring a mechanical obstruction.

CT: Computed tomography.

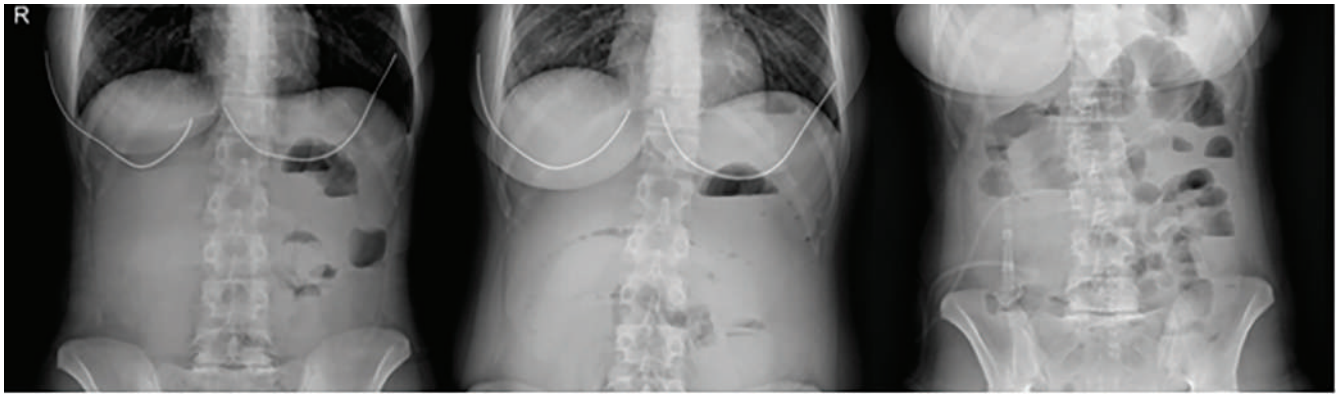

Figure 3. Upright abdominal radiograph series.

The presence of prominent air-fluid levels on serial upright abdominal radiographs supported the diagnosis of mechanical ileus.

Figure 4. Intraoperative brid images.

Approximately 100 cm distal to the ligament of Treitz, a thin fibrotic band measuring about 1 cm in length originating from the right inferolateral border of the liver was identified, extending to the small bowel mesentery and causing mechanical obstruction; proximal bowel loops were dilated, distal segments were normal, bowel viability was preserved, and the band was divided by bridotomy without additional pathology.

[P-560]

Atypical presentation and emergency surgical management of spontaneous hepatic rupture in amyloidosis: A case report

Yunus Yüksel, Murat Hatip, Ebubekir Gündeş

Diyarbakır Gazi Yaşargil Training and Research Hospital, Diyarbakır

Objective: Systemic amyloidosis is a rare disease characterized by extracellular amyloid fibril deposition. While hepatic involvement is generally asymptomatic, amyloid infiltration increases liver parenchyma and vascular fragility, predisposing patients to spontaneous hepatic rupture a rare but fatal complication. This report presents a patient with amyloidosis who underwent emergency surgery for spontaneous hepatic rupture and hemorrhagic shock triggered by severe coughing fits.

Material and Methods: A 60-year-old male with systemic amyloidosis presented to the emergency department with nausea, vomiting, and dizziness. His history included intermittent liver function test elevations, non-nephrotic proteinuria, and chronic kidney disease. Notably, he reported severe coughing for the past week. Initially hypotensive, he received intravenous fluids, achieved hemodynamic stability, and was discharged. Hours later, he returned with a deteriorating condition, confusion, tachycardia, and a blood pressure of 70/40 mmHg. Laboratory tests revealed a hemoglobin level of 5.1 g/dL. Due to hemodynamic instability and acute abdomen, a non-contrast abdominal CT was performed, showing hemorrhagic free fluid in the subhepatic, perihepatic, and right paracolic regions. The patient was taken for emergency laparotomy. Approximately 1000 cc of hemorrhagic fluid was aspirated. A massive rupture with active bleeding was observed in the right liver lobe. Because the amyloid-infiltrated liver tissue was extremely fragile, making primary suturing impossible, perihepatic packing was applied for hemorrhage control. After receiving 3 units of packed red blood cells, the abdomen was closed, and the intubated patient was transferred to the ICU.

Results: Spontaneous hepatic rupture in systemic amyloidosis is rare but carries a high acute-phase mortality rate (30-70%). Amyloid fibril accumulation impairs vascular elasticity, causing extreme fragility. In our case, the sudden intra-abdominal pressure increase from a week of severe coughing fits created mechanical stress on the fragile liver and Glisson's capsule, triggering the rupture. The patient's initial presentation with non-specific symptoms and fluid-responsive transient hypotension demonstrates how amyloidosis-related bleeding can be insidious. While transarterial embolization is the first-line treatment for hemodynamically stable patients, emergency laparotomy is life-saving for those presenting with hemorrhagic shock. Because amyloid-infiltrated liver tissue cannot hold sutures, perihepatic packing—as successfully applied here—is the safest and most effective surgical maneuver to achieve hemostasis, avoiding the risks of primary suturing or resection.

Conclusion: In patients with known amyloidosis or unexplained hepatomegaly, spontaneous hepatic rupture must be considered if sudden hypotension and anemia develop following Valsalva-like maneuvers. In hemodynamically unstable patients, prompt laparotomy and perihepatic packing are life-saving.

Keywords: Spontaneous hepatic rupture, amyloidosis, packing

A rare cause of anal polypoid lesion: Perianal hidradenoma papilliferum

Burcu Çanakçı, Ahmet Batuhan Oruç, Ramazan Kubilay Tekcan, Mehmet Uluşahin, Mehmet Arif Usta

Department of General Surgery, Karadeniz Technical University Faculty of Medicine, Trabzon

Objective: Hidradenoma papilliferum is a rare benign tumor which is thought to originate from apocrine glands or anogenital mammary-like glands. It is most commonly seen in middle-aged women and usually located in the vulvar and perianal regions. Clinically, it generally presents as a slow-growing, well-circumscribed solitary nodule and may be confused with hemorrhoids, anal polyps, or other benign anal lesions. Malignant transformation is extremely rare; however, definitive diagnosis can only be made by histopathological examination. In this study, we aimed to present a rare case of hidradenoma papilliferum located in the perianal region.

Material and Methods: A 42-year-old female patient presented with a complaint of a swelling in the anal region for approximately 3-4 years. The patient reported intermittent bleeding and pain from time to time. On physical examination of the anal region, a polypoid lesion originating from the anal verge was observed. No additional pathology was detected. Rectosigmoidoscopy revealed no abnormal findings. Surgical excision of the anal polypoid lesion was planned. In the operating room, the lesion was totally excised under spinal anesthesia (Figures 1, 2).

Results: The patient was discharged uneventfully on the postoperative first day. No complications or recurrence were observed during follow-up. Histopathological examination of the excised specimen was reported as hidradenoma papilliferum. The macroscopic and clinical appearance of the lesion was similar to other benign anal tumors, and a specific preoperative diagnosis could not be established. Consistent with the literature, the definitive diagnosis was achieved after surgical excision and histopathological evaluation.

Conclusion: Hidradenoma papilliferum is a rare benign anogenital tumor most commonly observed in the vulvar and perianal regions. Since it may clinically mimic hemorrhoids and other benign anal lesions, it should be considered in the differential diagnosis of benign anal masses. Complete surgical excision is sufficient for both diagnosis and treatment, and the prognosis is generally favorable. Proctologists should keep hidradenoma papilliferum in mind during the evaluation of benign anal lesions.

Keywords: Hidradenoma papilliferum, perianal polyp, benign anal tumor

Ulcerative giant breast cancer: Case report

Erdi Aydın[1], Şevket Barış Morkavuk[1], Meltem Hızal[2], Çılga Ecem Lamba[2], Müjdat Turan[2], Gökhan Giray Akgül[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Large, ulcerated breast lesions are a rare and bothersome consequence of advanced breast cancer. The most significant factors in the etiology include patient denial of the illness, delayed diagnosis, psychological distress, low socioeconomic status, social isolation, and male gender. This means the condition can be seen not only in developing countries but also in developed ones.

Material and Methods: Patients typically present to healthcare facilities with complaints of uncontrolled bleeding, recurrent infections, chronic pain, aesthetic concerns, and, most importantly, foul odor. In this case report, we aim to present a breast cancer patient with a locally advanced, giant ulcerated wound, along with a review of the literature.

Results: A 42-year-old female patient presented to our clinic with complaints of discharge and bleeding from her left breast. Her medical history revealed no prior examination or imaging studies related to breast diseases. Physical examination revealed an ulcerated lesion approximately 15x20 cm in size, covered with fibrin, with occasional purulent discharge and bleeding in the left breast. A tru-cut biopsy was performed for pathological diagnosis. The pathology result was consistent with isolated Her2^{+} invasive ductal cancer, and a screening for distant organ metastases was performed. Lung and femur metastases were detected, and a multidisciplinary council decided on mastectomy due to the patient's uncontrollable bleeding and infection. The patient underwent salvage mastectomy with axillary sampling. The pathology report showed negative hormone levels, positive Her2^{+}, and a Ki67 index of 40%. The patient experienced no complications during postoperative follow-up and was discharged with oncology recommendations.

Conclusion: Patients with ulcerative tumors constitute a particularly challenging group due to the complexities in managing tumor-related symptoms such as pain, exudative discharge, foul odor, bleeding, infections, and aesthetic concerns. Individuals with ulcerative breast tumors experience a significant impairment in quality of life. This may be due to delays and disruptions in the healthcare system, but it can also be primarily attributed to psychological reluctance to accept their condition, advanced age, and male gender. Currently, there is no standard treatment approach for this patient group. Therefore, discussing optimal management within a multidisciplinary team is crucial. The primary approach in patient management is usually surgical intervention, total or modified radical mastectomy, or palliative procedures aimed at reducing tumor thickness.

Keywords: Ulcerative, breast cancer

Isolated heel pressure injury following peripheral arterial bypass surgery: A case report

Emine Acar[1], Zeliha Aydın[1], Tuğçe Gizem Coşgun[1], Canan Bulut Ayaz[1], Ali Cihat Yıldırım[2]

[1]*Kütahya City Hospital Chronic Wound Unit, Kütahya*

[2]*Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya*

Objective: Pressure injuries are difficult clinical problems to heal, especially in the elderly and in the presence of diabetes mellitus (DM). Microvascular disorders associated with DM, peripheral neuropathy, and the risk of infection negatively affect wound healing. The heel region is one of the high-risk areas due to bone protrusions and constant exposure to pressure.

Material and Methods: This case report aims to evaluate the effectiveness of current wound care methods and position changes on wound healing in the treatment of a pressure ulcer that developed on the heel of a patient with DM who underwent bypass surgery.

Results: A 69-year-old male patient with a history of hypertension, DM, and right femoropopliteal bypass graft presented to the Chronic Wound Care Clinic with a 4*5 cm unstaged stage 2 pressure ulcer in the right heel area. The wound margin was dry, and calluses were present on both heels. The patient was on insulin and smoked. He stated that he had undergone bypass surgery one month prior and presented to us with a complaint of a non-healing wound on his right heel due to immobility during the postoperative period. The patient's blood glucose level was 319 mg/dL, and HbA1C level was 7%. The wound was primarily treated with an autolytic debridement product and surgical debridement procedures, and necrotic tissue was removed from the wound. A barrier cream was applied to the dry edges of the wound. After preparing the wound bed, a topical growth factor was used to promote granulation and epithelialization. During this process, regular position changes were implemented to protect the foot from pressure, and metabolic control was ensured by monitoring blood glucose levels, which positively supported the healing process. The patient's wound healed in approximately 4 months under outpatient conditions; the patient and their family were informed about protective measures and foot care to prevent the recurrence of pressure injuries.

Conclusion: The combined use of autolytic debridement and topical growth factor is an effective approach in the treatment of heel pressure injuries in elderly patients with DM. Comprehensive treatment focused on wound bed preparation accelerated the healing process and prevented the development of complications. This combined approach can be considered a viable treatment option in similar patient groups. Applications focused on pressure protection, especially in high-risk patient groups, play a key role in reducing morbidity by preventing the development of pressure ulcers.

Use of a nanocellulose-based wound dressing in second-degree facial burns: Two case reports

Derya Özcan, Fatma Doğrul, Ömer Cennet

Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara

Objective: Burn injuries are among the traumatic conditions that lead to significant morbidity at both individual and societal levels. The frequent involvement of the head and neck region, along with the critical functional and aesthetic importance of the face, makes the management of burns in this area particularly challenging. Due to the complex anatomical structure of the face, resulting deformities may cause not only physical impairment but also psychosocial problems.

Material and Methods: In this study, the effectiveness of a nanocellulose-based wound dressing was evaluated in two patients with second-degree facial burns.

Results: In both cases, standard wound cleansing and topical antimicrobial therapy were applied in the early period, followed by continued treatment with a nanocellulose-based wound dressing. Granulation tissue formation was observed at an average of six days, and no infection, allergic reaction, or additional complications were detected.

Conclusion: No pathological scar formation was observed during the follow-up period. Our findings suggest that the nanocellulose-based wound dressing is a safe and effective biomaterial that supports tissue healing in facial burns.

Isolated endometrioid adenocarcinoma developing on the abdominal wall on the basis of endometriosis: A case report and current literature review

Mehmet Eşref Ulutaş[1], Ethem Ömeroğlu[2], Muhammed Emin Şahin[3]

[1]*Department of General Surgery, Gaziantep Islamic Science and Technology University, Gaziantep City Hospital, Gaziantep*

[2]*Clinic of Pathology, Konya City Hospital, Konya*

[3]*Clinic of General Surgery, Konya City Hospital, Konya*

Objective: Endometriosis predominantly develops during obstetric and gynecological procedures due to iatrogenic transplantation of endometrial tissue. Malignant transformation in endometriosis is exceedingly rare (0.3-1%). Cases of ectopic endometriosis demonstrating malignant transformation are even rarer.

Material and Methods: In this study, we report such a case and review previous literature. All studies addressing cases of ectopic endometriosis showing malignant transformation reported in the literature to date have been reviewed, and the study has been completed.

Results: This study presents a case of isolated endometrioid adenocarcinoma developing on the anterior abdominal wall on the basis of endometriosis, unrelated to surgical scars. A well-defined, fixed, and firm mass measuring 3-4 cm deep subcutaneously to the right of the umbilicus was identified in a 29-year-old female patient. The mass with a preliminary diagnosis of desmoid tumor was removed en bloc. Pathology result showed endometrioid adenocarcinoma. As a result of further examinations, no other focus was detected in the patient. Similarly, 54 cases were identified in the literature.

Conclusion: It is essential for clinicians to keep in mind that carcinomas may develop on the basis of endometriosis.

Keywords: Endometrioid adenocarcinoma, endometriosis, malignant transformation, abdominal wall

Clinical importance of inhalation injury in burn patients: A case report

Fatma Doğrul, Derya Özcan, Ömer Cennet

Hacettepe University, Ankara

Objective: Inhalation injury is an important clinical condition that describes damage to the respiratory tract and lung parenchyma caused by the inhalation of hot gases, smoke, and toxic chemicals, and it significantly increases morbidity and mortality in burn patients. Particularly when associated with flame burns, early recognition and appropriate management are of vital importance due to the risk of airway edema, impaired gas exchange, and a systemic inflammatory response.

Material and Methods: A 55-year-old male patient with a known history of hypertension and diabetes mellitus presented to the emergency department with flame burns involving the face, neck, anterior trunk, and left hand after being set on fire following the pouring of a flammable substance over him.

Results: The patient, whose total burn surface area was calculated as 12%, was intubated early and admitted to the intensive care unit for close monitoring due to inhalation injury and the development of laryngeal edema. Bronchodilator therapy, systemic corticosteroids, appropriate fluid resuscitation, and anticoagulant prophylaxis were administered. Fluid therapy was arranged according to the Parkland formula, and the patient was closely monitored with hourly urine output and clinical parameters. A multidisciplinary treatment plan was established with the involvement of ophthalmology, otorhinolaryngology, pulmonology, and psychiatry departments. Local wound care included antiseptic cleansing and the use of enzymatic and autolytic debridement methods; no infection developed during follow-up. The patient was successfully extubated after five days of intubation, and pulmonary complications were prevented with respiratory exercises. In the later course of hospitalization, tangential excision and grafting were performed, and the patient was discharged in stable condition.

Conclusion: In conclusion, in burn patients with inhalation injury, early establishment of airway security, controlled fluid resuscitation, effective pulmonary care, and a multidisciplinary approach improve treatment outcomes. This case demonstrates that timely intervention and coordinated clinical management play a critical role in preventing complications.

Keywords: Burn, inhalation injury, airway management

[P-575]

A rare case with pathology reported as giant distal esophageal diverticulum- leiomyoma with a diameter of 15 cm

Sedef Poşul, Önder Altın, Selçuk Kaya, Hasan Fehmi Küçük

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Esophageal diverticula are rare pathologies, most commonly measuring 2-5 cm in diameter. Lesions exceeding 10 cm are defined as giant esophageal diverticula and represent an extremely uncommon clinical entity. Giant diverticula may clinically and radiologically mimic gastric or other intra-abdominal masses, leading to diagnostic challenges. In rare instances, biopsies obtained from the diverticular wall may be interpreted as leiomyoma due to smooth muscle hypertrophy, irregular fasciculation of muscle fibers, and focal muscular thickening. Such findings may result in diagnostic confusion and necessitate careful clinicopathological correlation. In this report, we present a rare case of a 15×15 cm giant distal esophageal diverticulum with pathological findings reported as leiomyoma.

Material and Methods: A 55-year-old male patient with no known comorbidities presented to the emergency department with nausea, vomiting, epigastric discomfort, and inability to tolerate oral intake. Detailed clinical examination, laboratory investigations, radiological imaging, and endoscopic evaluations were performed. The patient's medical history, including previous surgical interventions and pathological reports, was thoroughly reviewed. Based on the overall assessment, a diagnosis of giant distal esophageal diverticulum was established, and the patient was scheduled for surgical treatment.

Results: Physical examination revealed epigastric tenderness. Laboratory tests showed a leukocyte count of 24,000/mm^3 and a CRP level of 22 mg/L. Approximately 2000 cc of dilatation fluid was aspirated via a nasogastric tube. Contrast-enhanced abdominal and pelvic computed tomography demonstrated an extra-gastric pouch-like structure.The patient's history revealed that three years earlier he had undergone emergency Graham patch repair for perforated peptic ulcer. During that operation, a giant intra-abdominal mass was observed and biopsied, and the pathology was reported as leiomyoma. Subsequent gastroscopy revealed a 40-cm-long esophagus and a distal esophageal diverticulum, after which the patient was referred for surgery. Intraoperative exploration demonstrated a giant diverticulum originating from the distal esophagus with a markedly hypertrophic muscular layer measuring approximately 15×15 cm. The diverticulum was excised, and an esophagogastric anastomosis was performed using a circular stapler, followed by pyloroplasty. Postoperatively, the patient tolerated oral intake well and was discharged in good condition.

Conclusion: Giant esophageal diverticula often present with non-specific gastrointestinal symptoms, including nausea, vomiting, early satiety, and intolerance to oral intake. In symptomatic cases, conservative management is usually inadequate. Surgical treatment serves both diagnostic and therapeutic purposes. Therefore, early surgical intervention is essential to relieve symptoms, prevent complications, and improve patient quality of life.

A giant sacrococcygeal chordoma: A case report

Erdi Aydın[1], Şevket Barış Morkavuk[1], Çılga Ecem Lamba[2], Meltem Hızal[2], Gökhan Giray Akgül[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Chordomas are rare, malignant, primary bone tumors with poor prognosis. They only account for 1-4% of all primary bone tumors which are thought to arise from ectopic embryonic notochord remnants along the neuroaxis. Although, not common, chordoma is the most frequent primary malignant neoplasm of the sacrum. It has been reported that the most common sites are the sacrum (40-50%), spheno-occipital area (35-40%), and the vertebral bodies (15%-20%). Although, histologically considered to be a benign neoplasm, chordomas have a malignant potential due to a remarkable recurrence. Anterior invasion to the rectum is uncommon due to presacral fascia.

Material and Methods: In this case report, we aim to present a case of sacral chordoma approximately 25 cm in size, along with a review of the literature.

Results: A 62-year-old male patient presented to our clinic with complaints of tenesmus and constipation. Physical examination revealed no pathological findings. Rectal examination revealed a well-defined mass 4 cm proximal to the anal verge, without disrupting mucosal integrity. Colonoscopy was planned. Colonoscopy showed an external compression image of the rectum extending approximately 10 cm proximally from the dentate line. CT scan revealed a 25x10 cm soft tissue lesion with smooth contours in the presacral area, clearly visible in relation to the rectum. Trucut biopsy was performed, and the result was reported as consistent with "well-differentiated chordoma". The patient underwent surgery in conjunction with neurosurgery. Initial extremity and anal sphincter neuromonitoring was performed. Sacrectomy was performed at the S2 level, the chondroma was excised, and a colostomy was created. Postoperatively, the patient had extremity movement, but no muscle tone was detected on rectal examination. The patient was referred to medical oncology based on the pathology results.

Conclusion: Chordoma is a rare, slow-growing but locally invasive tumor. It accounts for less than 5% of all primary bone neoplasms. Since chordoma is poorly sensitive to chemotherapy and radiotherapy, surgery is the treatment of choice. For the preoperative evaluation, CT scan is necessary to identify the local bony extension and MRI is used to determine the sacrectomy level. It is important to protect the lumbosacral trunks and sciatic nerves as much as possible.

Keywords: Sacrococcygeal chordoma, giant, sacrectomy

Squamous cell carcinoma secondary to pilonidal cyst: A case report

Emin Yılmaz, Gözde İğdeci Tut

Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: Pilonidal sinus (PS) is a disease characterized by recurrent abscess formation and chronic inflammation, usually seen in the sacrococcygeal region.Although rare, recurrent chronic cases may carry a risk of malignant transformation. Squamous cell carcinoma (SCC) may present as a rare but serious complication of PS. This article presents a case of chronic PS with a history of recurrent abscesses, in which SCC was diagnosed.

Material and Methods: A 58-year-old male patient presented to us with painful swelling in the anal region. The medical history revealed a history of recurrent abscesses and drainage due to chronic PS. It was learned that he had had a weeping wound adjacent to the anal opening on his right gluteal region for 2 months. Physical examination revealedextensive granulation tissue and signs of infection in the wound area. Based on clinical evaluation andimaging findings, he underwent surgery with a preliminary diagnosis of Fournier's gangrene. Infected and necrotic tissues were debrided, and a biopsy was taken from the wound area. Pathology results confirmed a diagnosis of SCC. The patient was referred to a plastic surgery council for a multidisciplinary approach. Based on the council's decision, it was decided to administer chemotherapy and radiotherapy after surgical excision.

Results: Patients with chronic PS experience recurrent abscesses and pain. There is no universally accepted classification to determine the severity of pilonidal disease, but factors such as the number, size, and location of the sinuses and the presence of abscesses may influence the treatment approach. Malignant degeneration, a rare but serious complication of PS, may occur in cases that have been neglected for a long time. The average age of patients with SCC described in the literature is 52. Malignant degeneration, a rare but serious complication of PS, may occur in cases that have been neglected for a long time. The literature reports high recurrence rates (39%) and mortality rates in patients diagnosed with SCC. Early diagnosis and aggressive treatment in the presence of SCC can improve survival rates.

Conclusion: Although malignant transformation is a rare complication in patients with PS,this risk should not be overlooked in long-term and recurrent cases. Chronic inflammation andrecurrent infections may play a triggering role in SCC development. Therefore, careful clinical evaluation and histopathological examination are important in long-term follow-ups. A multidisciplinary approach is critical in determining and implementing the optimal treatment strategy for patients diagnosed with SCC. In SCC, the use of radiotherapy in addition to surgery may reduce recurrence ratesand have positive effects on long-term survival.

Spindle cell mesenchymal tumor of the lower extremity: Case report

Kahraman Dinler[1], Şevket Barış Morkavuk[1], Buse İrem Koç[2], Güzin Aygün[2], İbrahim Burak Bahçecioğlu[1], Gökhan Giray Akgül[1], Mehmet Ali Gülçelik[1]

[1]Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

[2]Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

Objective: Soft tissue sarcomas are a heterogeneous group of neoplasms that mostly originate from embryonic mesoderm cells, i.e., connective tissue, muscle, joints, fat, blood vessels, and peripheral nerves. Spindle cell neoplasms originate from mesenchymal cells that make up the body's connective tissue system. These cells include nerve, fibroblast, myofibroblast, epithelial, or vascular tissue.

Material and Methods: Spindle cell sarcomas are generally deep-seated lesions originating from large nerves along the extremity and predominantly exhibiting local recurrence. In this case report, we aim to present a case of a malignant spindle cell mesenchymal tumor of approximately 10 cm located at the femoral-patella junction in the lower extremity, along with a review of the literature.

Results: A 56-year-old female patient presented to our clinic with complaints of a palpable mass and limited range of motion in her left leg. Physical examination revealed a palpable lesion extending from the distal femur to the patella; it was firm, fixed, immobile, but showed movement with joint movement. A CT scan of the extremity showed a soft tissue lesion extending to the patellar tendon, including the distal rectus femoris muscle of the left foot, with a spiculated extension that was not clearly defined by the vastus lateralis muscle. A mesenchymal tumor was suspected, and thoracic and abdominal CT scans were performed to rule out distant organ metastasis. No evidence of metastasis was found, and excision was performed, including the skin and rectus femoris tendon. The pathology report stated "High-grade pleomorphic and spindle cell malignant mesenchymal tumor." The patient was discharged with a postoperative physical therapy and rehabilitation plan and oncology recommendations.

Conclusion: Spindle cell neoplasms encompass a wide spectrum of clinical presentations, ranging from benign lesions to high-grade malignant tumors. These tumors typically originate in connective tissue layers, extending between muscle layers and encircling organs, forming a mass image. In the early stages, they are localized and generally do not spread beyond the encapsulated form. However, they can also develop malignant potential. The incidence of these tumors is three per 3.5 million, with a 2:1 predisposition in women compared to men. The preferred treatment for extremity spindle cell sarcoma is wide local excision, including the biopsy site. Wide local excision involves 1-2 cm of surrounding normal tissue and a narrower margin if there are large, unaffected critical neurovascular structures near the tumor. Postoperative radiotherapy may be supportive.

Keywords: Spindle cell, mesenchymal tumor

Retroperitoneal giant leiomyosarcoma: Case report

Kubilay Kenan Özlük[1], Şevket Barış Morkavuk[1], Mücahit Kaya[2], Nazlıcan Altındağ[2], Müjdat Turan[2], Gökhan Giray Akgül[1], Mehmet Ali Gülçelik[1]

[1]Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

[2]Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

Objective: Soft tissue sarcomas constitute less than 1% of all cancers. They originate from mesenchymal stem cells found in muscle, fat, and connective tissues. Soft tissue sarcomas most commonly develop in the extremities. The incidence in intra-abdominal and retroperitoneal areas is 40%. The most common intra-abdominal and retroperitoneal soft tissue sarcomas are gastrointestinal stromal tumors, leiomyosarcomas (LMS), and liposarcomas. LMS accounts for up to 25% of all newly diagnosed soft tissue sarcomas.

Material and Methods: In this presentation, we aim to present a case of extensive retroperitoneal leiomyosarcoma, along with a review of the literature.

Results: A 69-year-old female patient presented to our clinic with a complaint of a palpable mass in the right inguinal region and lower quadrant of the abdomen. Physical examination revealed a firm, approximately 20 cm lesion extending from the umbilicus to the lower quadrant. Oral and intravenous contrast computed tomography showed a well-defined mass originating in the right retroperitoneal region, invading the right renal capsule, and extending into the iliac fosa. Lung CT scan showed no pathological findings, and laparotomy was planned. Excision of a 4.5 kg, 21x18x19 cm mass consistent with retroperitoneal sarcoma was performed. The patient was discharged with no postoperative complications and recommendations. Pathology was reported as epithelioid type, consistent with high-grade leiomyosarcoma. Mitotic rate was >30 per 10 BBA.

Conclusion: LMS constitute less than 10% of all soft tissue sarcomas. With an incidence of 20%, they are the second most common type of retroperitoneal sarcoma. They are twice as common in women and are generally more frequent in the 50-70 age group. Due to their slow growth and anatomical location, retroperitoneal tumors usually reach large sizes by the time of diagnosis. Patients with retroperitoneal sarcoma have a low life expectancy. Low-grade tumors offer a 50% survival advantage compared to high-grade tumors. The primary goal in the treatment of retroperitoneal LMS is excision with clear surgical margins.

Keywords: Leiomyosarcoma, retroperitoneal

Clinical evaluation of thyroid surgery in a patient with congenital breast Absence compatible with Poland syndrome: A case report

Güvenç Diner, Hacı Vural Soyer, Boran Cihat Karakuş

Department of General Surgery, University of Health Sciences Türkiye, Mersin City Training and Research Hospital, Mersin

Objective: Poland syndrome is a rare congenital anomaly first described by Alfred Poland in 1841. It is typically characterized by unilateral hypoplasia or aplasia of the pectoralis major muscle, accompanied by ipsilateral absence of breast tissue and upper extremity anomalies. The condition most commonly affects the right side. In female patients, breast absence may lead to significant cosmetic and psychosocial concerns. The most widely accepted etiological theory suggests a disruption of subclavian artery blood flow during the embryonic period.

Material and Methods: Case report: A 23-year-old female patient presented to the general surgery clinic with a thyroid nodule. Her medical history revealed congenital absence of the right breast. Physical examination demonstrated absence of right breast tissue, including underdevelopment of the areola and nipple. Marked hypoplasia of the right pectoral region was noted. No obvious skeletal or digital anomalies of the upper extremity were detected. These findings were considered consistent with Poland syndrome. Thyroid ultrasonography revealed a nodule in the right lobe suspicious for malignancy. Fine-needle aspiration biopsy suggested a follicular neoplasm, and surgical intervention was indicated. Preoperative evaluation revealed no additional cardiopulmonary pathology. The patient underwent total thyroidectomy under general anesthesia. No intraoperative or postoperative complications occurred. Serum calcium levels and vocal cord functions remained normal throughout follow-up. The patient was discharged without complications. Postoperative histopathological examination revealed follicular variant papillary thyroid carcinoma.

Results: Discussion: The incidence of Poland syndrome has been reported to range between 1 in 30.000 and 1 in 50.000 live births. The clinical spectrum is broad, varying from mild pectoral muscle hypoplasia to severe chest wall and limb deformities. In female patients, breast aplasia is often the most prominent clinical feature. Diagnosis is primarily clinical, while imaging modalities assist in evaluating associated anomalies. In this case, the syndrome was re-evaluated during assessment for thyroid pathology. Although no direct association between Poland syndrome and thyroid disease has been established, awareness of chest wall anatomy is important for surgical planning. A multidisciplinary approach is particularly valuable when reconstructive procedures are considered.

Conclusion: Although Poland syndrome is rare, it may present with congenital breast absence, especially in female patients. Careful physical examination is essential in patients presenting to different specialties for unrelated conditions. This case demonstrates that thyroid surgery can be safely performed in patients with Poland syndrome. Multidisciplinary evaluation and individualized surgical planning are key to achieving optimal outcomes.

Keywords: Congenital absence of breast, Poland syndrome, thyroid surgery

A rare case of Graves' disease treated with therapeutic plasmapheresis as a preoperative rescue therapy for antithyroid and lithium-resistant disease

Mehmet Tolga Kafadar[1], Abdulkadir Akbaş[1], Hasan Alklay[1], Baran Demir[2], Zafer Pekkolay[3]

[1]*Department of General Surgery, Dicle University Faculty of Medicine, Diyarbakır*

[2]*Clinic of General Surgery, Tunceli State Hospital, Tunceli*

3Department of Endocrinology and Metabolic Diseases, Dicle University Faculty of Medicine, Diyarbakır

Objective: Antithyroid drugs are used as first-line treatment in the vast majority of patients with hyperthyroidism. If antithyroid drugs used in the treatment of thyrotoxicosis cannot be used due to their side effects, or if adequate hormone suppression cannot be achieved despite high-dose use, or if there is a rapidly developing clinical condition such as thyroid storm, plasmapheresis can be used as an alternative treatment method. This article presents a case of Graves' disease in which therapeutic plasmapheresis was used as a preoperative rescue treatment.

Material and Methods: A 36-year-old female patient presented to our university's endocrinology clinic with a history of approximately 3 years of antithyroid (propylthiouracil) medication use. Agranulocytosis was detected during follow-up, and propylthiouracil was discontinued, followed by initiation of lithium carbonate 300 mg (oral 2x1) treatment. Surgery was recommended, but sufficient hormone suppression could not be achieved, so preoperative plasmapheresis was planned.

Results: The patient's TSH: 0.001 mIU/L, sT3: 9.32 pg/mL, and sT4: 4.18 ng/dL before lithium carbonate treatment, and TSH: 000.1 mIU/L, sT3: 6.7 pg/mL, sT4: 2.17 ng/dL before plasmapheresis. Following 2 units of plasmapheresis, the TSH was found to be 0.001 mIU/L, sT3: 4.0 pg/mL, and sT4: 1.67 ng/dL. With these values and anesthesia approval, the patient underwent surgery. No postoperative complications occurred in this case of bilateral total thyroidectomy, and the pathology report was consistent with Graves' disease.

Conclusion: Preoperative therapeutic plasmapheresis emerges as an alternative treatment method for patients with thyrotoxicosis. It should always be kept in mind that it can be an effective treatment method, particularly in cases of inadequate hormonal suppression response or side effects associated with antithyroid drugs, and for rapidly achieving adequate hormonal suppression prior to surgical interventions.

Pylorus-preserving total pancreatectomy for a giant pancreatic cystic lesion of uncertain preoperative origin: A case report

Gültekin Hoş, Hasan Kumru, Süleyman Ümit Emanet, Olgun Erdem, Aylin Acar, Tolga Canbak

Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul

Objective: Giant cystic pancreatic lesions are often asymptomatic but may rarely cause obstructive jaundice due to compression of the hepatic hilum or duodenum. Although hepatocyte-specific magnetic resonance imaging (MRI) has high sensitivity for detecting biliary involvement, it may not always clearly differentiate between pancreatic and biliary origins. The management of large cystic lesions with uncertain origin poses significant diagnostic and surgical challenges. This report presents a case of a giant cystic pancreatic lesion presenting with obstructive jaundice and hyperosmolar hyperglycemic state (HHS), managed with pylorus-preserving total pancreatectomy (PP-TP).

Materiald and Methods: Clinical presentation, laboratory findings, radiological imaging, intraoperative findings, and postoperative course were retrospectively evaluated. Diagnostic workup included contrast-enhanced computed tomography (CT) and hepatocyte-specific MRI. Perioperative metabolic disturbances were managed using a multidisciplinary approach.

Results: A 58-year-old female patient presented with right upper quadrant pain, abdominal distension, dark-colored urine, and pruritus. Laboratory evaluation revealed findings consistent with obstructive jaundice and HHS. CT and MRI demonstrated a giant thin-walled cystic lesion measuring approximately 14×11×11 cm adjacent to the pancreatic head, causing latero-inferior displacement of the duodenum and marked intrahepatic bile duct dilatation. Hepatocyte-specific MRI showed no contrast uptake within the cyst, and biliary communication could not be demonstrated. A robotic surgical approach was initially attempted; however, due to significant anatomical distortion at the hepatic hilum, conversion to open surgery was required. Following portal triad dissection, PP total pancreatectomy was performed, and reconstruction was achieved with hepaticojejunostomy and gastrojejunostomy. Histopathological examination revealed a pancreatic pseudocyst with no evidence of malignancy. Postoperatively, rapid improvement in liver function tests and metabolic parameters was observed, and no major complications occurred.

Conclusion: Giant pancreatic pseudocysts may present with severe clinical manifestations such as obstructive jaundice and HHS, closely mimicking malignant or biliary pathologies. In selected patients with large cystic lesions of uncertain origin and complex anatomical relationships, PP total pancreatectomy represents a safe and effective surgical option. Successful outcomes depend on careful patient selection, multidisciplinary perioperative management, and early initiation of endocrine and exocrine replacement therapy.

Surgical management of ectopic opening of the common bile duct (EOCBD): A report of two rare cases

Sarp Tunalı[1], Yalçın Ural Turhan Akbulut[1], Tufan Gümüş[1], Fatih Tekin[2], Alper Uğuz[1]

[1]*Department of General Surgery, Ege University Hospital, İzmir*

[2]*Division of Gastroenterology, Department of Internal Medicine, Ege University Hospital, İzmir*

Objective: Ectopic opening of the common bile duct (EOCBD) is an exceedingly rare biliary anomaly arising from the early division of the hepatic diverticulum (Boyden's hypothesis). Its incidence ranges from 0.1% to 2.7%. The absence of the sphincter of Oddi in EOCBD leads to alkaline reflux, predisposing patients to chronic gastritis, refractory duodenal ulcers, apical stenosis, and recurrent cholangitis.

Material and Methods: Two rare cases treated surgically for recurrent peptic ulcer fibrosis and biliary stasis are presented with a literature review.

Results: Case 1: A 49-year-old male presented with a 4-day history of jaundice, fever, and abdominal pain. Laboratory results showed cholestatic enzyme elevation and hyperbilirubinemia. MRCP revealed intrahepatic duct dilatation and 16 mm stones in the distal common bile duct (CBD). Gastroscopy identified a "choledochobulbar fistula" at the bulbar level, where the pancreatic and CBD orifices opened separately. During ERCP, the CBD was cannulated via this atypical orifice with difficulty due to bulbar stenosis. After failed balloon dilatation, an 8.5F pigtail stent was placed. Following the resolution of cholangitis, the patient underwent cholecystectomy and Roux-en-Y hepaticojejunostomy. He was discharged on postoperative day 14. Case 2: A 60-year-old male with a history of cholecystectomy presented with abdominal pain and rigors. CT showed left portal vein thrombosis and a characteristic "hook-shaped" angulation of the distal CBD. MRCP measured the CBD at 20 mm with duodenal narrowing. Gastroscopy revealed an atypically located papilla. During ERCP, a 25 mm dilated CBD was cannulated via the atypical papilla, and a stent was placed. Surgery was performed for EOCBD and gastric outlet obstruction. Following Roux-en-Y hepaticojejunostomy and gastroenterostomy, the patient was discharged on day 16 without complications.

Conclusion: EOCBD should be suspected when the normal papilla is absent and the pylorus-papilla distance is <50 mm. The "hook-shaped" distal CBD is a key radiological criterion. The lack of a sphincter mechanism causes duodenal reflux, leading to recurrent stones and cholangitis. Endoscopic extraction often fails (40-70%) due to anatomical challenges. In cases of recurrent cholangitis or failed ERCP, Roux-en-Y hepaticojejunostomy remains a curative surgical option.

[P-596]

Abdominal epilepsy: Diagnosis and follow-up results in an adult case

Özge Bozdemir Altınışık, Ekrem Koç, Aydın Aktaş

Department of General Surgery, Trabzon University Faculty of Medicine, Trabzon

Objective: Abdominal epilepsy is a rare form of epilepsy that is difficult to diagnose because epileptic seizures are accompanied by primarily gastrointestinal symptoms. It presents with recurrent abdominal pain, nausea, vomiting, and autonomic symptoms, while the absence of motor seizure findings can lead to diagnostic delays. Although it is mostly diagnosed in childhood, an increasing number of cases are being reported in the adult age group.

Material and Methods: A 54-year-old female patient with recurrent abdominal pain attacks for approximately 20 years was evaluated for increasingly frequent and particularly severe abdominal pain, nausea, vomiting, and autonomic symptoms occurring at night in recent years. Given the stereotypical nature of the attacks, their termination with marked fatigue suggestive of a postictal period, and the absence of organic pathology on comprehensive gastrointestinal investigations, abdominal epilepsy was considered as a preliminary diagnosis. Although routine electroencephalography (EEG) was normal, lamotrigine treatment initiated based on the clinical picture resulted in a marked reduction in attacks, and the patient became completely asymptomatic during one year of follow-up.

Results: Abdominal epilepsy is a rare form of focal epilepsy characterised by recurrent abdominal pain, nausea-vomiting, and autonomic symptoms, and often results in delayed diagnosis due to its tendency to mimic gastrointestinal disorders. During the diagnostic process, the paroxysmal and stereotypical nature of the attacks, the presence of accompanying autonomic or neurosensory symptoms, the exclusion of other gastrointestinal causes, and the clinical response to antiepileptic treatment are of great importance. The diagnostic sensitivity of electroencephalography is limited, and normal EEG findings are frequently observed, particularly during the interictal period. This is explained by the fact that epileptic activity may originate from deep cortical or autonomic networks. In the presented case, the typical clinical pattern, the history of long-standing stereotypical attacks, and the complete clinical improvement that began shortly after lamotrigine treatment and became permanent in the long term strongly supported an epileptic aetiology despite normal EEG findings. Therefore, clinical evaluation should be prioritised in the diagnosis of abdominal epilepsy.

Conclusion: Abdominal epilepsy must always be considered in the differential diagnosis of unexplained and recurrent abdominal pain attacks, particularly in adult patients. Normal EEG findings should not rule out the diagnosis; clinical features, the stereotypical nature of the attacks, and the response to antiepileptic treatment should be decisive in the diagnostic process. With early diagnosis and appropriate treatment, significant and lasting clinical improvement can be achieved in patients.

Keywords: Abdominal epilepsy, recurrent abdominal pain attacks

Psoas abscess presenting with atypical symptoms: Case report

Sümeyra Güler[1], Şevket Barış Morkavuk[1], Asgar Huseyinov[2], Ahmet Kürşat Gören[2], İbrahim Burak Bahçecioğlu[1], Müjdat Turan[2], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Psoas abscess was first described by Mynter in 1881. It can be classified as primary or secondary depending on the presence or absence of an underlying disease. Primary psoas abscesses develop hematogenously, usually from an infection focus in another part of the body, particularly in immunocompromised patients. The most common cause of secondary psoas abscesses is Crohn's disease. Its classic presentation is characterized by fever, back pain, and pain in the thigh and groin area. In this presentation, we aim to present a case of atypical psoas abscess diagnosed with the symptom of difficulty walking, along with a review of the literature.

Material and Methods: Different causes are implicated in the etiology of primary and secondary psoas abscesses. Patients usually describe their symptoms with abdominal pain, flank pain,weakness, high fever, sweating, weight loss, limping, and lower back and leg pain.

Results: A 50-year-old male patient presented to the emergency department with fever, weakness, weakness in the right leg, and difficulty walking. Physical examination revealed no pathological findings on the abdominal examination. However, increased temperature and edematous skin tissue (cellulitis) were detected in the right lateral quadrant. The patient had a high fever, with a WBC of 21,000 and a CRP of 212 mg/L. Plastron appendicitis was suspected, and abdominal ultrasound revealed a fluid collection consistent with a dense abscess in the right psoas region. CT scan showed a prominent 76x81 mm abscess in the right psoas region containing air densities. The patient was hospitalized, and a percutaneous drainage catheter was placed. Approximately 500 cc of abscess was drained. Broad-spectrum antibiotic therapy was initiated, and post-drainage physical examination showed improvement in the motor loss in the right leg and a decrease in WBC and CRP levels. The patient, who showed no signs of infection in urinary and gastrointestinal examinations, underwent Brucella antibody and PPD tests. The patient, whose general condition remained stable, was discharged after recovery.

Conclusion: Psoas abscess is a rare disease that develops secondary to inflammation in the psoas muscle and iliac muscle fascia. The incidence of psoas abscess is three times higher in men than in women. Patients typically present with abdominal pain, flank pain, weakness, fever, sweating, weight loss, limping, lower back pain, and leg pain. Treatment of psoas abscess involves antibiotic therapy and abscess drainage. Abscess drainage is recommended as percutaneous drainage with surgical or radiological guidance. In secondary psoas abscess, treatment should include drainage along with treatment of the primary disease causing the abscess.

Keywords: Percutaneous drainage, psoas abscess

[P-598]

A rare gastric schwannoma presenting as a suspected gastrointestinal tumor

Erdi Aydın[1], Ömer Kılıç[2], Muhammed Taha Turan[2], İbrahim Burak Bahçecioğlu[1], Gökhan Giray Akgül[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Gastric schwannomas are rare benign mesenchymal tumors originating from Schwann cells of the peripheral nerve sheath and account for a small proportion of gastrointestinal mesenchymal neoplasms. They are most commonly located in the stomach and are often detected incidentally. Due to significant overlap in radiological and endoscopic features, they are frequently misdiagnosed preoperatively as gastrointestinal stromal tumors (GISTs). Unlike GISTs, which carry malignant potential, gastric schwannomas typically follow a benign clinical course. Therefore, accurate diagnosis is essential for appropriate management and prognosis.

Material and Methods: A 71-year-old male patient presented with nausea and vomiting. His medical history was significant only for hypertension. Physical examination and laboratory findings were unremarkable. Contrast-enhanced computed tomography revealed a 26×18 mm well-circumscribed, homogeneous hypodense solid mass on the lesser curvature of the stomach. Upper gastrointestinal endoscopy demonstrated a 1.5 cm submucosal lesion in the gastric corpus. Based on imaging findings, GIST was suspected. The patient underwent laparoscopic wedge resection of the stomach.

Results: The postoperative course was uneventful, and the patient was discharged on postoperative day five. Macroscopic examination of the specimen revealed a 2.5 cm gray-white solid tumor. Histopathological analysis showed spindle cell proliferation. Immunohistochemical staining demonstrated strong S-100 positivity and negativity for CD34, SMA, desmin, and DOG1, confirming the diagnosis of gastric schwannoma. Surgical margins were negative.

Conclusion: Although rare, gastric schwannomas should be considered in the differential diagnosis of gastric submucosal tumors. Preoperative distinction from GIST is challenging, and definitive diagnosis relies on immunohistochemical evaluation. Complete surgical resection with negative margins is curative, and the prognosis is excellent. This case highlights the importance of accurate pathological diagnosis in guiding appropriate treatment and follow-up strategies.

Foreign body ingestion in adults with intellectual disability: A rare case of pacifier-induced jejunal perforation

Ersin Uslu[1], Uğur Topal[2]

[1]*University of Health Sciences Türkiye, Osmaniye Training and Research Hospital, Osmaniye*

[2]*Department of Surgical Oncology, Çukurova University Faculty of Medicine, Adana*

Objective: Foreign body ingestion in adults is common, with 80-90% passing spontaneously and less than 1% requiring surgical intervention. Pacifier ingestion causing bowel obstruction has been reported in children but never documented in adults with resulting jejunal necrosis and perforation.

Material and Methods: A 23-year-old male with intellectual disability and epilepsy presented with acute abdominal pain and vomiting. Clinical examination revealed peritonitis. Computed tomography demonstrated small bowel obstruction with a non-radiopaque foreign body and pneumoperitoneum. Emergency laparotomy revealed a pacifier lodged in the jejunum 100 cm distal to the ligament of Treitz, causing segmental necrosis and a 3-cm perforation. The patient underwent segmental jejunal resection with primary hand-sewn anastomosis. Histopathology confirmed transmural necrosis. The postoperative course was uncomplicated, with resumption of oral intake on day 2 and discharge on postoperative day 4. Antiepileptic therapy continued throughout hospitalization without seizure recurrence.

Results: This represents the first documented case of pacifier-induced jejunal perforation in an adult. The jejunum is an uncommon perforation site due to lack of anatomical narrowing. Non-radiopaque plastic objects pose diagnostic challenges requiring high clinical suspicion and computed tomography imaging. Primary anastomosis in jejunal resections demonstrates excellent outcomes with leak rates of 0.6-3%, substantially lower than colonic anastomoses. Individuals with intellectual disability and epilepsy face elevated risk for foreign body ingestion, necessitating preventive supervision strategies.

Conclusion: Pacifier ingestion in adults with intellectual disability can cause life-threatening jejunal complications. Early recognition, computed tomography diagnosis, and prompt surgical intervention with primary anastomosis achieve favorable outcomes.

Keywords: Intestinal obstruction, foreign bodies, jejunal perforation

A rare case report of delayed colon perforation due to blunt trauma

Sinan Şener, Emre Zengin, Reşad Mirzayev, Fatih Kocalar

Selçuk University Faculty of Medicine Hospital, Konya

Objective: In abdominal trauma, perforations of hollow organs and injuries to solid organs such as the liver and spleen may be observed. Although hollow organ perforations are more commonly seen in penetrating injuries, they can also occur in hollow organs following high-energy blunt trauma. While perforation usually occurs in the early period after trauma, in some cases it may also present in a delayed phase.

Material and Methods: A 29-year-old male patient presented to the emergency department of our hospital due to a fall from an electric scooter that occurred 6 days earlier. Upon further history taking, it was learned that after falling from the scooter, he struck the left side of his abdomen against stone bollards. The patient stated that he came to the hospital because of pain in the left lower quadrant and reported that the pain was not severe. On abdominal examination, no abnormal findings were noted except for tenderness in the left lower quadrant. No acute pathology was observed on the radiographs obtained.

Results: The patient evaluated by our team was hemodynamically stable. On abdominal examination, no significant findings were detected except for tenderness in the left lower quadrant. Laboratory investigations revealed elevated infectious markers: WBC 14.2 (normal range: 4.01-9.75), CRP 79.8 (normal range: 0-5), and procalcitonin 6.06 (normal range: 0-0.5). Due to the elevationhan elevated infectious markers and left lower quadrant tenderness on abdominal examination, a computed tomography (CT) scan was performed for further evaluation. The CT findings were reported as follows: "A suspicious wall defect is present in the proximal sigmoid colon and distal descending colon. Inflammatory stranding is observed in the surrounding adipose tissue. Mesenteric fat stranding and millimetric free air are noted distal to the sigmoid colon."

Conclusion: The patient was admitted to the ward for surgical management due to a perforation secondary to trauma that had occurred 6 days earlier. A millimetric perforation was identified in the sigmoid colon, and the omentum was observed to be covering the perforated area.Due to colonic distension and intra-abdominal contamination, it was decided that a safe anastomosis could not be performed; therefore, a colostomy was created and a Hartmann procedure was performed. Oral intake was started at the 8th postoperative hour. The patient passed gas from the colostomy on postoperative day 1 and had stool output on postoperative day 2. After completion of antibiotic therapy, the patient was discharged from our ward.

Keywords: Blunt trauma, perforation

A rare case: Low-grade (Grade 1) dedifferentiated liposarcoma in a giant intra-abdominal mass and surgical management

Alparslan Ertenlice[1], Yiğit Baydar[2], Aydanur Pehlivan[2], Abdussamed Yalçın[1]

[1]*Department of General Surgery, Ankara Yıldırım Beyazıt University Faculty of Medicine, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Ankara City Hospital, Ankara*

Objective: Liposarcomas are the most common subtype of retroperitoneal and intra-abdominal soft tissue sarcomas. Dedifferentiated liposarcoma (DDLPS) typically exhibits high-grade malignancy and an aggressive course. However, rarely, the dedifferentiated component may display low-grade (FNCLCC score 3) features. We present the surgical management of a giant Grade 1 DDLPS case requiring partial cystectomy, which was initially considered inoperable at an external center.

Material and Methods: A 69-year-old male patient presented with abdominal swelling lasting for 6 months. External center imaging revealed a 30x30 cm mass filling the abdomen and causing bilateral Grade 3 hydronephrosis. After placement of bilateral nephrostomy and DJ stents, the patient was referred to our surgery clinic following oncology board evaluation. After preoperative preparation, the patient underwent surgery. A midline incision revealed a giant, lobulated, septated, fixed mass containing cystic and solid areas, originating from the anterior abdominal wall and displacing the intestines laterally.

Results: The mass was separated from the peritoneum and intra-abdominal organs with careful dissection. The lower lobe was observed to be adherent to the bladder and vascular structures, invading the bladder. The upper lobe was removed with its capsule. Since the posterior capsule of the lower lobe was adherent to vascular structures, it was resected over the capsule, preserving vital structures. Due to bladder invasion, partial cystectomy was performed en-bloc with the mass, and the bladder was repaired. Bilateral ureters were preserved. Histopathological examination revealed dedifferentiated liposarcoma. According to FNCLCC scoring, the total score of tumor differentiation, mitosis, and necrosis was reported as 3 (Grade 1). The patient had an uneventful postoperative course and was discharged.

Conclusion: Giant intra-abdominal liposarcomas are surgically challenging cases due to their close proximity to vascular structures and urinary system organs. As in this case, management of urological compression signs (hydronephrosis) in the preoperative period and achieving complete clearance with organ resections (partial cystectomy) if necessary during surgery are vital. Encountering a rare score like “Grade 1” despite the pathological diagnosis of “Dedifferentiated” contributes to the literature in terms of demonstrating the biological behavioral diversity of these tumors.

Massive gastrointestinal bleeding due to a dieulafoy lesion: A rare case report

Sedef Poşul, Mustafa Özgün Yüksek, Hasan Fehmi Küçük

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Dieulafoy lesion is a rare but potentially life-threatening cause of gastrointestinal bleeding, resulting from erosion of an abnormally large submucosal artery through the mucosa. It accounts for approximately 1-2% of cases of acute gastrointestinal bleeding. Approximately 70-80% of Dieulafoy lesions are located in the stomach, with the most common site being the lesser curvature. Less frequently, Dieulafoy lesions may be observed in the duodenum, jejunum, colon, and rectum. Its presentation with sudden-onset, intermittent, and massive bleeding episodes may complicate the diagnostic process. Although endoscopic therapy is the first-line treatment, surgical intervention may be required in cases of massive and uncontrolled bleeding.

Material and Methods: A 77-year-old female patient presented to the emergency department with complaints of hematemesis that began overnight. Her medical history included diabetes mellitus, hypertension, congestive heart failure, and rivaroxaban (Xarelto) use. She had no prior history of gastroscopy or colonoscopy. After insertion of a nasogastric tube, dilated gastric contents with clotted hemorrhage were aspirated. Initial laboratory evaluation revealed hemoglobin/hematocrit levels of 8.5 g/dL and 26.7%, respectively, a platelet count of 264×10^3/L, and an INR of 1.4. During follow-up and erythrocyte suspension replacement, the patient developed intermittent episodes of bright red rectal bleeding. At times, abundant hemorrhage reaching 500-600 cc was observed. Despite transfusion therapy, hemoglobin and hematocrit levels decreased to 6.2 g/dL and 19.8%. In total, 7 units of erythrocyte suspension and 3 units of fresh frozen plasma were transfused. Although a transient increase in hemoglobin was achieved, recurrent massive bleeding episodes accompanied by clinical deterioration, hypotension, and tachycardia developed. Inotropic agent support was initiated, and the patient underwent emergency surgery with the diagnosis of massive gastrointestinal bleeding.

Results: Intraoperative exploration revealed an actively spurting Dieulafoy lesion located on the anterior wall of the gastric bulb. The bleeding vessel was ligated, and the lesion was excised. Postoperatively, the patient was transferred intubated to the intensive care unit. During ICU follow-up, inotropic support was discontinued, and vital signs stabilized.**Conclusion:** The patient was transferred to the surgical ward, tolerated oral intake, and showed no further decrease in hemoglobin levels, allowing discharge in stable condition. This case emphasizes that Dieulafoy lesions should be considered in the differential diagnosis of elderly patients receiving anticoagulant therapy who present with massive gastrointestinal bleeding mimicking both upper and lower sources, and that timely surgical intervention can be lifesaving when bleeding is uncontrollable.

Keywords: Dieulafoy lesion, massive upper gastrointestinal bleeding, emergency surgery

Isolated sister Mary Joseph's nodule allowing curative resection in cecal adenocarcinoma: A rare case and review of the literature

Aytaç Selman, Elif Elgiz Aktarı, Emre Berat Akçay, Enver Açıkgöz, Meryem Günay Gürleyik

University of Health Sciences Türkiye, Haydarpasa Numune Training and Research Hospital, İstanbul

Objective: Sister Mary Joseph's nodule (SMJN) is a rare clinical finding that typically indicates advanced intra-abdominal malignancy and is associated with a poor prognosis. However, in uncommon circumstances, it may present as an isolated metastasis amenable to curative resection. It is most commonly related to gastrointestinal and gynecological cancers and usually reflects disseminated disease. Here, we present a rare case of cecal adenocarcinoma in which an isolated SMJN was the initial clinical manifestation and permitted curative surgical treatment.

Material and Methods: A 76-year-old male patient presented with a painful umbilical mass that had persisted for several weeks. His medical history revealed an unintentional weight loss of approximately 8 kg over the preceding four months, without nausea, vomiting, or changes in bowel habits. Physical examination demonstrated a firm and tender umbilical mass measuring approximately 2 cm in diameter; no additional pathological findings were detected on abdominal examination.Abdominal computed tomography revealed a mass lesion in the cecum consistent with a primary tumor, along with an isolated lesion in the umbilical region. Tumor markers (AFP, CEA, and CA 19-9) were within normal limits. Biopsy of the umbilical mass demonstrated metastatic adenocarcinoma consistent with colorectal origin (CK20 positive, CK7 negative). FDG-PET/CT showed no evidence of distant organ metastasis or diffuse peritoneal involvement apart from the cecal and umbilical lesions. Colonoscopy revealed an ulcerovegetative mass in the cecum. Based on the clinical and radiological findings, curative surgical resection was planned.

Results: The patient underwent a right hemicolectomy with simultaneous umbilical metastasectomy. The operation and postoperative course were uneventful, and the patient was discharged on postoperative day 6. Histopathological examination revealed a moderately differentiated cecal adenocarcinoma invading the visceral peritoneum (pT4a), with metastases in five regional lymph nodes (pN2a). The umbilical lesion was consistent with metastatic adenocarcinoma (pM1a). Surgical margins were negative. The patient was referred to the oncology department for planned adjuvant chemotherapy.

Conclusion: Although SMJN is generally regarded as a sign of advanced and disseminated malignancy, it may rarely present as an isolated metastasis amenable to curative resection. This case underscores the importance of thorough staging and careful patient selection, as early recognition of this rare presentation may allow potentially curative surgical treatment.

Keywords: Sister Mary Joseph's nodule, umbilical metastasis, colorectal cancer

Mechanical ileus caused by a degenerated hydatid cyst: A case report

Nebile Çamaş, Kutay Sağlam

Bursa Uludağ University Faculty of Medicine, Bursa

Objective: Hydatid disease is a zoonotic infection caused by the parasite Echinococcus granulosus. It most commonly affects the liver and lungs. Rarely, intraabdominal hydatid cysts may lead to complications and cause gastrointestinal obstruction. In this report, we present a rare case of mechanical ileus due to a degenerated hydatid cyst.

Material and Methods: Case presentation patient information -83-year-old male- Abdominal pain for 2 days -ınability to pass gas or stool physical examination -abdominal distension -diffuse tenderness -no guarding or rebound tenderness -decreased bowel sounds -empty rectal ampulla on digital rectal examination -laboratory findings -leukocytosis: 11,050 $\times 10^9$/L -CRP: 8.5 mg/L -liver function tests: within normal limits -sodium: 126 mmol/L radiological findings abdominal CT scan: -sigmoid colon displaced anteriorly -diffuse colonic dilatation with closed -loop obstruction (possible sigmoid volvulus) -multiple intraabdominal calcified lesions suggestive of degenerated hydatid cyst -obstruction likely related to a 5 cm lesion in the left lower quadrant. Treatment and surgical findings -the patient underwent emergency surgery with a preliminary diagnosis of mechanical ileus.

Results: Intraoperative findings: -sigmoid colon twisted around a degenerated hydatid cyst located in the sigmoid mesocolon -colon diameter reached 7-8 cm -Hartmann procedure was performed. Hydatid disease is usually asymptomatic but may cause complications such as rupture, infection, or compression. Degenerated mesenteric hydatid cysts are a rare cause of mechanical ileus. Abdominal CT is highly valuable for diagnosis. Treatment typically includes surgical excision and antiparasitic therapy.

Conclusion: Degenerated hydatid cysts, although rare, should be considered in the differential diagnosis of mechanical ileus. Early diagnosis and surgical intervention are critical to reduce morbidity.

Keywords: Hydatid cyst, mechanical ileus, mesenteric involvement

Advanced appendiceal adenocarcinoma in a patient presenting with unexplained abdominal pain and weight loss: The role of diagnostic laparoscopy in staging

Mustafa Karahan, Emre Atmaca, Büşra Hilal Arasan, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Appendiceal adenocarcinoma is a rare malignancy among gastrointestinal system cancers and usually presents with non-specific clinical findings. This often complicates the diagnostic process and may result in detection at an advanced stage. In patients with unexplained abdominal pain and systemic symptoms, diagnostic laparoscopy may provide significant contribution to both diagnosis and staging.

Material and Methods: A 62-year-old male patient presented with long-standing abdominal pain and unintentional weight loss. Due to the detection of anemia and elevated tumor markers during initial evaluation, the patient was hospitalized for further investigation. Laboratory analysis revealed a hemoglobin level of 8.2 g/dL, CA 19-9 level of 18,569 U/mL, and CEA level greater than 995 ng/mL. Abdominal computed tomography demonstrated marked thickening of the appendiceal wall, luminal dilatation up to 12 mm, contrast enhancement, and paracecal lymph nodes. Colonoscopy revealed no pathological findings. As no definitive diagnosis could be established clinically or radiologically, the patient was evaluated at a multidisciplinary tumor board and diagnostic laparoscopy was planned. Laparoscopic exploration revealed a firm and distended appendix, along with diffuse flat lesions on the peritoneal surfaces suggestive of widespread involvement. Appendectomy was performed using a linear stapler to include the entire palpable lesion, and peritoneal biopsies were obtained.

Results: Histopathological examination revealed a moderately differentiated (G2) adenocarcinoma measuring 7 cm in greatest dimension, involving the entire appendix with transmural invasion including the serosa. Lymphovascular and perineural invasion were present. The proximal and mesenteric surgical margins were reported as positive. The tumor was staged as pT4a according to the AJCC 8th edition. Peritoneal biopsies were consistent with metastatic adenocarcinoma.

Conclusion: Appendiceal adenocarcinoma may present with unexplained abdominal pain and systemic symptoms, leading to diagnostic challenges. Diagnostic laparoscopy is an important modality for determining disease extent and guiding appropriate oncological treatment planning. In this case, laparoscopic assessment revealed peritoneal metastasis, and the patient was referred for chemotherapy followed by HIPEC.

A rare case of upper gastrointestinal bleeding: Our clinical experience

Kubilay Sertkaya, Berat Demir, Seda Külekçi, Samet Şahin

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Gastrointestinal stromal tumors (GISTs) are mesenchymal neoplasms originating from interstitial Cajal cells and constitute approximately 1-2% of all gastrointestinal cancers. While most commonly found in the stomach and small intestine, duodenal localization is quite rare, accounting for only about 3% of all GIST cases. Duodenal GISTs present unique challenges in surgical management due to their close anatomical relationship with the papilla of Vater and the head of the pancreas. Therefore, balancing oncological competence with organ-preserving approaches is of paramount importance in treatment planning.

Material and Methods: A 71-year-old male patient was evaluated for gastrointestinal bleeding. Abdominal computed tomography revealed a mass lesion in the descending duodenum, approximately 6 cm in diameter, with well-defined and heterogeneous features, suggestive of GIST (gastrointestinal stimulation). Upper gastrointestinal endoscopy showed a subepithelial lesion in the second portion of the duodenum, with visible vascular structures in the center.

Results: Based on the current clinical, radiological, and endoscopic findings, the patient was diagnosed with duodenal GIST and surgical treatment was planned. Considering the location of the tumor between the third and fourth segments of the duodenum and its possible anatomical relationship with the papilla of Vater, the need for pancreaticoduodenectomy was evaluated; however, due to the appropriate patient and tumor characteristics, an organ-conserving surgical approach was preferred. Accordingly, the patient underwent duodenal wedge resection. Lymph node dissection was not performed due to the low tendency of GISTs to metastasize lymphadically. In the patient's postoperative follow-up, no anastomotic leakage or surgical complications occurred, and the patient, whose clinical course was uneventful, was discharged in good health.

Conclusion: Duodenal GISTs present surgical challenges due to their rarity and close association with critical anatomical structures. Pancreaticoduodenectomy may be unavoidable, particularly in cases with close association with the papilla of Vater or the head of the pancreas. However, the literature reports that organ-preserving surgical approaches such as wedge resection or limited duodenal resection can be safely applied in appropriately selected cases. These approaches reduce surgical morbidity while maintaining adherence to oncological principles. The presented case is important because it demonstrates that organ-preserving surgery, with careful preoperative evaluation and surgical planning, can be an effective option in duodenal GISTs.

A rare cause of ileus: Ileus due to compression from an abdominal aortic aneurysm

Fatih Kocalar, Sinan Şener, Emre Zengin, Reşad Mirzayev

Selçuk University Faculty of Medicine Hospital, Konya

Objective: Ileus can occur as a slowing or cessation of normal intestinal motility, and it may also be caused by internal or external compression of the bowel. Mechanical causes are usually mass lesions. Although rare, ileus may also occur due to compression of the intestines by an abdominal aortic aneurysm.

Material and Methods: A 75-year-old male patient presented to our hospital's emergency department with complaints of nausea, vomiting, and abdominal pain. His medical history included hypertension, angina pectoris, and cysts in the right kidney. He had previously undergone graft surgery for the abdominal aorta and iliac arteries due to an abdominal aortic aneurysm (AAA). The patient had not passed gas for one day and had no bowel movements for two days. Because of his pain and tenderness, especially in the epigastric region, an upright abdominal radiograph was obtained, which did not show any significant pathology.

Results: He had tenderness in the epigastric region and minimal abdominal distension. WBC 10.19 (4.01-9.75), CRP 14.7 (0-5), potassium 5.11 (3.5-5.1). A CT scan was performed to investigate the cause of the ileus. The CT findings were reported as follows: "The stomach appears markedly distended. Additionally, dilation up to 5 cm with air-fluid levels was observed in the first and second parts of the duodenum. The transition zone is located in the third part of the duodenum adjacent to the AAA sac". The patient was admitted to our ward with a diagnosis of ileus due to compression of the third part of the duodenum by the AAA. An NG tube was placed, and over 24 hours it drained approximately 1.000 cc of bile- and gastric fluid-mixed content. Despite 24 hours of medical treatment, the patient's symptoms did not improve and his distension persisted. The patient underwent a laparoscopic gastrojejunostomy for duodenal obstruction caused by the AAA in the third part of the duodenum.

Conclusion: In our review of the literature and case reports, only a few studies were found describing ileus caused by compression from an AAA due to intestinal malrotation in adults. Intestinal malrotation is usually diagnosed in the neonatal period, but studies have shown that its incidence in adults is approximately 0.2%. Although malrotation was not present in this case, the patient developed ileus due to duodenal compression by an AAA. As the ileus did not resolve with medical treatment, a gastrojejunostomy was performed and the patient was discharged in complete remission.

Double pyramidal lobe of the thyroid gland: Report of two consecutive cases with surgical and oncologic implications

Enver Tansu Ağar, Cemil Yüksel

University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: The thyroid gland typically consists of two lateral lobes connected by an isthmus. A pyramidal lobe (PL), derived from the thyroglossal duct remnant, may extend superiorly toward the hyoid bone and is reported in up to 40-65% of individuals. Because of this frequency, the PL is often regarded as a common anatomical component. We present two consecutive surgically documented cases of DPL, one associated with papillary thyroid carcinoma and the other with benign multinodular goiter, emphasizing the surgical and oncologic implications of this rare anatomical variant.

Material and Methods: Case 1: Fifty one old woman with chronic kidney diseaseand hypertension was referred for evaluation of a thyroid nodule. Her surgical history included cervical spine surgery, multiple renal stone operations, and cesarean sections. Family history revealed multiple thyroid surgeries for benign disease. Preoperative evaluation neck ultrasonography demonstrated a 19×13 mm hypoechoic nodule with lobulated margins and internal microcalcifications in the posterior mid-zone of the left thyroid lobe (TI-RADS 4-5). Fine-needle aspiration biopsy reported suspicion for malignancy; papillary carcinoma could not be excluded. No PL was identified on imaging. Surgery total thyroidectomy with central lymph node dissection was performed. During routine cervical exploration, two distinct PLs arising from the superior aspect of the isthmus and extending cranially toward the infrahyoid region were incidentally identified and completely excised. Case 2A: Fifty five-year-old man with a history of asthma underwent thyroidectomy for multinodular goiter. He had no history of thyroid malignancy. Preoperative evaluation. Neck ultrasonography revealed an enlarged thyroid gland with heterogeneous parenchyma and multiple solid nodules. Bilateral cervical lymph nodes were reactive in appearance. No PL was reported on imaging. Surgery during routine cervical exploration, two distinct PLs arising from the superior aspect of the isthmus were clearly identified.

Results: Failure to recognize and excise PLs may have significant clinical consequences. Residual thyroid tissue following total thyroidectomy can lead to recurrence of benign disease and may present years later as a midline cervical mass. In patients with differentiated thyroid carcinoma, remnant pyramidal tissue may compromise oncologic completeness and interfere with postoperative radioactive iodine therapy by acting as a competing site for iodine uptake. Furthermore, secondary surgery in the central neck carries an increased risk of complications compared to meticulous primary resection.

Conclusion: Double pyramidal lobe (PL) is an extremely rare thyroid anatomical variation. Two consecutive cases were identified within a short time interval. One case was associated with papillary thyroid carcinoma and nodal metastasis. Preoperative imaging failed to identify the PLs in both patients. Systematic prelaryngeal exploration is crucial during thyroidectomy.

Giant retroperitoneal liposarcoma: Diagnosis and en block resection in a 59-year-old male patient

Mesut Tetik, Yasemin Özdemir Dündar, Kemal Eyvaz, Arif Aslaner Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Liposarcomas are rare malignancies originating from primitive mesenchymal cells rather than mature adipose tissue. Although they constitute less than 0.2% of all malignancies, they make up approximately 40-50% of retroperitoneal sarcomas. More than half of the masses are larger than 20 cm at the time of diagnosis. The main goal in treatment is radical surgical resection with negative surgical margins.

Material and Methods: A 59-year-old male patient presented with complaints of abdominal swelling and intermittent abdominal pain, which he had noticed for approximately three months, without any known chronic disease or history of previous abdominal surgery. Detailed physical examination revealed a palpable, well-defined mass in the right quadrant of the abdomen. The patient was scheduled for a complete blood count, extensive biochemistry and tumor markers, along with abdominal ultrasonography and contrast-enhanced abdominopelvic computed tomography. On abdominal ultrasonography, the pancreas, midline, and abdominal aorta could not be visualized due to high echogenicity. A hyperechoic solid/fatty mass lesion measuring 273x186 mm at its largest dimension was reported in this echogenic area, with no significant vascular signal.

Results: The definitive treatment of RPLSs is complete surgical resection. In giant tumors, the rate of invasion of surrounding organs can reach up to 80%. In these cases, in order to reduce the risk of recurrence and increase local control, en bloc resection of organs such as the kidney, colon, or spleen may be necessary in selected patients. Local recurrence is the most fundamental problem responsible for a large part of mortality in cases where distant metastasis does not develop. According to the World Health Organization classification, histological subtype is the most critical determinant of prognosis. While well-differentiated liposarcomas carry a low metastatic risk but a high potential for local recurrence, dedifferentiated liposarcomas may show a more aggressive clinical course. Although aggressive surgical approach has been shown to reduce recurrence, its effect on overall survival continues to be debated in the literature.

Conclusion: En bloc resection is the key step in achieving cure in giant retroperitoneal liposarcomas. Due to the rarity of the disease and the complexity of the surgery, a multidisciplinary approach and management by an experienced surgical team are crucial. Long-term and close follow-up of patients is necessary due to the high potential for local recurrence.

Peritoneal loose body in a 66-year-old male patient: A case report

Ayşe Göksu Bozdoğan Kılıç[1], Hakkı Çoşkun[1], Kübra Karahan[1], Enes Gül[2]

[1]*Department of General Surgery, Sivas Cumhuriyet University Faculty of Medicine, Sivas*

[2]*Department of Radiology, Sivas Cumhuriyet University Faculty of Medicine, Sivas*

Objective: Peritoneal loose body (PLB), also known as a peritoneal mouse, is a rare intra-abdominal condition. Most cases are asymptomatic and are incidentally detected during radiological imaging. PLBs are usually smaller than 2-3 cm in diameter, although in rare cases they may grow to several centimeters. They are most commonly thought to originate from torsion of an epiploic appendage or from small intra-abdominal fat necrosis.

Material and Methods: A 66-year-old male patient was referred to our university hospital with decreased urine output, benign prostatic hyperplasia (BPH), and glob vesicale managed with catheterization. The patient had no complaints of abdominal pain, constipation, or palpable mass. Contrast-enhanced computed tomography (CT) performed for evaluation of his urinary symptoms incidentally revealed a well-defined, nodular lesion measuring approximately 40×27 mm, showing heterogeneous contrast enhancement, located between the bowel loops adjacent to the right lateral aspect of the urinary bladder (Figure 1). An open surgical procedure for BPH was planned by the urology department, and the general surgery team accompanied the operation. During surgery, a freely mobile, white, ovoid mass was identified between the urinary bladder and the bowel loops, floating freely within the mesentery. The mass was removed from the abdominal cavity without the need for dissection (Figure 2). No additional intra-abdominal pathology was detected during exploration.

Results: Peritoneal loose bodies are rare benign entities, and their true incidence worldwide remains unknown. Although their exact etiopathogenesis has not been fully elucidated, they are most commonly believed to result from torsion of epiploic appendages followed by ischemia, fat necrosis, and subsequent calcification. PLBs are more frequently observed in male patients and are generally asymptomatic. However, when the mass enlarges or exerts pressure on adjacent organs, symptoms such as urinary retention, constipation, or small bowel obstruction may occur. CT and magnetic resonance imaging (MRI) are helpful diagnostic tools, and the mobility of the lesion—demonstrated by changes in position on serial imaging—may be a distinguishing feature.In the present case, the patient was male and had no symptoms suggestive of an intra-abdominal mass. His urinary complaints were attributed to pre-existing prostatic enlargement. The PLB was incidentally detected during surgery and was easily removed without the need for dissection.

Conclusion: Peritoneal loose bodies are most often diagnosed incidentally through radiological imaging. Evaluation by an experienced radiologist can facilitate accurate diagnosis and differentiation from other intra-abdominal pathologies. Surgical removal is recommended once the diagnosis is established. Subsequent histopathological examination is important to exclude malignancy.

A rare ileus in adults: Jejunal intussusception

Kubilay Kenan Özlük[1], Şevket Barış Morkavuk[1], Sema Horasan Hatipoğlu[2], Bilgi Karakaş[2], İbrahim Burak Bahçecioğlu[1], Mehmet Ali Gülçelik[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara*

Objective: Intussusception is the penetration of the proximal bowel segment into the distal bowel segment. Intussusception is a pathology usually seen in children. It is also rarely encountered in adults. It constitutes 1-5% of all bowel obstructions. In this presentation, we aim to present a case of jejunal intussusception along with a review of the literature.

Material and Methods: Adult intussusception cases are seen on average in the 5th decade. Unlike in children, intussusception in adult patients almost always occurs due to a secondary pathology.

Results: A 20-year-old male patient presented to the emergency department with sudden onset of severe abdominal pain, nausea, and vomiting. Physical examination revealed tenderness in all quadrants of the abdomen, particularly prominent in the left upper quadrant. The patient described enteritis, and rectal examination revealed liquid stool contamination. Laboratory evaluation showed no pathological findings except for a WBC count of 17.3x10³ µL. An upright plain abdominal X-ray showed air-fluid levels consistent with ileus in the proximal segments. Oral and IV contrast-enhanced abdominal CT scans revealed intussusception in the proximal jejunal segments, involving approximately 10 cm, consistent with the target sign. No further pathological findings were detected, and the patient was hospitalized. He underwent NG decompression, fluid resuscitation, and antibiotic therapy. On the second day after admission, spontaneous gas and stool discharge was observed. Follow-up X-rays showed regression of ileus findings, and the patient was discharged with an appointment for MR enterography.

Conclusion: The general consensus regarding the treatment of intussusception is that non-operative reduction is the primary approach. However, the main treatment for adult intussusception is surgical resection. This is because the likelihood of an underlying predisposing factor causing intussusception is higher in adult patients compared to pediatric patients. CT scan is the radiological method with the highest diagnostic accuracy rate. The most common symptom at presentation is abdominal pain. Bloody diarrhea and signs of obstruction are other symptoms.

Keywords: Intussusception, jejunum

Tailgut cyst case report

Metehan Satıroğlu, Nil Sıla Şıvgın, Mert Altaş, Gözde İğdeci, Rabia Can, Betül Akdal Dölek, Sadettin Er

University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: Tailgut cyst is a benign lesion that is rarely seen in the abdominal region and is often asymptomatic. Referred to as "tailgut cyst" in various sources, it is generally a congenital anomaly and is classified among "developmental cystic lesions". Tailgut cyst develops during the embryonic period, particularly as a result of an epithelial malformation originating from endodermal tissues. Clinical symptoms are usually absent; however, as the cyst enlarges, abdominal pain, a palpable mass, and, rarely, complications (e.g., infection or cyst rupture) may be observed. Tailgut cyst is often identified incidentally through radiological imaging methods. Imaging studies provide important information about the cyst's content, localization, and its relationship with surrounding tissues. Early diagnosis is critical in terms of enabling surgical intervention and preventing potential complications. Treatment generally consists of surgical excision, depending on the size of the cyst and the presence of symptoms. Management of these cysts may require a multidisciplinary approach.

Material and Methods: A 32-year-old female patient had previously presented to different medical centers with complaints of intermittent abdominal pain persisting for eight years, which did not significantly affect her daily life. During her gynecology consultation, a pelvic MRI was requested with a preliminary diagnosis of endometriosis. After imaging findings consistent with a tailgut cyst were identified on pelvic MRI, she was referred to our department.

Results: She had no known comorbidities and no history of prior surgery. On physical examination, minimal tenderness was noted in the suprapubic region. No pathological findings were detected in laboratory tests. On the follow-up MRI requested by our department, a lesion measuring approximately 66×37×52 mm was identified in the retrorectal space, surrounding the rectum, with no apparent relationship to adjacent structures. The imaging findings were primarily consistent with a tailgut cyst.

Conclusion: In this case, consistent with the general consensus in the literature, a follow-up strategy rather than surgical intervention was considered appropriate for an asymptomatic and small tailgut cyst. This approach allows for the management of potential complications before they develop and helps avoid unnecessary surgery.

Keywords: Tailgut, cyst, semptomq

A rare mechanical obstruction cause mimicking irritable bowel syndrome: Abdominal coza syndrome

Abdülaziz Emek[1], Ozan Can Tatar[2], Orhan Tatlı[1], Enes Şahin[1], Nihat Zafer Utkan[1]

[1]*Kocaeli University Faculty of Medicine, Kocaeli*

[2]*Kocaeli City Hospital, Kocaeli*

Objective: Abdominal cocoon syndrome (idiopathic sclerosing peritonitis) is a very rare clinical condition that develops as a result of the external wrapping of small or large bowel loops by fibrotic peritoneal bands or a thickened membrane. Clinical findings are often non-specific. It may present as recurrent abdominal pain, nausea, vomiting, abdominal distension, and subileus attacks. Due to diagnostic difficulties, patients may be diagnosed with functional gastrointestinal disorders, particularly irritable bowel syndrome (IBS), for a long time. A definitive diagnosis is often made by surgical exploration.

Material and Methods: The clinical, radiological, surgical, and pathological findings of a 58-year-old female patient who had intermittent gastrointestinal symptoms for approximately twenty years and had previously been followed up with an IBS diagnosis were retrospectively evaluated.

Results: The patient presented with recurrent episodes of nausea, vomiting, abdominal distension, and inability to pass gas or stool over the past year. Computed tomography and magnetic resonance imaging studies revealed no specific pathology explaining the obstruction. Colonoscopy was normal. Surgical exploration for a subileus attack revealed that the small and large bowel loops were externally wrapped by diffuse fibrotic peritoneal bands, with markedly restricted loop mobility and a cocoon-like appearance. Laparoscopy was converted to open surgery, and all fibrotic bands were excised, and a bridectomy was performed. Pathological examination revealed findings consistent with fibro-connective tissue proliferation and sclerosing peritonitis. No complications developed in the postoperative period, and the patient was discharged on the third day.

Conclusion: Abdominal cocoon syndrome should always be considered in the differential diagnosis of patients who have been followed up with an IBS diagnosis for a long time and who experience recurrent subileus attacks. In cases where radiological findings are insufficient, surgical exploration offers both a diagnostic and therapeutic approach.

Keywords: Abdominal coarctation syndrome, sclerosing peritonitis, mechanical bowel obstruction, subileus, irritable bowel syndrome

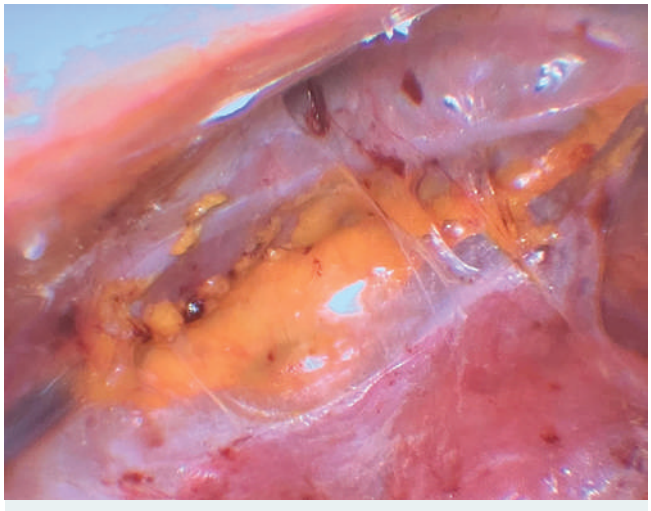

Figure 1. Intraoperative findings. The small and large bowel loops are surrounded externally by widespread peritoneal fibrotic bands and adhesions, giving them a cocoon-like appearance.

[5]*Department of Medical Genetics, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

Objective: Acute mesenteric ischemia (AMI) is a rare cause of acute abdomen and often occurs due to embolism or thrombosis in the mesenteric vascular structures. Despite advances in diagnosis and treatment, the disease still carries a mortality rate of 50-70%. Since there are no specific physical examination (PE) findings, clinical suspicion at the time of presentation is extremely important for diagnosis and especially for early treatment. Therefore, although the outcome was fatal, we aimed to draw attention to the importance of suspecting this disease at the time of diagnosis by presenting a young case that may highlight this issue.

Material and Methods: Our case was a 25-year-old previously healthy male who presented to the emergency department with sudden-onset, severe abdominal pain that began at night and persisted. He had no passage of gas or stool since the pain started and experienced nausea and vomiting. He smoked one pack per day, and his family history included cerebrovascular disease and deep vein thrombosis in second-degree relatives. He was evaluated with physical examination, laboratory tests, and radiological imaging.

Results: The abdomen was minimally distended with generalized tenderness but no guarding or rebound. The white blood cell count was 26,000/μL. The contrast-enhanced abdominal CT reported through outsourced service as normal; however, due to pain disproportionate to examination findings, we re-evaluated the images and detected a thrombus at the root of the superior mesenteric artery (Figure 1). After radiology consultation, AMI was diagnosed, and tissue plasminogen activator was administered. As the patient did not improve, laparotomy was performed 24 hours later, revealing necrosis of most of the small intestine, right colon, and gallbladder (Figure 2). Following Fogarty catheter thrombectomy, bowel resections and anastomoses were completed. Postoperatively, heparin infusion was initiated, and hematology and genetics consultations were obtained. At second-look surgery 48 hours later, necrosis involved all remaining intestinal segments and the distal stomach, and the operation was terminated. Further tests showed deficiencies of protein C, protein S, and antithrombin III, heterozygous factor II and factor V Leiden mutations, and homozygous MTHFR mutation. The patient died one week after the second-look procedure.

Conclusion: AMI is caused by the sudden interruption of intestinal blood flow. Early diagnosis and treatment are life-saving, and clinical suspicion is essential. Severe abdominal pain disproportionate to PE findings strongly suggests AMI and should be considered the diagnosis until proven otherwise.

Top 5 ultra-rare intra-abdominal tumors: A clinical review

Ali Cihat Yıldırım, Yalçın Sönmez, Sezgin Zeren

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: General surgeons frequently manage common abdominal pathologies; however, ultra-rare intra-abdominal tumors present unique diagnostic and therapeutic challenges. These entities often mimic more common conditions, such as gastrointestinal stromal tumors (GIST) or common adenocarcinomas, leading to significant diagnostic delay and complex surgical requirements. This study reviews the clinical presentation and management of five of the rarest documented intra-abdominal malignancies: desmoplastic small round cell tumor (DSRCT), extraosseous ewing sarcoma (EES) of the mesentery, primary retroperitoneal melanoma (PRM), malignant gastric glomus tumor, and primary peritoneal serous carcinoma (PPSC).

Material and Methods: A comprehensive review of surgical literature and pathological case series was conducted to identify intra-abdominal tumors with an incidence typically lower than 1 case per million or those with fewer than 100 documented cases. Data were synthesized focusing on anatomical location, specific immunohistochemical markers required for differentiation, and the extent of surgical resection necessary for local control.

Results: The identified tumors exhibit distinct biological behaviors requiring specialized interventions. DSRCT primarily affects young males and is characterized by the t(11;22)(p13;q12) translocation, requiring aggressive cytoreductive surgery (CRS). EES of the mesentery necessitates wide local excision and is identified via strong CD99 positivity, distinguishing it from GIST. PRM represents a diagnostic enigma, occurring in the retroperitoneum without a detectable cutaneous primary, requiring S100 and HMB-45 staining for confirmation. Malignant gastric glomus tumors are rare variants of perivascular neoplasms that present as submucosal masses, requiring gastrectomy when mitotic activity is high. Finally, PPSC involves widespread peritoneal "caking" while sparing the ovaries, managed through extensive cytoreduction and HIPEC. Across all five entities, R0 resection remains the primary determinant of long-term survival, though the aggressive nature of these tumors often necessitates multi-visceral resection.

Conclusion: Ultra-rare intra-abdominal tumors represent a frontier in general surgery where standardized protocols are often unavailable. Because preoperative imaging is rarely definitive, the surgeon must be prepared for unexpected findings during laparotomy. A multidisciplinary approach involving advanced molecular testing and specialized surgical techniques like CRS/HIPEC is essential. While surgical resection remains the cornerstone of treatment, prognosis remains guarded due to the late presentation and high recurrence rates characteristic of these obscure pathologies.

Keywords: Glomus tumour, melanoma, sarcoma

Should routine cholecystectomy be performed during total gastrectomy? A retrospective analysis of gastric cancer patients

Nesibe Altay, Atahan Hüseyin Karaaslan, Elif Didem Terzi, Ömer Faruk Özkan

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: It is well known that gallstone formation and related biliary complications increase after total and subtotal gastrectomy performed for gastric cancer. Vagotomy, rapid weight loss, and impaired gallbladder motility are considered the main contributing factors. Therefore, the necessity of performing concomitant cholecystectomy during gastrectomy remains controversial. This study aimed to evaluate the effect of simultaneous cholecystectomy on biliary complications in patients undergoing gastrectomy for gastric cancer.

Material and Methods: Sixty patients who underwent total or subtotal gastrectomy for gastric cancer at our center between 2023 and 2025 were retrospectively analyzed. Patients were divided into two groups: those who underwent concomitant cholecystectomy (n=15) and those who did not (n=45). The development of biliary complications and mortality rates during follow-up were evaluated. Data were analyzed using percentages (%) and patient numbers (n).

Results: Of the 60 patients, 25% (n=15) underwent concomitant cholecystectomy during gastrectomy, while 75% (n=45) did not. No biliary complications were observed in 100% (n=15) of patients who underwent simultaneous cholecystectomy during the follow-up period. In the group without cholecystectomy, 4.4% (n=2) of patients developed acute cholecystitis. One patient presented to the emergency department in the second postoperative month and the other in the first postoperative year with right upper quadrant pain, fever, and signs of acute abdomen. All patients who developed acute cholecystitis were in the non-cholecystectomy group. The overall mortality rate was 8.3% (n=5). The causes of death were not related to biliary complications.

Conclusion: Concomitant cholecystectomy during gastrectomy for gastric cancer may be considered a safe approach to prevent biliary complications. The absence of biliary complications in patients who underwent cholecystectomy in this study is noteworthy. The decision for routine cholecystectomy should be individualized, taking into account surgical risks and patient characteristics. Larger patient cohorts and longer follow-up periods are required to clarify the effectiveness of this approach.

Keywords: Total gastrectomy, cholecystectomy, gastric cancer, biliary complications, retrospective analysis

Time-dependent analgesic effects of botulinum toxin and topical glyceryl trinitrate after excisional hemorrhoidectomy: A systematic review and meta-analysis

Mert Yiğit Akdoğan, Furkan Uğur, Ahmet Berkay Arat, Veysel Barış Turhan, Bahadır Kartal, Murat Kendirci

Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: Postoperative pain following excisional hemorrhoidectomy remains a significant clinical problem, adversely affecting patient comfort, recovery, and return to daily activities. Internal anal sphincter spasm is considered a major contributing factor, along with other multifactorial mechanisms. Chemical sphincter relaxation strategies, including botulinum toxin and topical glyceryl trinitrate (GTN), have been proposed to reduce postoperative pain. However, their time-dependent efficacy has not been clearly established. This study aimed to evaluate and compare the effectiveness of botulinum toxin and GTN in postoperative pain control using a systematic review and meta-analysis.

Material and Methods: This systematic review and meta-analysis was conducted in accordance with PRISMA 2020 guidelines. PubMed was systematically searched for randomized controlled trials evaluating botulinum toxin or topical GTN for pain control after excisional hemorrhoidectomy. Studies involving stapled hemorrhoidopexy or Doppler-guided techniques were excluded. Pain outcomes were standardized to a 0-10 visual analog scale (VAS). Mean differences (MD) with 95% confidence intervals (CI) were calculated using a random-effects model for postoperative days 1, 3, and 7.

Results: Nine randomized controlled trials were included in the systematic review, and eight studies comprising 452 patients were eligible for meta-analysis. On postoperative day 1, GTN significantly reduced pain compared to controls (MD -0.72, 95% CI -1.18 to -0.26; p=0.002; I^2=48%), whereas botulinum toxin showed no significant effect (MD -0.21, 95% CI -0.58 to 0.16; p=0.26). On postoperative day 3, both GTN (MD -0.64, 95% CI -1.09 to -0.19; p=0.005; I^2=52%) and botulinum toxin (MD -0.68, 95% CI -1.12 to -0.24; p=0.003; I^2=46%) significantly reduced pain scores. On postoperative day 7, botulinum toxin demonstrated a greater and more consistent analgesic effect (MD -1.12, 95% CI -1.63 to -0.61; p<0.001; I^2=34%), while GTN was not statistically significant (MD -0.38, 95% CI -0.82 to 0.06; p=0.09). Headache was the most common adverse event with GTN, occasionally leading to discontinuation. Botulinum toxin was not associated with increased serious adverse events.

Conclusion: Chemical sphincter relaxation demonstrates time-dependent effects on postoperative pain following excisional hemorrhoidectomy. GTN provides superior pain relief in the early postoperative period, whereas botulinum toxin offers more sustained analgesia in later stages. Considering its single-dose administration and favorable safety profile, botulinum toxin may represent a more durable analgesic option. Further high-quality randomized controlled trials are required to determine optimal treatment strategies.

Keywords: Botulinum toxin, excisional hemorrhoidectomy, postoperative pain

[P-006]

Inflammatory breast cancer: A single-center experience

Kübra Ergin Karabalık, Firdevs Melike Onuktav, Gülay Özbölük, Ebru Şen

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Inflammatory breast cancer is a disease that requires a multidisciplinary approach due to its aggressive biology and high risk of metastasis. Currently, the standard treatment consists of a trimodality approach including neoadjuvant systemic therapy, surgery, and adjuvant radiotherapy. In recent years, advancements in systemic therapies have led to a significant increase in pathological response rates. This development has raised questions regarding the traditional use of modified radical mastectomy in inflammatory breast cancer. The aim of this study was to evaluate the outcomes of patients with inflammatory breast cancer treated with contemporary trimodality therapy.

Material and Methods: In this retrospective study, 24 patients diagnosed with inflammatory breast cancer between 2021 and 2025 were included. Demographic data, clinical and pathological characteristics, disease progression, recurrence, metastatic status, and survival data were obtained from patient medical records.

Results: All patients received neoadjuvant chemotherapy followed by modified radical mastectomy and adjuvant radiotherapy, achieving trimodality treatment. The mean age of the patients was 54.3 years (range: 36-74). The mean follow-up period was 28.6 months (range: 0.7-60.5). Pathological complete response was achieved in 7 patients (29.2%). Axillary evaluation revealed node-negative disease in 45.8% of patients. One patient developed local axillary recurrence, and distant metastases were detected in three patients. Patients who developed metastases died in the second postoperative year.

Conclusion: Trimodality treatment provides significant pathological response rates in patients with inflammatory breast cancer. The pCR rate of 29.2% observed in our series is consistent with the literature and supports the effectiveness of neoadjuvant therapy. High rates of axillary node negativity support current discussions in the literature suggesting that axillary surgery may be limited in selected patients. Further studies with larger cohorts are needed to re-evaluate the axillary approach in inflammatory breast cancer.

Keywords: Inflammatory breast cancer, trimodality treatment, pathological complete response

Vocal cord paralysis after total thyroidectomy: A bibliometric analysis of the global literature

Serkan Demir[1], M Salih Süer[1], Faruk Yazıcı[2], Melih Akıncı[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut State Hospital, Ankara*

Objective: Vocal cord paralysis after total thyroidectomy is a significant complication that directly affects patient quality of life and surgical outcomes. This study aims to bibliometrically analyze the historical evolution, productivity patterns, leading countries, institutions, authors, and thematic trends of the scientific literature on vocal cord paralysis following total thyroidectomy.

Material and Methods: In this bibliometric analysis, studies published in the PubMed database between 1978 and 2025 were reviewed. The search strategy used the keywords: "total thyroidectomy" AND ("vocal cord paralysis" OR "recurrent laryngeal nerve palsy") AND ("complication" OR "postoperative"). Data were analyzed using the Bibliometrix (R) software, evaluating annual publication trends, Bradford's and Lotka's laws, country and institutional productivity, author networks, keyword frequencies, and thematic trends over time.

Results: A total of 536 publications, 202 sources, and 2,565 authors were analyzed. Annual output increased markedly after 2010, with an annual growth rate of 7.72% (Figure 1). The leading contributing countries were Italy, Türkiye, China, France, and the United States. The University of Pisa, the University of Palermo, and the University of Wisconsin-Madison were among the most productive institutions. Bradford's law identified World Journal of Surgery, International Journal of Surgery, and Surgery as core journals (Figure 2). Keyword analysis showed dominance of "humans," "female," "male," "middle aged," "retrospective studies," and "thyroidectomy/methods". Trend analysis indicated an early focus on anatomy and etiology, while recent studies emphasize intraoperative neuromonitoring, prevention strategies, and patient-centered outcomes.

Conclusion: This bibliometric analysis reveals not only the quantitative growth but also the conceptual and methodological evolution of the literature on vocal cord paralysis after total thyroidectomy. The findings show that early research primarily focused on anatomical descriptions and etiological observations, whereas recent studies increasingly emphasize prevention strategies, intraoperative neurophysiological monitoring, standardization of surgical techniques, and patient-centered outcome measures. By systematically identifying the countries, institutions, and journals driving this transition, the study delineates the intellectual hubs and core publication channels of the field. Moreover, keyword and trend analyses indicate a paradigm shift in which vocal cord paralysis is no longer viewed as an inevitable complication but as a predictable, preventable, and manageable surgical outcome. Beyond a descriptive overview of past literature, this analysis provides a strategic roadmap for future clinical research, quality improvement initiatives, and guideline development, offering a robust reference point for advancing surgical outcomes in total thyroidectomy practice.

Keywords: Recurrent laryngeal nerve injury, total thyroidectomy, vocal cord paralysis

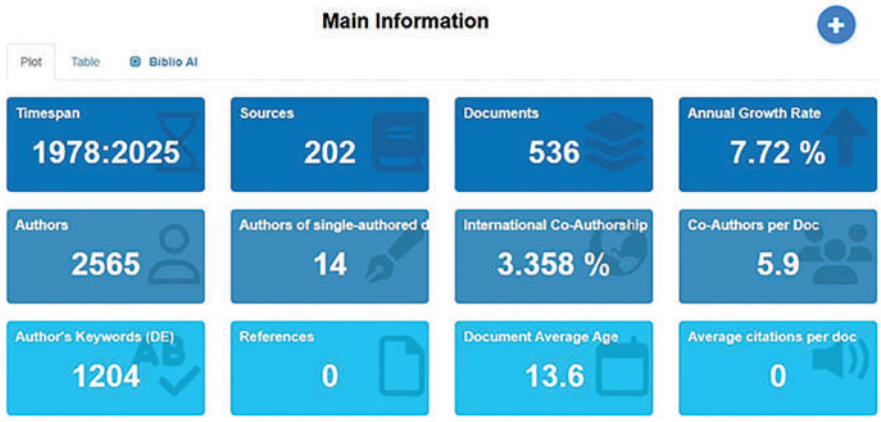

Figure 1. Bibliometric main indicators of the literature on vocal cord paralysis after total thyroidectomy (1978-2025).

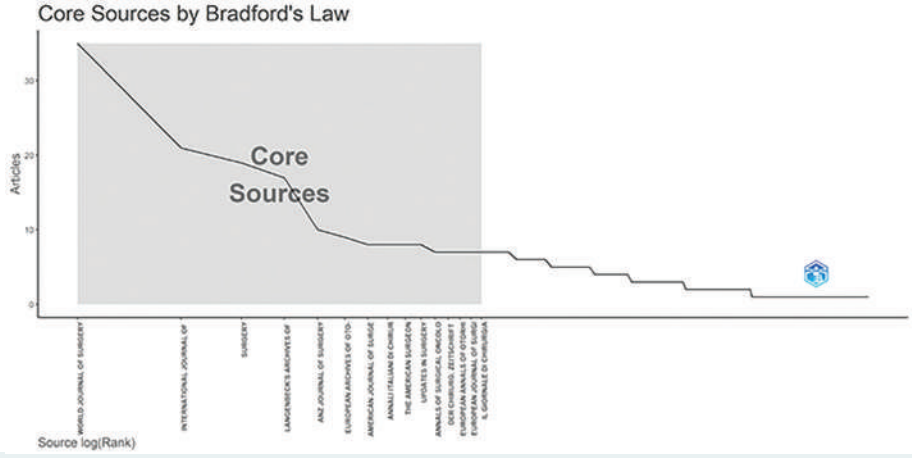

Figure 2. Distribution of core journals in the literature on vocal cord paralysis after total thyroidectomy based on Bradford's law.

Surgical management of complications of endoscopic cystogastrostomy: 7 years of tertiary center experience and technical analysis

Mariya Maşta[1], Enes Şahin[1], Miray Maden[2], Mahmut Burak Kılcı[1], Nihat Zafer Utkan[1]

[1]*Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: Endoscopic cystogastrostomy is used as a minimally invasive method for draining peripancreatic collections. However, serious complications can develop during endoscopic cystogastrostomy; which may require "rescue surgery" as an emergency surgical intervention in a field dominated by intense inflammation and anatomical distortion. This study analyzes the surgical management strategies and clinical outcomes of life-threatening complications occurring after endoscopic cystogastrostomy that could not be managed via endoscopic techniques.

Material and Methods: A total of 58 endoscopic cystogastrostomy performed on 49 patients at our hospital between 2019 and 2025 were reviewed; 9 patients (5 males, 4 females) who required surgical exploration due to procedural complications were retrospectively analyzed. Complications were classified as early-stage perforation and late-stage necrotizing/fistulizing processes. The surgical techniques applied, the need for resection, infection control strategy, postoperative morbidity, mortality, and length of hospital stay were examined.

Results: The mean age of the patients was 53.7 years. The most frequent surgical indication was gastric perforation with necrotizing pancreatitis (44.4%), these cases were treated with necrosectomy and open primary gastric repair. In isolated gastric perforation, laparoscopic primary gastric repair was performed (11.1%). In more complex cases, segmental colon resection+splenectomy+gastric wedge resection (11.1%) was performed due to gastrocolic fistula. For duodenal perforation, antrectomy+loop gastrojejunostomy+ choledochal T-tube drainage (11.1%) was performed. In cases of isolated widespread infected necrosis where endoscopic cystogastrostomy was unsuccessful, necrosectomy (11.1%) and necrosectomy+Bogota bag (11.1%) with open abdomen follow-up were performed. In the postoperative period, 22.2% of patients died due to septic shock and multiple organ failure. The average hospital stay for surviving patients was determined to be 15.6 days.

Conclusion: Although endoscopic cystogastrostomy is a minimally invasive approach with high success rates, serious complications following endoscopic cystogastrostomy are high-risk situations requiring rapid intervention. Perforations due to stent migration and vascular/visceral injuries can be fatal. Early surgery is life-saving in gastric perforations; however, in cases complicated by late-stage necrotizing processes, "rescue" procedures, including aggressive organ resections, are the most critical factor in limiting mortality. As seen in our study, perforation and sepsis management form the basis of surgical success. The high surgical success rate in our series is based on early recognition of the complication and aggressive surgical debridement strategies. Surgical management is one of the key factors determining the prognosis of these patients, and timely surgical intervention is the gold standard. To ensure the successful management of endoscopic cystogastrostomy complications, it is recommended that the procedure be performed in advanced multidisciplinary centers where general surgery and gastroenterology departments operate in coordination.

[P-009]

Scalpel, numbers, and facts: A 22-month surgical experience of 2. 778 cases from a city hospital general surgery department

Ali Cihat Yıldırım, Yalçın Sönmez, Faik Yaylak, Mehmet Fatih Ekici, Sezgin Zeren, Ahmet Tekin

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Regular analysis of surgical departmental activity is essential for quality assurance, resource allocation, and continuous improvement of surgical training programs. This study aims to present a comprehensive statistical analysis of operations performed by four general surgeons (surgeon A, B, C, D) at a city hospital general surgery department.

Material and Methods: Operative notes from all general surgery procedures performed between April 2024 and February 2026 (22 months) were retrospectively reviewed. A total of 2.778 operative notes were extracted from digital records and converted into a structured dataset. For each case, surgeon identity, procedure type, surgical approach (laparoscopic vs. open), urgency status (elective vs. emergency), malignancy status with tumor localization, and perioperative complications were recorded. Emergency cases were further subclassified by indication. Procedures were classified into main categories, and surgeon-specific distributions, year-over-year comparisons, laparoscopic surgery rates, and oncological surgery profiles were analyzed.

Results: The distribution of 2,778 cases among surgeons was: Surgeon A 1.086 (39.1%), surgeon B 997 (35.9%), surgeon C 470 (16.9%), and surgeon D 225 (8.1%). The most common procedures were hernia repair (n=677, 24.4%), cholecystectomy (n=613, 22.1%), thyroid surgery (n=246, 8.9%), appendectomy (n=218, 7.8%), and breast surgery (n=154, 5.5%). Of all cases, 86.9% (n=2,413) were elective and 13.1% (n=365) were emergency procedures. Emergency cases: Acute appendicitis 118 (32.3%), ileus/obstruction 88 (24.1%), acute cholecystitis 67 (18.4%), gastrointestinal perforation 33 (9.0%), and other causes including incarcerated hernia and trauma 59 (16.2%). In cases amenable to laparoscopic approach (cholecystectomy, appendectomy, hernia repair), the overall laparoscopic rate was 64.6%. Procedure-specific laparoscopic rates were 95.9% for cholecystectomy, 79.8% for appendectomy, and 36.6% for hernia repair. Twenty- nine patients (4.2%) had perioperative complications including conversion to open surgery and organ injury. A total of 173 cases (6.2%) involved malignant pathology. Malignancies were breast (n=93, 53.8%), colorectal (n=45, 26.0%), thyroid (n=8), skin/soft tissue (n=6), and gastric (n=5). The monthly average surgical volume increased from 113.3 cases in 2024 to 130.7 in 2025 (a 15.3% increase), while laparoscopic rates remained stable (66.5% vs. 67.9%).

Conclusion: Our department performed a high volume of operations spanning both benign and malignant pathologies over the 22-month study period. The laparoscopic cholecystectomy rate of 95.9% is consistent with current literature standards. The finding that 79.8% of malignant cases were of breast and colorectal origin reflects the department's oncological surgical experience. The low perioperative complication rate (4.2%) and increasing operative volume over time indicate effective and safe surgical practice. Laparoscopic hernia repair was identified as an area for further development.

Keywords: General surgery, surgical activity analysis, laparoscopic surgery, emergency surgery, oncological surgery, perioperative complications

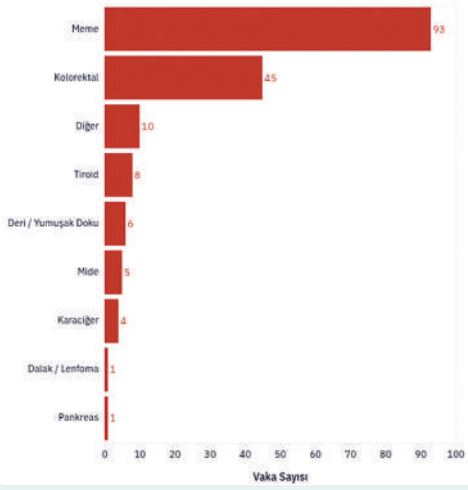

Figure 1. Distribution of the emergency cases.

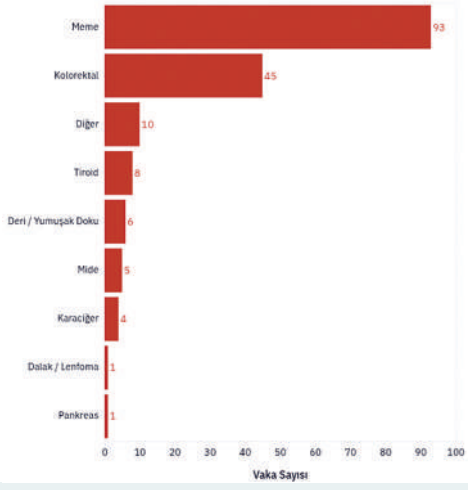

Figure 2. Distribution of the malignant cases.

Clinical, radiological, and histopathological analysis of emergency department-admitted Meckel's diverticulitis cases: A single-center retrospective study

Abdurrahman Özkubat[1], Esra Durmuş[1], Serkan Demir[1], M. Salih Süer[1], Ender Ergüder[1], Alper Yavuz[1], Engin Ölçücüoğlu[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Meckel's diverticulitis is a rare congenital gastrointestinal anomaly that may require surgical treatment when complicated. It often presents with an acute abdomen and may mimic other abdominal pathologies. This study aimed to evaluate the demographic, clinical, radiological, and histopathological characteristics of patients with Meckel's diverticulitis who were admitted to the emergency department and treated surgically.

Material and Methods: Patients who were admitted to the emergency department and diagnosed with Meckel's diverticulitis intraoperatively at the General Surgery Clinic of University of Health Sciences Türkiye, Ankara Etlik City Hospital between October 2022 and August 2025 were retrospectively analyzed. In most cases, the preoperative diagnosis was not Meckel's diverticulitis, and acute appendicitis or other causes of acute abdomen were initially suspected. Age, sex, presenting complaints, physical examination findings, computed tomography (CT) reports, and histopathological results were evaluated. Patients who underwent elective surgery were excluded from the study.

Results: A total of 19 patients were included in the study. The mean age was 39.9±18.8 years (18-74) (Table 1). The most common presenting symptoms were abdominal pain, nausea, and vomiting (15.8%). The most frequent physical examination finding was minimal tenderness in the right lower quadrant (26.3%). CT reports suggested Meckel's diverticulitis in only 3 cases (15.8%), whereas other acute abdominal pathologies were reported in the remaining cases (Table 2). Histopathological examination revealed ectopic gastric mucosa in 4 cases and ectopic pancreatic tissue in 1 case. In many cases, necrosis, hemorrhage, and active inflammation were observed. Histopathological analysis played a decisive role in confirming the diagnosis and identifying ectopic tissue and associated complications.

Conclusion: Although Meckel's diverticulitis is rare, it represents an important cause of acute abdomen and can clinically and radiologically mimic acute appendicitis. Consistent with the literature, the rate of preoperative diagnosis using CT was low; in this study, correct preoperative diagnosis was achieved in only 15.8% of cases (Table 3). Therefore, systematic intraoperative evaluation of the ileal loops is critical, particularly when the appendix appears normal. Histopathological examination not only confirms the diagnosis but also reveals ectopic tissue and associated complications such as necrosis, hemorrhage, and active inflammation, thereby supporting clinical management. In conclusion, Meckel's diverticulitis should be considered in the differential diagnosis of acute abdomen, and careful intraoperative assessment combined with histopathological confirmation may reduce diagnostic delay and morbidity.

Keywords: Acute abdomen, emergency surgery, histopathology, Meckel's diverticulitis, retrospective study

Characteristic	Value
Number of patients (n)	19
Age, mean ± SD (min–max)	39.9 ± 18.8 (18–74)
Most common presenting complaint	Abdominal pain, nausea, and vomiting (15.8%)
Most frequent physical examination finding	Minimal tenderness in the right lower quadrant (26.3%)

Characteristic	Value
Number of cases diagnosed as Meckel's diverticulitis preoperatively by CT	3 (15.8%)
Number of cases with alternative acute abdomen diagnoses on CT	16 (84.2%)
Ectopic gastric mucosa on histopathology	4 cases
Ectopic pancreatic tissue on histopathology	1 case
Necrosis, hemorrhage, and active inflammation on histopathology	Observed in multiple cases

Figure 1. Demographic and clinical characteristics, radiological and histopathological findings.

Study	Design / Population	n	Predominant Clinical Presentation	Preoperative Diagnosis (Imaging)	Ectopic Tissue (Pathology)	Main Message
Hernández et al., 2023 (Frontiers in Surgery)	2004–2022, adults; symptomatic = incidental Meckel	27	Abdominal pain predominant (symptomatic cases)	Very low preoperative diagnostic rate in symptomatic cases (~9%); diagnosis mostly intraoperative	Ectopic gastric mucosa 53% (symptomatic cases)	Preoperative diagnosis is challenging in adults; systematic intraoperative evaluation and pathology are critical
Domínguez et al., 15-year series (complicated Meckel)	Single center, mostly adults; complicated cases	25	Right lower quadrant syndrome 80%	Preoperative diagnosis rare (2 cases) and achieved by CT	Gastric epithelium + ectopic pancreas reported in 1 case	Appendicitis mimicry is frequent; CT may be diagnostic but many cases are missed
TJCL DergiPark, 2023 (Adult symptomatic Meckel, single center)	Adult symptomatic Meckel; clinicopathological analysis	22	Pain 72.7%; nausea–vomiting 50%; bleeding 22.7%	Variable use of US/CT; emphasis on CT in complicated cases	Heterotopic tissue 40.9%; gastric 31.8%; pancreas 4.5%	Ectopic tissue is common; pathology is essential for diagnosis and complication assessment
Dong et al., 2020 (Indian Journal of Surgery)	Emergency adult complicated Meckel; CT-focused	23	Spectrum of inflammation/bleeding/obstruction	Diagnostic yield improved by identifying "blind-ending pouch" patterns on CT	Limited pathology data reported	CT findings are polymorphic; pattern recognition is critical in acute abdomen
Won et al., 2016 (MDCT – Meckel-related SBO)	Small bowel obstruction due to Meckel; MDCT findings	10	All cases presented with SBO	Diverticulum visualized in 50% on MDCT (diagnostic when visible)	Not primary focus	If diverticulum is not visualized, preoperative diagnosis remains difficult; pelvic midline transition zone may provide clues
Bennett et al., 2004 (AJR – CT series)	CT findings of Meckel's diverticulitis	11	Acute abdomen / RLQ–midabdomen pain	Blind-ending pouch and surrounding inflammation on CT	—	Radiological morphological signs facilitate diagnosis
Lequet et al., 2017 (Adult Meckel review)	Review	—	Bleeding/obstruction/inflammation	Diagnosis difficult; imaging limited even in complicated cases	—	Clinical suspicion and intraoperative exploration emphasized
Our study (Etlik City Hospital, 2022–2025)	Emergency admissions; intraoperatively diagnosed Meckel's diverticulitis; retrospective	19	Acute abdomen, appendicitis mimicry; minimal RLQ tenderness prominent	Direct CT diagnosis rate: 15.8% (3/19)	Gastric: 4; pancreas: 1; frequent necrosis/hemorrhage/active inflammation	Consistent with literature: low preoperative diagnostic rate; systematic intraoperative final evaluation and pathology are decisive

Figure 2. Comparison with current literature.

Long-term follow-up results after rectal cancer surgery

Edip Akpınar, Ali Sönmez

Department of General Surgery and Organ Tranplantation, Adana Faculty of Medicine, University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Rectal cancer is among the most common malignancies worldwide and continues to be a significant public health problem. Significant advances have been made in surgical techniques and multimodal treatment strategies over the last decade. This study aimed to evaluate the clinicopathological features and long-term oncological outcomes of patients who underwent surgical resection for rectal cancer at a single center, focusing on five-year follow-up data.

Material and Methods: Patients who underwent surgical resection for rectal cancer at our institution between January and December 2020 were retrospectively evaluated. Demographic data, surgical procedures performed, oncological treatment protocols, pathological staging, tumor grade, lymph node involvement, and tumor status at the distal and peripheral resection margin (CRM) were analyzed. Five-year survival and recurrence data were recorded during periodic follow-ups. Statistical analyses were performed using R software; Student's t-test was used for continuous variables, Fisher's exact test for categorical variables, and the Cox proportional hazards model was applied to determine factors affecting survival. $P<0.05$ was considered statistically significant.

Results: A total of 61 patients were included in the study [median age: 69 years (39-98)]; 39 (64%) were male and 22 (36%) were female. 34% of the patients received neoadjuvant chemoradiotherapy, while 56% received adjuvant therapy. Pathological evaluation revealed T3-T4 tumors in 62% of patients and lymph node positivity in 41%. During the five-year follow-up period, the local recurrence rate was 10%, and the distant metastasis rate was 23%. 71% of recurrences occurred within the first 24 months. The five-year disease-free survival (DFS) rate was calculated as 67%. In Cox proportional hazard analysis, advanced age (HR: 1.04; $p=0.05$) and recurrence (HR: 6.31; $p<0.005$) were identified as independent risk factors for mortality. Recurrence emerged as the strongest predictor of overall survival. Furthermore, CRM positivity, N2b lymph node status, and vascular invasion were strongly associated with disease progression and mortality. Advanced age was consistently associated with increased hazard ratios in all models. Recurrences were observed mostly within the first 24 months, particularly in patients with advanced T and N stages.

Conclusion: Long-term oncological outcomes after rectal cancer surgery are closely related to accurate pathological staging and adherence to multidisciplinary treatment protocols. Given that recurrences are particularly concentrated in the first two years in high-risk patients, stricter and more intensive follow-up strategies are necessary for this patient group.

Keywords: Rectal cancer, 5-year follow-up, LAR, APR, disease-free survival

The role of colonoscopic decompression and surgery in patients with sigmoid volvulus: A single-center experience

Osman Gökhan Gökdere, Bilal Aydoğmuş, Zeynep Arda Acar, Erhan Kızılkaya, Burhan Hakan Kanat, Gökhan Söğütlü

Malatya Turgut Özal University Faculty of Medicine, Malatya

Objective: Sigmoid volvulus is a significant cause of acute mechanical intestinal obstruction and is associated with considerable morbidity and mortality, particularly in elderly patients and those with multiple comorbidities. Management strategies vary depending on the patient's clinical condition, bowel viability, and the presence of complications. Colonoscopic decompression is recommended as the initial treatment in hemodynamically stable patients without signs of peritonitis; however, the optimal timing and role of surgery remain controversial. The aim of this study was to compare the outcomes of colonoscopic decompression and surgical treatment in patients presenting with sigmoid volvulus and to evaluate the effectiveness of different treatment strategies.

Material and Methods: This retrospective, single-center study included 37 patients diagnosed with sigmoid volvulus between January 2021 and December 2025. Demographic data, clinical presentation, treatment modality, length of hospital stay, postoperative complications, and mortality were reviewed. Colonoscopic decompression was performed as the initial treatment in 11 patients (29.7%), while 26 patients (70.3%) underwent primary surgical intervention. The success rate of colonoscopic decompression and the need for conversion to surgery were analyzed. In surgically treated patients, the type of resection—resection with primary anastomosis or Hartmann's procedure—and stoma formation were evaluated.

Results: Successful colonoscopic decompression was achieved in 9 of 11 patients (81.8%). Two patients (18.2%) required early surgical intervention due to failure of endoscopic reduction. Among the 26 patients who underwent surgical treatment, resection with primary anastomosis was performed in 8 patients (30.8%), whereas Hartmann's procedure was performed in 18 patients (69.2%). The mean length of hospital stay was 4.2 days in the colonoscopic decompression group and 8.6 days in the surgical group. The complication rate was lower in the colonoscopic group compared with the surgical group (9.1% vs. 23.1%). The overall mortality rate was 5.4%, and all deaths occurred in the surgical treatment group.

Conclusion: Colonoscopic decompression is a safe and effective initial treatment option in appropriately selected patients with sigmoid volvulus, offering shorter hospital stays and lower complication rates. Surgical intervention remains indispensable in cases of bowel ischemia, perforation, peritonitis, or failed endoscopic decompression. Individualized treatment planning based on patient characteristics and clinical findings is essential to reduce morbidity and mortality in patients with sigmoid volvulus.

Mortality	0 (0%)	2 (7.7%)

[P-025]

Surgical treatment outcomes in siewert type III esophagogastric junction tumors: A single-center experience

Fırat Aslan, Serhat Binici

Department of General Surgery, Van Yüzüncü Yıl University Faculty of Medicine, Van

Objective: Esophagogastric junction (EGJ) tumors constitute a distinct group of patients from a surgical perspective due to their anatomical location and biological behavior. The Siewert classification serves as a guide in treatment planning for these tumors, and type III tumors are subcardial carcinomas considered to be of gastric origin, with the tumor center located 2-5 cm distal to the EGJ. The aim of this study was to evaluate the clinical characteristics and surgical outcomes of patients with Siewert type III EGJ tumors who were surgically treated at our center.

Material and Methods: Between 2024 and 2025, 18 patients who underwent surgical treatment at our clinic with a diagnosis of Siewert type III EGJ tumor were retrospectively analyzed. Patients' demographic data, pathological stages, surgical procedures performed, postoperative complications, and follow-up outcomes were evaluated. All patients underwent total gastrectomy with D2 lymph node dissection and transhiatal distal esophageal resection. Splenectomy was performed only in patients with involvement of the splenic hilum.

Results: Eleven patients were male (61%) and seven were female (39%), with a mean age of 62.4±8.1 years. According to pathological staging, 56% of the patients were stage III, 33% were stage II, and 11% were stage I. The mean number of harvested lymph nodes was 31±6, and R0 resection was achieved in all patients. The postoperative major complication rate was 11%, with no observed mortality. The mean length of hospital stay was 9.2 days, and the mean follow-up period was 24 months. During this period, the overall survival rate was determined to be 72%.

Conclusion: In Siewert type III EGJ tumors, a surgical approach based on gastric cancer principles provides effective and reliable outcomes with acceptable morbidity rates. A multidisciplinary approach and appropriate surgical technique are decisive factors in achieving treatment success.

Keywords: D2 lymphadenectomy, esophagogastric junction, gastric cancer, siewert type III, total gastrectomy

[P-026]

Assessment of malignancy risk in proliferative breast lesions

Çağan Aykurt, Serdar Çoban, Abdülkadir Ünsal

Clinic of Surgical Oncology, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: In our study, we examined clinical and radiological findings to predict the risk of malignancy in proliferative breast lesions.

Material and Methods: Patients who underwent breast tru-cut biopsy at our clinic between August 2020 and 2025 were examined. Fifty cases undergoing wide local excision among patients with biopsy results indicating proliferative breast lesions were included in our study. Patients were evaluated based on four different variables. First, patients with histopathology showing *in situ* or invasive carcinoma were assigned to the malignant group, while patients with other histopathological results were assigned to the benign group. Second, patients were divided into those aged 50 years and older and those younger than 50 years. Third, patients were divided according to the BIRADS category in the mammography findings. Fourth, patients were divided into those with breast density classification A-B and those reported as C-D.

Results: According to histopathological results, the number of patients with malignancy was n=12/50 (24%), and benignity was n=38/50 (76%), and proliferative lesions of the breast were associated with an increased risk of malignancy. In terms of age group, the malignancy rate was n=9/27 (33%) in 27 cases over the age of 50 and n=3/23 (13%) in 23 cases under the age of 50. An increase in malignancy risk was observed with increasing age. The number of patients according to the BIRADS category was BIRADS-0 n=12/50 (24%), BIRADS-3 n=6/50 (12%), BIRADS-4 n=32/50 (64%), while the malignancy rate in the subgroups was BIRADS-0 n=0/12 (0%), BIRADS-3 n=2/6 (33%), BIRADS-4 n=10/32 (31%). The increase in the BIRADS category was parallel to the increase in breast cancer risk. In breast density classification, the number of patients was found to be: A-B pattern n=10/50 (20%), C-D pattern n=40/50 (80%). The incidence of proliferative lesions in the breast was higher in the C-D pattern patient group. Malignancy rates were n=3/10 (30%) in the A-B pattern and n=9/40 (22.5%) in the C-D pattern, with a higher increase in malignancy risk detected in A-B pattern breasts.

Conclusion: Proliferative lesions in the breast increase the risk of breast cancer and are more common in older patients, those with a high BIRADS category, and those with breast density in the C-D pattern. Our study highlights that proliferative lesions in breasts rich in fatty tissue and with an A-B pattern carry a high risk of malignancy. It is recommended that proliferative lesions detected in low-density breasts be evaluated more carefully for malignancy.

Keywords: Proliferative breast lesions, breast density, breast mammography

Our experience with multivisceral resection in retroperitoneal liposarcomas: Surgical management and short-term outcomes of a case series

Bahattin Bayar Bayar, Turgay Sayın, Ahmet Yiğit Kalelioğlu, Betül Alçelik, Batuhan Alp Akpolat, Ata Türker Arikok, Ahmet Oğuz Hasdemir

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Although retroperitoneal, intraabdominal giant liposarcomas are rare among soft tissue sarcomas, they are among the most challenging tumor groups from a surgical perspective due to their large size, late onset of symptoms, and close anatomical relationship with vital neighboring organs. In particular, dedifferentiated and myxoid histopathological subtypes are characterized by aggressive biological behavior, high local recurrence rates, and frequent multiple organ invasion. This necessitates extensive resection and combined organ resection in surgical treatment. Current literature reports that complete surgical resection is the most important prognostic factor determining survival. This study presents the surgical management and short-term clinical outcomes of giant liposarcoma cases with different histopathological subtypes requiring multiple resection.

Material and Methods: Three giant liposarcoma cases with tumor diameter ≥20 cm, operated on at our clinic between 2021, 2025, were evaluated. The patients' demographic characteristics, tumor location and size, surgical procedures performed, concomitant organ resections, perioperative complications, and pathological findings were analyzed in detail. The primary goal of surgical treatment in all cases was to achieve complete or maximal cytoreductive resection by ensuring the widest possible surgical margins. A multidisciplinary approach was adopted in the surgical planning and implementation process; simultaneous urological and gastrointestinal reconstructions were performed when necessary.

Results: The patients' ages ranged from 26 to 71 years, and all patients were male. The tumors were retroperitoneal and/or intraabdominal, with the largest mass measuring 39 cm in diameter. The basic characteristics of the patients are summarized in Table 1. Colon resection was performed in two cases, small bowel resection in two cases, and ureter reconstruction in two cases (Figure 1). Debulking surgery was performed in one case that had undergone seven previous operations due to multicentric recurrences (Figure 2). Pathological examination revealed high-grade undifferentiated liposarcoma in one case and low-grade myxoid liposarcoma in two cases (Figure 3). In the postoperative period, anastomotic leakage and sepsis developed in one patient, which was successfully controlled with a second surgical intervention. All patients were discharged.

Conclusion: Surgical resection is the primary approach in the treatment of giant liposarcomas; however, due to the tumor's close relationship with adjacent organs, multiple organ resections are often necessary in most cases. Therefore, a multidisciplinary approach is essential in the surgical planning and implementation process. Multidisciplinary management is critical for optimizing surgical outcomes and effectively managing perioperative complications. Furthermore, due to the high risk of local recurrence, long-term and close oncological follow-up is mandatory in these patients and may require sequential surgical interventions.

Demographic and clinical analysis of cases tested for *BRCA1* and BRCA2 in breast cancer screening and treatment in the Şanlıurfa Region

Ali Uzunköy[1], Halis Bağ[1], Özlem Öz[2]

[1]*Division of Surgical Oncology, Department of General Surgery, Harran University Faculty of Medicine, Şanlıurfa*

[2]*Department of Medical Genetics, Harran University Faculty of Medicine, Şanlıurfa*

Objective: This study aims to evaluate the relationship between demographic characteristics, genetic test results, and breast cancer molecular subtypes in individuals who underwent *BRCA1* and *BRCA2* gene testing due to a diagnosis of breast cancer or a family history in the Şanlıurfa region.

Material and Methods: A total of 266 individuals who underwent *BRCA1* and *BRCA2* gene testing at the Harran University Faculty of Medicine, Department of Medical Genetics between 2022 and 2025 were retrospectively analyzed. The cases were classified into those diagnosed with breast cancer and those with a family history. *BRCA1* and *BRCA2* positivity, variant of uncertain significance (VUS) status, mean ages, and breast cancer molecular subtypes were analyzed.

Results: Of the 266 cases included in the study, 110 (41.4%) were diagnosed with breast cancer, and 156 (58.6%) were individuals tested due to family history. Pathogenic variants were detected in *BRCA1* in eight cases and in *BRCA2* in twelve cases. Among the *BRCA1*-positive cases, four were breast cancer patients, and all were of the triple-negative subtype. Of the five *BRCA2*-positive breast cancer cases, one was triple-negative, two were Luminal A, and two were Luminal B. The mean age was found to be 38 years for *BRCA1*-positive cases and 40 years for *BRCA2*-positive cases. A *BRCA1* VUS was detected in one case (45 years old, Luminal B subtype). *BRCA2* VUS was detected in six cases, three of whom had breast cancer; the mean age was 44 years. Of the *BRCA2* VUS-positive breast cancer cases, two were triple-negative, and one was Luminal B.

Conclusion: The strong association between *BRCA1* mutations and triple-negative breast cancer in the Şanlıurfa region is noteworthy. Conversely, *BRCA2* mutations are associated with more heterogeneous molecular subtypes. The expansion of regional genetic screening programs and long-term clinical follow-up of BRCA VUS cases are of great importance.

Keywords: Breast cancer, *BRCA1*, *BRCA2*, genetic screening

Cholecystoenteric fistulas: A two-center retrospective analysis

Mustafa Satır[1], Fatih Büyüker[2], Şurahbil Yağbasa[2], Recep Erçin Sönmez[2], Aylin Acar[1], Tolga Canbak[1], Gürhan Baş[2], Orhan Alimoğlu[2]

[1]*University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul*

[2]*İstanbul Medeniyet University, Göztepe Prof. Dr. Süleyman Yalçın City Hospital, İstanbul*

Objective: Cholecystoenteric fistulas are rare clinical entities that usually develop secondary to chronic gallbladder diseases and are often difficult to diagnose. This study aimed to evaluate the clinical characteristics and surgical outcomes of patients treated for cholecystoenteric fistulas in two centers.

Material and Methods: Patients treated for cholecystoenteric fistulas between 2012 and 2025 at Göztepe Prof. Dr. Süleyman Yalçın City Hospital, İstanbul Medeniyet University, and Ümraniye Training and Research Hospital, University of Health Sciences Türkiye, were retrospectively analyzed. A total of 47 patients were included in the study. Demographic characteristics, fistula types, diagnostic modalities, surgical approaches, operative time, and postoperative outcomes were evaluated.

Results: There were 25 males and 22 females. The mean age was 63 years (range: 27-91). Cholecystoduodenal fistula was detected in 25 patients, 7 of whom had concomitant gallstone ileus. Cholecystogastric fistula was present in 8 patients, cholecystocolonic in 9, cholecystocoloduodenal in 3, cholecystogastroduodenal in 1, and cholecystocutaneous fistula in 1 patient. In the preoperative evaluation, ultrasonography was performed in 26 patients, computed tomography in 9, and magnetic resonance imaging in 6, while 7 patients underwent more than one imaging modality. Preoperative suspicion of a fistula was reported in only 5 patients, whereas the diagnosis was established intraoperatively in the remaining cases. Regarding the surgical approach, open surgery was performed in 10 patients and laparoscopic surgery in 8 patients, while conversion from laparoscopy to open surgery was required in 29 patients. The mean operative time was 140 minutes. Early postoperative complications occurred in five patients; bile leakage was observed in two patients and duodenal leakage in one patient. Three patients died in the postoperative period due to comorbidities.

Conclusion: Cholecystoenteric fistulas are rare clinical conditions that are difficult to diagnose and are frequently identified intraoperatively. Although a laparoscopic approach is feasible, conversion rates remain high. Appropriate surgical planning and perioperative management by an experienced and multidisciplinary team are crucial in the management of these patients.

A rare surgical emergency: Diagnosis, surgical strategy, and clinical outcomes in cecal volvulus

Yiğit Kalelioğlu, Muhammed Metin Yüksel, Muhammed Salih Süer, Serkan Demir, Bahattin Bayar, Engin Ölçücüoğlu

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Although rare among colonic volvuluses, cecal volvulus is a surgical emergency that can lead to severe clinical consequences, including intestinal ischemia, perforation, and sepsis, if diagnosis is delayed. This study aims to evaluate the clinical characteristics, surgical management, and postoperative outcomes of cecal volvulus cases treated at the University of Health Sciences Türkiye, Ankara Etlik City Hospital, Department of General Surgery, and to discuss these findings in light of the current literature.

Material and Methods: In this retrospective observational study, four patients who presented to the emergency department between October 2022 and October 2025 and were intraoperatively diagnosed with cecal volvulus were evaluated. All patients underwent surgical treatment. Demographic characteristics, presenting symptoms, laboratory and imaging findings, intraoperative surgical approaches, and postoperative clinical outcomes were analyzed retrospectively. Continuous variables were presented as mean ± standard deviation and median (IQR), while categorical variables were expressed as frequencies and percentages.

Results: The mean age of the patients was 48.0±27.7 years, and 50% were female (Table 1). All patients presented via the emergency department, with a median interval of 2.5 days from admission to surgery. Computed tomography (CT) provided an accurate preoperative diagnosis in all cases (Table 2). Intraoperative evaluation revealed 360 °C cecal rotation in all patients; ischemic bowel was present in 75%, necrosis in 50%, and perforation in 25%. All patients underwent bowel resection: 75% received a right hemicolectomy and 25% an ileocolic resection. A stoma was created in half of the patients (Table 3). The postoperative complication rate was 50%, with a Clavien-Dindo Grade III complication rate of 25%. No 30-day or 90-day mortality occurred (Table 4).

Conclusion: This study demonstrates that despite its rarity, cecal volvulus is a surgical emergency with high rates of intestinal ischemia, necrosis, and resection requirements, offering low tolerance for delay. Consistent with the literature, CT provided high diagnostic accuracy, significantly facilitating the surgical decision-making process. The absence of 30-day and 90-day mortality in our series highlights the decisive role of timely intervention. In the presence of ischemic or necrotic bowel, a resection-based surgical strategy stands out as a safe and effective option with acceptable morbidity. Consequently, early diagnosis, prompt surgical decision, and an appropriate resection strategy based on intraoperative findings are the fundamental elements determining patient prognosis.

Keywords: Bowel ischemia, cecal volvulus, colonic volvulus, emergency surgery, right hemicolectomy

Urachal cyst: A single-center retrospective clinical and surgical experience

Esra Durmuş[1], Abdurrahman Özkubat[1], Faruk Yazıcı[2], M.Salih Süer[1], Serkan Demir[1], Bahattin Bayar[1], Serhat Tokgöz[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Ankara Sait Ertürk City Hospital, Ankara*

Objective: Urachal cyst is a rare congenital anomaly that may become symptomatic in adulthood or be detected incidentally. This study aimed to evaluate the clinical, surgical, and pathological characteristics and postoperative outcomes of patients who underwent surgery for urachal cyst at the Clinic of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital between October 2022 and August 2025.

Material and Methods: Twenty-two patients who underwent excision for urachal cyst were retrospectively analyzed. Demographic data, symptoms, surgical approach, performance of umbilectomy, histopathological findings, and postoperative complications were evaluated according to the Clavien-Dindo classification. Descriptive statistics were presented as frequency, percentage, mean ± standard deviation, and median (min-max).

Results: The mean age of the patients was 63.4±14.0 years, and 77.3% were male. The most common presenting symptom was pain (68.2%), followed by hematuria (18.2%) and discharge (9.1%). All patients underwent open surgery, and umbilectomy was performed in 13.6% of cases. Histopathological examination revealed benign pathology in 95.5% and malignancy in 4.5% of patients. Lesions were non-infected in 90.9% and infected in 9.1% of cases. In the postoperative period, Clavien-Dindo Grade I complications were observed in 77.3% of patients, while Grade II (4.5%), Grade III (4.5%), and Grade IV (13.6%) complications were rare. No recurrence was detected. The mean length of hospital stay was 17.5±21.3 days, with a median of 14 (3-100) days.

Conclusion: The detection of malignancy in only one patient (4.5%) among 22 cases suggests that malignant transformation, although rare, should be considered in urachal cysts. Therefore, surgical excision of urachal cysts is important for both diagnostic and therapeutic purposes. The absence of recurrence and the predominance of minor complications (Clavien-Dindo Grade I, 77.3%) support the safety of surgical intervention. Despite being a single-center study with a limited sample size, satisfactory outcomes with low complication rates highlight the effectiveness and reliability of urachal cyst surgery and emphasize the indispensable role of histopathological evaluation in clinical management.

Prognostic role of histopathological features on survival in gallbladder cancer: A single-center retrospective study

Muhammet Halil Duru, Hasan Özmen, Furkan Uğur, Mahmut Arif Yüksek, Orhan Aslan, Muhammed Gömeç

Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: Gallbladder cancer (GBC) is a rare gastrointestinal malignancy characterized by aggressive behavior, frequent diagnosis at advanced stages, and poor prognosis. Although surgical resection is the only potentially curative treatment, survival outcomes vary considerably depending on histopathological features. However, reliable prognostic histopathological parameters remain limited. This study aimed to evaluate the prognostic impact of histopathological features on survival in patients undergoing surgery for gallbladder tumors.

Material and Methods: Patients who underwent cholecystectomy for gallbladder lesions between 2021 and 2025 were retrospectively analyzed. Cases with biliary intraepithelial neoplasia (BilIN) and non-epithelial tumors were excluded. In patients with invasive GBC, histological type, tumor stage (pT), lymph node status (pN), surgical margin status, lymphovascular invasion (LVI), and perineural invasion (PNI) were recorded. Overall survival (OS) was defined as the time from the start of postoperative follow-up to death or last follow-up. Survival was analyzed using the Kaplan-Meier method and compared using the log-rank test. Due to the small sample size, Cox regression analyses were considered exploratory.

Results: A total of 12 patients were evaluated; 9 with invasive GBC were included in the survival analysis. Histologically, 66.7% were adenocarcinoma, 22.2% adenosquamous carcinoma, and 11.1% carcinosarcoma. Tumors were classified as pT3 in 66.7% of patients. Lymph node metastasis was detected in 33.3%, and positive surgical margins (R1) in 55.6%. Lymphovascular invasion was present in 44.4% and perineural invasion in 66.7% of patients. Among 8 patients with available OS data, 5 deaths occurred during follow-up, and the median OS was 257 days (approximately 8.5 months). Although shorter survival was observed in patients with advanced stage (pT3), positive margins, lymph node metastasis, and PNI, these associations were not statistically significant ($p>0.05$).

Conclusion: This single-center retrospective study suggests that adverse histopathological features, including advanced tumor stage, positive surgical margins, lymph node involvement, and perineural invasion, may be associated with poorer survival in GBC. Although statistical significance was not achieved, the findings are clinically relevant and consistent with the literature. Further multicenter studies with larger cohorts are needed to confirm these results.

Complex hepatic resection for alveolar echinococcosis: A single-center experience with vascular reconstruction in 14 patients

Burak Kutlu[1], Kaan Sünter[2], Anıl Tugay Özcan[3], Erkin İsmail[1]

[1]*Clinic of General Surgery, Ankara Acıbadem Hospital, İstanbul*

[2]*Clinic of General Surgery, Sivas Numune Hospital, Sivas*

[3]*Department of General Surgery, Ankara University Faculty of Medicine, Ankara*

Objective: Alveolar echinococcosis (AE) is a rare zoonosis caused by the larval form of Echinococcus multilocularis, but it has a high mortality rate if left untreated. This study evaluated the epidemiological characteristics, radiological findings, surgical approaches, and early outcomes of hepatic AE cases operated on at our center.

Material and Methods: This retrospective, single-center cohort study included patients over 18 years of age who underwent elective liver resection for hepatic AE at Acıbadem Ankara Hospital between 2019 and 2024. Patients who received only medical treatment were excluded. All cases were evaluated in a multidisciplinary council, and preoperative staging was performed according to the WHO-IWGE PNM classification. Surgical margins, need for vascular and biliary reconstruction, complications (Clavien-Dindo), and length of hospital stay were analyzed.

Results: A total of 14 patients were included in the study. The mean age was 32.8±9.1 years, and the mean BMI was 25.2±4.5 kg/m²; 42.8% of the patients were female. All cases were referred from Kyrgyzstan, and 50% had recurrent disease. The mean tumor diameter was 11.1±3.3 cm. Local invasion of adjacent organs was detected in 35.7%, and major vascular invasion in 71%. One patient (7.1%) had pulmonary metastasis. Segmentectomy (50%) was the most frequently performed procedure among resection types. Vascular reconstruction was frequently necessary; there were cases where inferior vena cava and/or portal vein repair was performed. Biliary reconstruction was performed in 35.7% of cases. The mean hospital stay was 7.5 days (5-15). Three patients (21%) developed early major complications. Histopathologically, AE was confirmed in all cases; R1 resection was present in 92.8%. All patients received postoperative albendazole treatment.

Conclusion: Complete resection is the only curative treatment option for hepatic AE when possible; however, advanced stage and vascular invasion are common. Multidisciplinary evaluation and aggressive surgical approach with major vascular/biliary reconstruction when necessary can be safely applied. Long-term postoperative albendazole treatment plays a critical role in disease control, especially in the presence of positive surgical margins. Early diagnosis and appropriate surgical planning in young patient populations from endemic regions can improve long-term survival.

Safety, efficacy, and outcomes of percutaneous endoscopic gastrostomy (PEG) performed under local anesthesia in ASA III-IV patients

Yasemin Dönmez Yurtsever

Çarşamba State Hospital, Samsun

Objective: Percutaneous endoscopic gastrostomy (PEG) is an effective method for providing long-term enteral nutritional support in patients who are unable to receive adequate and safe oral nutrition. However, due to advanced age, high ASA scores, and accompanying comorbidities, the use of sedation may pose significant risks in this patient population. The aim of this study was to evaluate the safety, efficacy, and complication rates of PEG performed under local anesthesia in ASA III-IV patients and to identify potential risk factors associated with the procedure.

Material and Methods: In our clinic, 196 patients in ASA III-IV risk group who underwent PEG after indication was determined between 2024 and 2025 were retrospectively analyzed. Thirty eight patients who could not tolerate topical pharyngeal anesthesia and required sedation during the procedure were excluded from the study, leaving 158 patients for analysis. In all cases, upper gastrointestinal endoscopy was performed under topical pharyngeal anesthesia. After identifying the appropriate entry site, local infiltrative anesthesia with lidocaine and adrenaline was administered to the anterior abdominal wall, and the PEG catheter was placed using the standard pull technique. Demographic characteristics, body mass index (BMI), procedure duration, hospitalization unit, comorbidities, and early and late complications were recorded. Factors associated with complications were analyzed using univariate and multivariate statistical methods.

Results: The mean age of the patients was 81.6±9.7 years, and the mean BMI was 24.7±3.6 kg/m². The average procedure duration was 15.4±3.6 minutes. Of the patients, 29.7% were hospitalized in the intensive care unit, while 70.3% were followed in palliative care units. Early complications occurred in 7.0%, late complications in 13.3%, and the overall complication rate was 19.6%. No statistically significant association was found between complication development and age, hospitalization unit, comorbidities, or procedure duration ($p>0.05$). While the presence of a tracheostomy did not affect complication rates, procedure duration was significantly longer in patients with tracheostomy (19.0±2.4 minutes). No significant correlation was observed between BMI and procedure duration. Furthermore, triple analyses did not identify any independent predictors of complication development.

Conclusion: Performed under local anesthesia, the PEG procedure is a safe and feasible procedure with procedure times similar to those reported in the literature and acceptable complication rates. In patient populations at high risk for sedation, a local anesthesia-based PEG approach represents an effective and strong alternative in clinical practice.

Keywords: PEG, local anesthesia, ASA 3-4

Deep learning-based detection of perianal fistula on pelvic MRI using a transfer learning approach

Hamide Figen Batu[1], Volkan Doğru[1], Anıl Ozan Karaaslan[2]

[1]*Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya*

[2]*Department of Radiology, Akdeniz University Faculty of Medicine, Antalya*

Objective: Accurate detection of perianal fistula on pelvic MRI is critical for surgical planning and recurrence prevention. Deep learning-based image analysis may provide objective support for radiologic assessment; however, capturing complex or subtle fistulous tracts using only two-dimensional (2D) images remains a significant challenge.

Material and Methods: In this retrospective study, pelvic MRI images from patients with suspected perianal fistula were labeled according to expert radiologic evaluation. The dataset was divided into training (n=312), validation (n=39), and independent test (n=39) sets. Individual MRI slices were classified using a transfer learning approach based on a pretrained ResNet18 architecture. Model performance on the independent test set was evaluated using accuracy, sensitivity (recall for fistula), specificity, area under the receiver operating characteristic curve (AUC-ROC), precision, and F1-score. The confusion matrix for the test set is presented in Figure 1.

Results: On the independent test set (n=39), the model achieved an overall accuracy of 64.1% and an AUC-ROC of 0.772. Sensitivity for fistula detection was 54% (14/26), and specificity was 85% (11/13). Precision was 0.88 and the F1-score was 0.67. The model demonstrated higher specificity than sensitivity, indicating better performance in ruling out fistula absence (Figure 1). Training and validation loss and accuracy curves showed stable convergence without evident overfitting (Figure 2). The relatively low sensitivity may reflect limitations inherent to slice-based 2D analysis; in some cases, fistulous tracts were not clearly visualized on individual slices due to their tortuous course and plane dependency. An example of a perianal fistula MRI image (left: original; right: annotated) is shown in Figure 3.

Conclusion: The transfer learning-based CNN demonstrated moderate diagnostic performance in detecting perianal fistula on 2D pelvic MRI slices, with particularly strong specificity and acceptable discriminative ability (AUC-ROC). This approach may serve as an adjunct tool for radiologic assessment, particularly in excluding fistula presence. However, limited sensitivity highlights the constraints of single-slice classification in fully representing complex fistula anatomy. Future improvements may include multi-slice or 3D volumetric analysis, incorporation of additional MRI sequences, and more advanced architectures. Larger, multicenter validation studies are warranted.

A rare cause of mechanical ileus: Small intestine epithelioid mesothelioma

Abdülaziz Emek, Turgay Şimşek, Mahmut Burak Kılcı, Enes Şahin, Sertaç Ata Güler, Mehmet Furkan Avcı, Orhan Tatlı, Fatih Özsaray, Nuh Zafer Cantürk

Kocaeli University Faculty of Medicine, Kocaeli

Objective: Mesothelioma is a rare and aggressive malignancy that primarily affects the pleura and peritoneum. Peritoneal mesothelioma usually presents with diffuse involvement. Focal involvement of the small bowel is extremely rare and may present with mechanical ileus. Rare malignancies should be considered in the differential diagnosis of mechanical ileus cases developing in patients without a history of abdominal surgery. This case presents a mechanical ileus due to an epithelioid-type mesothelioma located in the ileum.

Material and Methods: The clinical, imaging, endoscopic, and surgical findings, as well as the histopathological result, of a 67-year-old male patient with intermittent cramping abdominal pain, abdominal distension, vomiting, and constipation for approximately two months were retrospectively evaluated.

Results: The patient had no history of abdominal surgery. Physical examination revealed abdominal distension and widespread tenderness. Rebound tenderness and abdominal guarding were not observed. Laboratory values were within normal limits. Contrast-enhanced abdominal computed tomography (CT) showed a mass consistent with asymmetric wall thickening at the ileal level. Significant small bowel dilatation was observed proximally. Enteroscopy revealed a semianular stricture in the distal ileum that significantly narrowed the lumen, which was marked with a hemoclip. Surgical exploration for mechanical ileus revealed a methylene blue-marked ileal mass and proximal dilatation. Two implants were also identified adjacent to the mass. Segmental small bowel resection and primary anastomosis were performed to include the mass and implants. Histopathological examination showed that the mass and implants were consistent with epithelioid-type mesothelioma. Intestinal function improved on the third postoperative day, and the patient was discharged without complications on the sixth day.

Conclusion: Small bowel epithelioid mesothelioma is an extremely rare malignancy that can present with mechanical ileus. Rare malignancies should be considered in the differential diagnosis of patients presenting with unexplained mechanical ileus findings and no history of surgery. Surgical resection is the primary diagnostic and therapeutic approach in these cases.

Carcinoid tumors detected after appendectomy: A single-center experience of 11 cases

Yiğit Kalelioğlu, Uğurcan Bulut, Serkan Demir, Alper Yavuz, Muhammed Salih Süer, Deniz Kütük, Engin Ölçücüoğlu

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Although incidental detection of carcinoid tumors after emergency appendectomy performed for acute appendicitis is rare, it is of critical importance in determining the appropriate post-pathological treatment strategy. This study aimed to comprehensively evaluate the clinical, surgical, and histopathological characteristics of patients diagnosed with carcinoid tumors following appendectomy at our institution.

Material and Methods: Patients who underwent surgery with a preliminary diagnosis of acute appendicitis at University of Health Sciences Türkiye, Ankara Etlik City Hospital General Surgery Department between October 2022 and October 2025 and were diagnosed with carcinoid tumors on histopathological examination were retrospectively analyzed. Demographic characteristics, presenting symptoms, surgical technique, tumor localization and size, histological grade, Ki-67 proliferation index, presence of lymphovascular and perineural invasion, and surgical margin status were evaluated.

Results: A total of 11 patients (3 males, 8 females) were included in the study (Table 1). The mean age was 30.5±12.4 years, with a median age of 25 years. The most common presenting symptom was right lower quadrant tenderness (Table 2). Laparoscopic appendectomy was performed in 9 patients (82%), while open appendectomy was performed in 2 patients (18%). Tumor size was ≤1 cm in 2 patients, 1-2 cm in 5 patients, and ≥2 cm in 4 patients (Table 3). Most tumors were located distally. The Ki-67 proliferation index was below 5% in 91% of cases. No lymphovascular or perineural invasion was detected. Surgical margins were negative in all patients, and no additional resection was required.

Conclusion: Incidental carcinoid tumors detected after appendectomy for acute appendicitis are more commonly observed in young female patients and small-sized lesions. Low proliferative activity and absence of invasive features eliminate the need for additional surgical intervention in most cases. These findings are consistent with current guidelines and large case series reporting that the majority of appendiceal neuroendocrine tumors are low-grade and low-proliferative, and appendectomy alone is usually sufficient in patients without risk factors (Table 4). Our results emphasize the indispensable role of routine histopathological evaluation of appendectomy specimens in diagnosis and treatment planning.

Sessile serrated adenoma in the etiology of acute appendicitis: Clinical and histopathological analysis of six cases

Sıddık Solak, Uğurcan Bulut, Muhammed Salih Süer, Serkan Demir, Alper Yavuz, Şener Balas

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Luminal obstruction is the most common etiological factor in the pathogenesis of acute appendicitis. In rare cases, neoplastic lesions located within the appendiceal lumen may also lead to acute appendicitis. Although sessile serrated adenoma (SSA) is recognized as an important precursor lesion in colorectal carcinogenesis, its association with appendicitis etiology has been reported only rarely. The aim of this study was to present cases of acute appendicitis associated with SSA along with their clinical, laboratory, and histopathological characteristics, and to discuss the potential implications for surgical practice.

Material and Methods: Patients who underwent appendectomy with a preliminary diagnosis of acute appendicitis between October 2022 and October 2025 and were found to have SSA on histopathological examination were retrospectively evaluated. Demographic data, clinical symptoms, laboratory parameters (WBC, CRP), imaging findings, macroscopic examination results, histopathological findings, presence of accompanying inflammation, postoperative colonoscopy findings, mortality, and follow-up data were analyzed.

Results: Six patients (three female and three male) were included. The mean age was 64.8±20.2 years, and the median age was 72.5 years. Presenting symptoms were typical in three cases and atypical in three cases. Imaging findings were consistent with acute appendicitis in five patients, while one patient exhibited atypical imaging features. Laboratory evaluation revealed the pattern “normal WBC - elevated CRP” (n=3); two patients had elevations in both WBC and CRP, whereas one patient had normal values for both parameters. Macroscopically, four cases demonstrated normal specimens, one case showed inflammatory changes, and one case exhibited a thick-walled cystic appearance.Histopathology revealed “SSA with low-grade dysplasia” in three cases and “SSA without dysplasia” in three cases. Accompanying inflammation was present in three patients. Postoperative colonoscopy was performed in all patients, and a polyp/lesion was detected in one patient. During follow-up, no recurrence or lesions were observed. One patient died during follow-up.

Conclusion: SSA represents a rare but significant cause of acute appendicitis. Our findings indicate these cases tend to occur at an older age than appendicitis, frequently present with elevated CRP levels in the presence of normal WBC values, and demonstrate a rate of low-grade dysplasia on histopathology. Furthermore, the detection of lesions on postoperative colonoscopy in one patient suggests that this patient population may carry an increased risk for colorectal neoplasia. These results emphasize, in cases of appendicitis, particularly in the presence of age, atypical clinical presentation, and elevated CRP levels, SSA should be considered, and all such patients should undergo postoperative colonoscopic surveillance following evaluation.

In the treatment of pilonidal sinus, the distance from the pilonidal line for primary closure and flap techniques: 2 cm rule

Emrah Uludağ

Kocaeli State Hospital, Kocaeli

Objective: The basic principle accepted in the treatment of pilonidal sinus is to shift the line of gravity from the midline to the lateral side by performing asymmetric excision and primary closure or by applying a flap technique. However, primary closure is not possible in cases where the sinus pathways reach distant points. In this study, we wanted to present the techniques we applied in two different patient groups according to whether the sinus was located 2 cm below or above the midline.

Material and Methods: From January 2019 to December 2023, 104 patients with pilonidal sinus disease were operated on according to the distance of the sinus from the interglutealmedian line. We wanted to prospectively present the experiences of two general surgeons from a single center. In cases where pilonidal sinus openings were less than 2 cm from the intergluteal line, we applied the asymmetric excision and primary closure technique (group 1), and in cases where the sinuses were at least 2 cm away from the midline, we applied the flap technique (group 2). The demographic characteristics of the patients, postoperative course and recurrence rates were recorded. The average follow-up period was 24 months.

Results: In group I (N:67, 40M/27F), the mean age was 21 (range 18-35), and in group II (N:37, 30M/17F), it was 27 (range 18-51). There was no significant difference in terms of postoperative infection (5% vs. 3%), wound dehiscence (3% vs. 2%), and recurrence rate (2% vs. 1%). Hospital stay was longer in group 2.

Conclusion: The key point in pilonidal cyst treatment is to reposition the intergluteal line of gravity in a way that prevents recurrence.In cases where primary closure is difficult, and in pilonidal openings exceeding 2 cm from the midline, the flap technique, which prevents possible tension, wound dehiscence, and recurrence, can be reliably applied.

Our results of open lateral internal sphincterotomy performed under local anesthesia in the surgical treatment of chronic anal fissure

Emrah Uludağ

Clinic of General Surgery, Kocaeli State Hospital, Kocaeli

Objective: Chronic anal fissure is one of the most frequently encountered diseases in general surgery outpatient clinics. Although many medical treatment options have been developed in recent years, open lateral internal sphincterotomy remains one of the best treatment options. This technique is performed under spinal anesthesia in most places, or less frequently under general anesthesia. The aim of this study is to evaluate our results of lateral internal sphincterotomy performed under local anesthesia.

Material and Methods: This study includes 94 patients who underwent surgery in the minor surgical intervention room of the Clinic of General Surgery at Kocaeli State Hospital between January 2021 and April 2023. 75 of the patients were women and 19 were men. These patients were operated on by two different specialists. Before the operation, patients were not asked to fast except for a rectal enema. In all patients, a silicone cushion-supported Sims position and band stretching were used. Before local anesthesia, a cream containing 25 mg lidocaine and 25 mg prilocaine, which provides a highly effective anesthetic to the mucous membranes, was applied (approximately 15 minutes beforehand). (This cream used before local anesthesia greatly relieved the anal local anesthesia). Afterwards, 4-quadrant anorectal anesthesia was applied. Along with LIS, anal papilla excision and possible external hemorrhoid packets were also excised. Patients were called for follow-up at certain intervals. The findings were recorded digitally.

Results: Demographic data, clinical complaints, surgical data, early and late complications, recurrence rates, and follow-up periods of the patients were recorded. The patients' incontinence status was evaluated using the Cleveland continence score. Only 1 patient experienced an early complication (perianal infection), while 1 patient experienced recurrence. Permanent incontinence was not observed in any patient.

Conclusion: Open lateral internal sphincterotomy performed under local anesthesia is an effective, outpatient procedure with an extremely low recurrence rate for the treatment of chronic anal fissures.

Keyword: Rapid relief with minimal procedures in the treatment of chronic anal fissures

Applicability of oncoplastic breast surgery at different technical levels and clinical outcomes: Findings from a tertiary care center

Derya Selamoğlu, Murat Demır, Işıl Aladağlı, Baki Ekçi

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Breast cancer is the most common malignancy in women, and surgery remains the primary treatment in eligible patients. In recent years, oncoplastic breast-conserving surgery (O-BCS), which preserves oncological safety while improving cosmetic outcomes, has gained increasing importance. O-BCS includes the techniques that allow adequate tumor excision with simultaneous reshaping of the breast. This study aimed to demonstrate the feasibility and present the clinical outcomes of oncoplastic surgery performed using different techniques and levels in a tertiary care center.

Material and Methods: Patients who underwent O-BCS at the 3rd Department of Surgery of University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital between August 1, 2022 and August 31, 2025 were retrospectively evaluated. Demographic characteristics, tumor laterality, operative time, length of hospital stay, pathological diagnosis, and surgical procedures were analyzed.

Results: A total of 69 patients were included, with a mean age of 55.07±12.55 years. Forty patients had left-sided, 27 right-sided, and 2 bilateral breast cancer. The mean operative time was 129.20±72.41 minutes and the mean hospital stay was 2.26±1.90 days. Pathological evaluation revealed invasive ductal carcinoma in 57 patients, invasive lobular carcinoma in 5, ductal carcinoma *in situ* in 2, angiosarcoma in 1, lobular carcinoma *in situ* in 1, mucinous carcinoma in 1, synchronous IDC + ILC in 1, and ILC + DCIS in 1 patient. Modified radical mastectomy was performed in 11 patients and breast-conserving surgery in 58. Among patients undergoing BCS, sentinel lymph node biopsy was performed in 52, axillary dissection in 4, and BCS alone in 2. Four patients underwent bilateral subcutaneous mastectomy with reconstruction (three implant-based and one DIEP flap). Considering all procedures, reconstruction was performed using a latissimus dorsi flap in 4 patients, prepectoral implant in 3, DIEP flap in 3, and racquet mammoplasty in 2, while volume displacement techniques were used in 29 patients.

Conclusion: O-BCS is based on three main principles: tumor excision within reduction mammoplasty patterns, the use of modified techniques to facilitate resection, and volume replacement with local perforator flaps. Optimal outcomes require a multidisciplinary approach involving breast and plastic surgeons or surgeons trained in both fields. Patients should be informed about the possible aesthetic and oncological changes and complications. O-BCS can be performed at different levels according to the surgeon's training and experience. In our clinic, oncoplastic procedures at all levels can be safely performed, with plastic surgery support particularly important for advanced techniques. In selected patients, O-BCS provides satisfactory oncological and cosmetic outcomes.

Late-onset giant lateral metastasis of papillary thyroid carcinoma: The significance of dynamic surveillance in light of the 2025 ATA guidelines

Hakan Ataş[1], Eda Nural[2], Tanju Tütüncü[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

[2]*Department of General Surgery, Kahramanmaraş State Hospital, Kahramanmaraş*

Objective: Although papillary thyroid carcinoma (PTC) is generally considered an indolent malignancy, it may manifest aggressive regional recurrences after latent periods exceeding a decade. Regardless of the initial staging, the 2025 ATA guidelines emphasize the importance of lifelong "dynamic risk stratification" and "individualized management" approaches. This case presents a giant metastatic recurrence emerging 11 years after primary surgery, encasing neurovascular structures and presenting with a cutaneous fistula, discussed in the context of current guideline principles.

Material and Methods: A 75-year-old female presented with a rapidly enlarging, painful neck mass on the left side, which had fistulized to the skin. Her medical history included bilateral total thyroidectomy and 100 mCi RAI therapy for PTC in 2011; however, she had been lost to follow-up in recent years due to pandemic-related conditions. Radiologic evaluations (CT and PET/CT) identified a necrotic mass approximately 7 cm in size at levels 3-4 on the left side, characterized by 360-degree encasement of the carotid artery, invasion of the internal jugular vein, and infiltration of the sternocleidomastoid muscle (SUV_{max}: 33.3) (Figure 1). Following confirmation of metastasis via FNAB and Tg-washout (1752 ng/mL), a radical left lateral neck dissection was performed (Figure 2).

Results: Histopathological examination revealed metastasis in 7 of the 40 resected lymph nodes. The largest metastatic focus measured 4.5 cm in diameter, with extensive extracapsular extension and soft tissue invasion. Immunohistochemical analysis demonstrated TTF-1 positivity, while the absence of thyroglobulin, PAX-8, and Napsin-A expression—combined with high metabolic activity—was interpreted as "aggressive biological transformation" or "dedifferentiation".

Conclusion: The 2025 ATA guidelines advocate for an "individualized dynamic surveillance" model based on temporal disease evolution rather than "static staging" in modern thyroid cancer management. This case proves that even patients previously categorized as having an "excellent response" can develop structural recurrences with vascular invasion risks more than ten years later. Specifically, a metastatic lymph node size exceeding 3-cm and the loss of Tg/PAX-8 expression are critical parameters indicating that the tumor has entered a dedifferentiation process and transformed into an aggressive phenotype resistant to standard therapies.In conclusion, a lack of follow-up, even in low-risk cases, delays the detection of recurrences and necessitates radical surgical procedures with high morbidity. In accordance with 2025 ATA principles, continuity of oncological surveillance and risk-adaptive approaches are vital for capturing recurrences while still within "resectability limits" and for preserving patient survival.

Keywords: Papillary thyroid carcinoma, 2025 ATA guidelines, dynamic risk stratification, late metastasis

Effect of preoperative radiological imaging on surgical success in minimally invasive parathyroidectomy: A retrospective single-center experience

Türker Kaymak, Orhan Aslan

Department of General Surgery, Hitit University Faculty of Medicine, Çorum

Objective: Minimally invasive parathyroidectomy is an effective surgical approach for the treatment of primary hyperparathyroidism when appropriate patient selection is achieved. Accurate preoperative localization of the parathyroid adenoma is one of the most important determinants of surgical success. Ultrasonography, parathyroid scintigraphy, and advanced cross-sectional imaging techniques are commonly used; however, the impact of these modalities on surgical outcomes remains unclear. This study aimed to evaluate the effect of preoperative radiological imaging on surgical success in patients undergoing minimally invasive parathyroidectomy.

Material and Methods: This retrospective single-center study included patients who underwent minimally invasive parathyroidectomy for primary hyperparathyroidism at our institution within the last two years. Demographic data, biochemical parameters, and preoperative radiological imaging modalities (ultrasonography, parathyroid scintigraphy, and/or computed tomography) were recorded. Concordance between radiological localization and intraoperative findings was assessed. Surgical success was defined as postoperative normocalcemia with a significant decrease in parathyroid hormone (PTH) levels.

Results: A total of 96 patients were included in the study. The median age was 54 (46-63) years. Preoperative imaging correctly localized the parathyroid adenoma in 78 patients (81.3%). The surgical success rate was 94.9% in patients with accurate preoperative localization, compared to 76.5% in patients with inconclusive or discordant imaging findings. A significant association was observed between concordant preoperative imaging and surgical success.

Conclusion: Preoperative radiological imaging plays a significant role in determining surgical success in minimally invasive parathyroidectomy. Accurate localization of the parathyroid adenoma is critical for achieving optimal surgical outcomes. Appropriate imaging strategies may enhance the effectiveness of minimally invasive approaches.

Multimodal imaging-guided and intraoperatively verified resection of mediastinal ectopic parathyroid adenomas: A five-case series

Mustafa Yılmaz[1], Mahsum Barçın[1], Cansu Zerey[2], Mahmut Süleymanoğlu[3], Sami Benli[1], Mustafa Berkeşoğlu[4]

[1]*Division of Surgical Oncology, Department of General Surgery, Mersin University Faculty of Medicine, Mersin*

[2]*Department of Radiology, Mersin University Faculty of Medicine, Mersin*

[3]*Department of Nuclear Medicine, Mersin University Faculty of Medicine, Mersin*

[4]*Department of General Surgery, Mersin University Faculty of Medicine, Mersin*

Objective: To present the diagnostic approach, surgical management, and early outcomes of patients with mediastinal ectopic parathyroid adenoma (MEPA) causing primary hyperparathyroidism.

Material and Methods: Between January 2015 and January 2025, among 458 patients who underwent surgery for a solitary parathyroid adenoma, cases of MEPA due to mediastinal location were retrospectively evaluated, and five cases (1%; n=5) were identified. Diagnostic evaluation included cervical ultrasonography, single-photon emission computed tomography/computed tomography (SPECT/CT), and computed tomography (CT). The surgical strategy was individualized according to lesion location and proximity to major vascular structures. Intraoperative confirmation was achieved using radioguided surgery, frozen section analysis, and intraoperative parathyroid hormone (ioPTH) monitoring. Patients were followed for one year with serial serum calcium and PTH measurements.

Results: The median age was 62 years (40-70), and three patients were female. Bone pain and fatigue were the most common presenting symptoms, while one patient was asymptomatic. Preoperative albumin-corrected serum calcium levels ranged from 11.24 to 13.43 mg/dL, and PTH levels ranged from 161 to 1493 pg/mL. Lesion sizes varied between 8×8 mm and 35×22 mm, with anterior mediastinal localization in four cases. Four patients were treated via J-shaped median sternotomy and one via a transcervical approach. The 10-minute ioPTH decline ranged from 48.3% to 85.5%. No major surgical complications were observed. All patients remained normocalcemic and clinically stable at one-year follow-up.

Conclusion: In MEPA cases, the combined use of functional and anatomical imaging, supported by multiple intraoperative confirmation modalities, may facilitate curative resection with low morbidity through individualized surgical strategies.

Have surgical thresholds changed for IPMN with a 5-9 mm main pancreatic duct? A comparative analysis of the Fukuoka 2017, European 2018 and Kyoto 2024 guidelines

Elif Yiğit Kaymak, Murat Şerifoğlu, Veysel Barış Turhan, Ertuğrul Gazi Alkurt

Department of General Surgery, Hitit University Faculty of Medicine, Çorum

Objective: Intraductal papillary mucinous neoplasms (IPMN) with a main pancreatic duct (MPD) diameter of 5-9 mm constitute a clinical "gray zone" with heterogeneous malignant potential. As recommendations for this range differ across guidelines, operative decision-making may vary between centers. We compared the surgical thresholds and decision frameworks proposed by the Fukuoka 2017, European 2018 and Kyoto 2024 IPMN guidelines for patients with MPD 5-9 mm dilatation and outlined potential implications for practice.

Material and Methods: Full-text versions of the three guidelines were reviewed using a structured comparative approach. We extracted how MPD 5-9 mm is categorized; definitions of surgical indications (high-risk features, "worrisome features", and relative indications); recommended downstream assessment [particularly endoscopic ultrasonography (EUS)]; and surveillance strategies. Additional risk markers embedded in the algorithms (mural nodules, serum CA19-9, symptoms, cyst growth dynamics, concomitant pancreatitis and new-onset diabetes) were mapped. Statements were tabulated in a standardized format and decision pathways were examined side-by-side; reported evidence grading, when available, was recorded.

Results: In Fukuoka 2017, MPD 5-9 mm is not a stand-alone indication for resection; it is addressed within the "worrisome features" framework and prompts further risk confirmation, most commonly with EUS. The European 2018 guideline defines MPD 5-9.9 mm as a "relative indication" for surgery and supports a lower operative threshold when additional risk factors coexist, including mural nodularity, elevated CA19-9, symptoms, or rapid growth. The Kyoto 2024 update frames MPD 5-9 mm as a heterogeneous risk category and shifts emphasis from a single morphologic cut-off to individualized, multiparametric risk assessment; surgical decision-making is positioned within multidisciplinary discussion integrating imaging, biomarkers, operative risk and patient preferences. These differences may influence EUS utilization, surveillance intensity, and the balance between overtreatment and missed malignancy in the MPD 5-9 mm subgroup.

Conclusion: Across guideline iterations, thresholds for MPD 5-9 mm IPMN have moved away from fixed duct-size cut-offs toward risk-based, individualized decision-making. MPD diameter should not be used in isolation; decisions should be guided by EUS findings, mural nodules, CA19-9, symptoms and longitudinal change, within a multidisciplinary and shared decision-making framework. Given that the underlying evidence base remains largely observational, prospective multicenter studies using standardized outcomes, structured EUS reporting and validated risk models are needed to refine operative thresholds, particularly in patients at higher surgical risk.

The changing definition of "elderly patient" and the problem of the future: Acute appendicitis in the geriatric population

Ayberk Dursun, Nurullah Damburacı, Barış Sevinç

Department of General Surgery, Uşak University Faculty of Medicine, Uşak

Objective: Globally, a growing elderly patient population has emerged, increasingly burdening healthcare services. The definition of the term "geriatrics" is somewhat complex. While traditionally 65 years and older were considered "elderly," WHO and the Japanese Geriatric Society now recommend 75 years and older as a threshold for old age due to increased physical capacity over the last 10-20 years. Based on this new definition of old age, geriatric emergencies managed in surgical departments are increasing,and appendectomy, the most frequently performed surgery worldwide, is becoming more common. In our study, we aimed to examine the outcomes of appendectomies due to acute appendicitis, which are increasingly performed in patients over 75 years of age, and to draw attention to the silent but rapid increase in geriatric emergency surgeries in our country.

Material and Methods: Data from patients over 65 years of age who underwent surgery for acute appendicitis at our institution between January 1, 2021, and January 1, 2026, were retrospectively reviewed. Demographic characteristics, type of operation, chronic diseases, presence of perforation, length of hospital stay, 30-day postoperative complications and pathology results were recorded.In this population group, data from patients over, and under 75 years of age were compared. Patients under 65 years of age and those without a 30-day postoperative follow-up result were excluded from the study.

Results: A total of 88 patients were included in the study, 30 of whom were over 75 years old (34%). The mean age was 72.2±6.06. 21 (23.9%) of the surgeries were performed laparoscopically. The rate of laparoscopy was 10% in those over 75 years old and 31% in those under 75 years old, and the difference was statistically significant (p<0.05). The most common chronic disease was in both patient groups was; hypertension. COPD was particularly prevalent in 23.3% of patients over 75 years old, while the rate was 10.3% in those under 75 years old (p>0.05). Appendix perforation was observed in 43.3% of patients over 75 years old, while this rate was 35.5% in the other group, but the difference wasn't significant (p>0.05). The development of complications was higher in those over 75 years of age, but the difference wasn't significant [(50-29.3%) (p>0.05)]. The mean length of hospital stay was significantly higher in patients over 75 years of age [6.8±10.43 vs. 3.48±4.07 days (p<0.05)].

Conclusion: Our current study shows that perforation rates and hospital stays are increased in patients over 75 years of age. It is thought that the tendency towards open surgery increases with age among surgeons. It should be remembered that in these patients with high comorbidities, speed can lead to complications; delay can lead to perforation.

Scientific response to the 2023 Kahramanmaraş earthquake: A bibliometric study

Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Ender Ergüder[1], Şener Balas[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: On February 6, 2023, Türkiye experienced two devastating earthquakes with epicenters in Pazarcık and Elbistan, measuring 7.7 and 7.6 on the Richter scale. These earthquakes caused over 50,000 deaths and widespread destruction of infrastructure. The disaster triggered a large-scale humanitarian crisis, with significant medical and psychological challenges. Understanding the scientific response to such events is essential for improving future disaster preparedness and management.

Material and Methods: A systematic search was conducted in the Web of Science database using the terms "Kahramanmaraş earthquake," "Pazarcık earthquake," "Elbistan earthquake," and "Türkiye earthquake 2023" The search covered the period from February 6, 2023 and focused on medical literature. A total of 371 articles were initially identified, of which 350 were included after excluding geological, engineering, and social science studies. Bibliometric analysis was performed using the Bibliometrix package in R Studio and visualized with Biblioshiny. Key indicators analyzed included publication volume, citation count, author collaboration, and thematic clustering.

Results: The analysis identified 350 articles from 173 journals, involving contributions from 1,739 authors. The average number of co-authors per document was 6.03, indicating high collaboration, but only 5.429% of studies involved international authors. The annual growth rate of publications was -11.11%, reflecting a projected decline in research activity. The most cited article was Emergency Medicine Association of Türkiye Disaster Committee Summary of Field Observations of February 6th Kahramanmaraş Earthquakes, highlighting emergency response challenges. Psychological studies were more numerous, but emergency response and trauma care publications received higher citation counts. Keyword analysis revealed a focus on trauma care, PTSD, surgical management, and public health (Figure 1). The SAFE-QUAKE scoring system for predicting dialysis needs and the mangled extremity severity score (MESS) for amputation triage were notable clinical advancements (Figure 2).

Conclusion: The research response to the Kahramanmaraş earthquakes followed a clear pattern: Early focus on emergency response and public health, followed by injury and surgical management, and later emphasis on psychological recovery. Despite the strong domestic research effort, low international collaboration limits broader knowledge exchange. Sustained funding, enhanced global collaboration, and integrated mental health and trauma care strategies are essential for improving future disaster preparedness and healthcare resilience.

Mortality by etiology in emergency-operated intestinal obstruction: A single-center experience

Fatih Çepil, Özkan Subaşı, Adem Yüksel, Ali Çiftçi, Hamdi Taner Turgut, Murat Burç Yazıcıoğlu

Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli

Objective: Intestinal obstruction is a heterogeneous emergency surgical condition arising from diverse etiologies and pathophysiological mechanisms. Among patients presenting with similar clinical symptoms, the underlying cause of obstruction and the presence of concomitant ischemia or strangulation are the main determinants of prognosis. Therefore, etiology-based risk stratification plays a crucial role in guiding emergency triage, surgical timing, resuscitation strategies, and intensive care planning. This study aimed to evaluate the impact of etiology on 30-day mortality in patients undergoing emergency surgery for intestinal obstruction.

Material and Methods: A retrospective analysis was conducted on 94 adult patients (aged ≥18 years) who underwent emergency surgery for intestinal obstruction between January and December 2024. Cases and mortality data were classified according to etiology (Tables 1 and 2). Complication severity was assessed using the Clavien-Dindo classification. Length of hospital stay, requirement for intensive care, and 30-day mortality were recorded.

Results: Of the 94 patients included, 50 were male (53.2%) and 44 were female (46.8%). The mean length of hospital stay was 13.8 days. Postoperative intensive care was required in 31 patients (33.0%). Adhesions were the most common etiological factor, accounting for 63.8% of cases (n=60). The overall 30-day mortality rate was 11.7% (11/94). Mortality varied significantly by etiology and was highest in the mesenteric ischemia group (71.4%), followed by incarcerated hernia and malignancy-related obstruction. Our findings demonstrate that mortality in emergency-operated intestinal obstruction varies considerably according to etiology. Although adhesion-related obstruction was the most frequent cause, the mortality burden was predominantly concentrated in patients with mesenteric ischemia. These results are consistent with previous studies reporting high mortality rates in ischemic obstruction, while adhesion-related cases generally exhibit a more favorable prognosis. Early identification of ischemia or strangulation through clinical assessment, laboratory markers, and contrast-enhanced CT or CT angiography is essential for timely surgical intervention and improved outcomes.

Conclusion: Early etiology-oriented diagnosis, prompt surgical management, and prioritization of intensive care resources for high-risk patients are critical in the management of intestinal obstruction. Although limited by its single-center design, this study highlights the prognostic importance of etiology and supports the need for further multicenter investigations.

Evaluation of MSI study in colon adenocarcinoma

Kübra Vural, Berkay Aksu, Salih Raşit Mizan, Ufuk Karabacak, İsmail Alper Tarım

Ondokuz Mayıs University Faculty of Medicine, Samsun

Objective: Colon cancer is one of the most common malignancies worldwide. Microsatellite instability (MSI) is an important molecular subtype resulting from defects in the DNA mismatch repair system and has clinical significance in terms of prognosis, treatment response, and the identification of hereditary cancer syndromes. This study aimed to evaluate the application rate and results of MSI studies in colon cancer cases.

Material and Methods: The study included a total of 86 patients diagnosed with colon adenocarcinoma in the pathology archives within the last 5 years. MSI studies were performed in 34 of the cases, while 52 cases did not undergo MSI. In patients who underwent MSI, the expression of MLH1, PMS2, MSH2, and MSH6 proteins was evaluated using immunohistochemical methods. The obtained data were analyzed retrospectively.

Results: Of the 86 colon cancer cases, 39.5% underwent MSI testing, while 60.5% did not. Of those who underwent MSI, 6 (17.5%) had positive results. No defects were observed in 83.5%. An examination of the results and clinicopathological features of the cases that underwent MSI testing revealed that the test was applied to a limited number of patients. It was observed that a large proportion of the cases that did not undergo MSI testing had earlier diagnoses. Current guidelines recommend MSI or MMR assessment in all cases of colon cancer. The absence of MSI assessment in a significant proportion of the cases in our study suggests a potential deficiency, particularly in terms of Lynch syndrome screening and patient selection for immunotherapy.

Conclusion: In colon cancer cases, the MSI (mean scale indicator) test is an important parameter in terms of both prognostic and predictive aspects. Our study once again demonstrates the necessity of routinely applying the MSI test to all colon cancer patients.

Clinical, diagnostic, and surgical characteristics of phyllodes tumors: A single-center retrospective experience

Abdurrahman Özkubat[1], M. Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Gamze Kızıltan[1], Gaye Ebru Şeker[1], Melih Akıncı[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Phyllodes tumors are breast tumors that complicate clinical management due to their rarity, histopathological heterogeneity, and the inability of preoperative diagnostic methods to reliably predict tumor grade. The aim of this study was to evaluate the demographic, diagnostic, surgical, and pathological characteristics of patients who underwent surgical treatment for phyllodes tumors at the University of Health Sciences Türkiye, Ankara Etlik City Hospital; to investigate the concordance between preoperative imaging methods and tru-cut biopsy with final pathology; and to determine differences in surgical approach and clinical outcomes according to pathological grade.

Material and Methods: Fifty patients who underwent surgery with a diagnosis of phyllodes tumor at the General Surgery Clinic of University of Health Sciences Türkiye, Ankara Etlik City Hospital between January 2023 and November 2025 were retrospectively analyzed. Demographic data, preoperative imaging findings, tru-cut biopsy results, surgical procedures, surgical margin status, re-excision requirement, and follow-up outcomes were evaluated. According to final pathology, cases were classified as benign, borderline, and malignant phyllodes tumors. Comparative analyses were performed between benign and borderline/malign groups.

Results: All patients were female, with a mean age of 40.98±11.39 years. Final pathological distribution was 68% benign, 24% borderline, and 8% malignant phyllodes tumors. Tru-cut biopsy was performed in 84% of patients, and discordance between tru-cut biopsy and final pathology was observed in 34%. A substantial proportion of discordant cases resulted from undergrading on tru-cut biopsy, which was more prominent in borderline and malignant cases. Discordance between preoperative imaging and final pathology was observed in 16% of patients. Additionally, 28% of cases initially assessed as benign or suspicious in the preoperative period were diagnosed as borderline or malignant on final pathology. Wide local excision was the most frequently performed surgical procedure (72%). As pathological grade increased, mastectomy rates and re-excision requirements increased significantly. During a median follow-up period of 18.5 months, no local recurrence was observed.

Conclusion: This study demonstrates that preoperative diagnostic methods, including tru-cut biopsy and imaging, are limited in predicting final pathology in phyllodes tumors due to histopathological heterogeneity, particularly in borderline and malignant cases. In line with the literature, the tendency of tru-cut biopsy to undergrade tumors and imaging-pathology discordance may lead to misclassification of surgical risk. However, individualized surgical management based on pathological grade and adequate surgical margin control were associated with low local recurrence rates in short- and mid-term follow-up, even in borderline and malignant cases. These findings strongly support the need to actively consider preoperative diagnostic uncertainty and prioritize surgical margin safety in the management of phyllodes tumors.

Gestational gigantomastia: Prolactin correlation in massive breast hypertrophy and surgical management strategy

Hakan Ataş[1], Ebru Menekşe[2], Eda Nural[3]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

[2]*Clinic of General Surgery, Private Koru Hospital, Ankara*

[3]*Clinic of General Surgery, Kahramanmaraş State Hospital, Kahramanmaraş*

Objective: Gestational gigantomastia (GG) is an exceptionally rare phenomenon occurring in ~1/100,000 pregnancies, characterized by rapid, pathological breast tissue proliferation. Literature typically defines gigantomastia as requiring single-breast excision of ≥1500 g. Although its exact pathogenesis is not fully elucidated, hypersensitivity of estrogen, progesterone, and particularly prolactin receptors, alongside autoimmune processes, are hypothesized to trigger this growth. Beyond aesthetics, GG causes functional morbidities including spinal-deformities and neural-compression. This report discusses the outcomes of surgical management in a case of GG that persisted significantly into the postpartum period.

Material and Methods: A 39-year-old female patient presented with progressive breast enlargement that initiated during the 14th week of her first pregnancy and failed to regress during the 4-year postpartum period. The patient had no history of systemic disease, specific medication use, or family history of malignancy. Physical examination revealed bilateral massive ptosis and prominent subcutaneous venous dilatation (Figure 1). Anthropometric measurements showed a sternal notch-to-nipple (SN-N) distance of 32-cm on the right and 30-cm on the left (BMI: 26.8 kg/m²). Laboratory analysis revealed a significantly elevated prolactin level of 110 ng/mL (normal: 1.2-29.9 ng/mL). A pituitary MRI was performed to rule out prolactinoma. Radiological investigations confirmed bilateral massive hypertrophy and secondary flattening of cervical lordosis due to the extreme weight of the breast tissue.

Results: The patient underwent reduction mammoplasty using the inferior pedicle technique, resulting in the excision of a total of 2830 g of tissue (right: 1450 g, left: 1380 g). Histopathological examination documented complex hyperplastic processes, including sclerosing adenosis, microcalcifications, and papillary apocrine metaplasia accompanied by increased stromal vascularization. The patient was discharged without complications on the 2nd postoperative day. During follow-up, a dramatic regression in shoulder pressure and chronic back pain was observed, significantly improving the patient's quality of life and functional independence (Figure 2).

Conclusion: Gestational gigantomastia is a rare entity requiring multidisciplinary management, as hormonal and histopathological changes can persist long after pregnancy ends. The detected hyperprolactinemia of 110 ng/mL reflects the profound pathophysiological depth of the proliferative response in the target tissue. While a 1500 g resection threshold per breast is often used for diagnosis, the total material of 2830 g in this case, combined with the loss of cervical lordosis and an SN-N distance of 32-cm, confirms the diagnosis clinically and radiologically. In conclusion, where conservative follow-up is insufficient, inferior pedicle reduction mammoplasty remains the gold-standard treatment for both halting skeletal deformities and restoring the patient's functional autonomy.

Keywords: Gestational gigantomastia, reduction mammoplasty, hyperprolactinemia

Retrospective analysis of laparoscopic inguinal hernia repair in patients with prior lower abdominal surgery

Nazım Güreş[1], Muratcan Fırat[2], Server Sezgin Uludağ[2]

[1]*University of Health Sciences Türkiye, Balıkesir Atatürk City Hospital, Balıkesir*

[2]*İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul*

Objective: Inguinal hernia repair is one of the most frequently performed surgical procedures worldwide. Laparoscopic techniques, including total extraperitoneal (TEP) and transabdominal preperitoneal (TAPP) approaches, have gained widespread acceptance due to their advantages over open surgery, such as reduced postoperative pain, shorter hospital stay, and faster recovery. However, the feasibility and safety of laparoscopic inguinal hernia repair, particularly the TEP technique, in patients with a history of prior lower abdominal surgery remain a subject of debate. Prior lower abdominal surgeries can lead to adhesions and altered anatomical planes, potentially increasing the difficulty and risks associated with TEP repair. This study aimed to evaluate the safety and feasibility of TEP inguinal hernia repair in patients with prior lower abdominal surgery and to determine the necessity of conversion to open surgery.

Material and Methods: This retrospective study included 150 patients who underwent TEP inguinal hernia repair between 2020 and 2024. The cohort consisted of 25 females and 125 males, with 60 patients having a history of prior lower abdominal surgery. These surgeries included cesarean section, appendectomy, lower abdominal laparotomy, radical prostatectomy, total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH+BSO), and laparoscopic low anterior resection. All patients initially underwent the classic TEP procedure.

Results: Among the 90 patients without prior lower abdominal surgery (45 right, 45 left inguinal hernias), ten were converted to the TAPP method due to complications (nine scrotal hernias and one sliding hernia). In the 60 patients with prior lower abdominal surgery, 24 required conversion to TAPP. All cases were completed laparoscopically, negating the need for open conversion. The average operation time was 72 minutes (range: 32-134 minutes), and the average hospital stay was 1.2 days. Complications included hematoma in five patients and seroma in five.

Conclusion: TEP inguinal hernia repair is a safe option for patients with a history of prior lower abdominal surgery. Although the likelihood of conversion to TAPP may be higher in these patients, this risk decreases with experience. The study supports the use of laparoscopic techniques in such cases, eliminating the need for open surgery.

The effect of long vs. short gastric pouch on bile reflux in mini gastric bypass surgery

Erkan Aksoy

Avrasya Medi-Tech Hospital, Ordu

Objective: The impact of gastric pouch length created during mini gastric bypass (MGB) surgery on bile reflux remains controversial. This study aimed to compare the effects of gastric pouches longer than 18-cm (long pouch) and shorter than 18-cm (short pouch) on clinical and endoscopic bile reflux.

Material and Methods: A total of 120 patients who underwent mini gastric bypass surgery were included in the study. Patients were divided into two groups according to gastric pouch length:

• Long pouch group (≥18 cm): 80 patients.

• Short pouch group (<18 cm): 40 patients.

All patients were evaluated clinically and endoscopically. Clinical evaluation: Bile vomiting and reflux symptoms were assessed two hours after meals. Endoscopic evaluation:

• Presence of bile in the stomach.

• Observation of bilious content.

• Presence of reflux esophagitis.

Results: Clinical findings:

• Long pouch group (n=80): Bile reflux was detected in 5 patients (6.25%). In these patients, reflux symptoms occurred after consumption of fatty foods and resolved with dietary modification.

• Short pouch group (n=40): Bile reflux was detected in 32 patients (80%). Although symptoms were associated with dietary intake, they persisted despite dietary modification.

Endoscopic findings:

• Long pouch group (n=40 patients who underwent endoscopy): Bile was observed in the stomach in 22 patients (55%). No bile was detected in 18 patients (45%). Reflux esophagitis was identified in 2 patients (5%).

• Short pouch group (n=40): Bile was detected in the stomach in all patients (100%). Reflux esophagitis was identified in 10 patients (25%).

Conclusion: Gastric pouch length appears to be a significant factor in the development of bile reflux following mini gastric bypass surgery. In patients with a gastric pouch length of 18-cm or more, the rate of clinical bile reflux was significantly lower, and symptoms generally resolved with dietary modification. In contrast, patients with a pouch shorter than 18-cm exhibited markedly higher rates of both clinical and endoscopic bile reflux, and symptoms persisted despite dietary intervention. These findings suggest that creating a longer gastric pouch during mini gastric bypass surgery may be an effective surgical strategy to reduce bile reflux.

What prolongs drain duration after breast cancer surgery? The role of reconstruction and nodal disease

Ahmet Çakcak, Murathan Erkent, Afig Gojayev, Semra Kamilova, Munis Baghirli, Ryzman Badalov, Sedat Yıldırım, Mehmet Haberal

Department of General Surgery, Başkent University Faculty of Medicine, Ankara

Objective: Drain placement is a standard practice in breast cancer surgery to prevent seroma and hematoma formation. However, the timing of drain removal may be influenced by patient-related factors such as tumor stage, obesity, and lymph node involvement, in addition to the surgical technique. The aim of this study was to compare drain removal times among different surgical procedures and to identify factors associated with prolonged drain duration.

Material and Methods: This single-center retrospective study included 226 patients who underwent breast cancer surgery in 2020-2025. Patients were divided into four groups: simple mastectomy (n=67), modified radical mastectomy (MRM) (n=87), implant-based reconstruction (n=32), and latissimus dorsi (LD) flap reconstruction (n=40). Demographic characteristics, tumor stage, body mass index (BMI), American Society of Anesthesiologists (ASA) score, and lymph node status were evaluated. Drain removal days were compared among groups.

Results: The mean drain removal time was 10.8±3.3 days in the simple mastectomy group, 11.4±4.7 days in the MRM group, 12.1±3.7 days in the implant-based reconstruction group, and 15.2±6.2 days in the LD flap reconstruction group. The difference among groups was statistically significant ($p<0.001$). Additional analyses revealed that higher tumor stage and positive lymph node status were significantly associated with prolonged drain duration, whereas BMI and ASA scores were comparable among groups.

Conclusion: Drain duration in breast cancer surgery is influenced not only by the type of surgical procedure but also by tumor stage and lymph node status. Prolonged drain duration is particularly observed in patients undergoing LD flap reconstruction and in those undergoing MRM with positive lymph nodes. These findings may contribute to improved postoperative patient management and more accurate discharge planning.

Surgical management and outcomes of colonoscopy-related perforations: An eight-year single-center retrospective study

Alper Varman

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: Colonoscopy-related colonic perforation is a rare but potentially life-threatening complication associated with significant morbidity and mortality. This study aimed to evaluate the clinical characteristics and outcomes of patients who underwent surgical treatment for colonoscopy-related perforations.

Material and Methods: Between January 1, 2018, and December 31, 2025, 10,098 procedures performed in the general surgery endoscopy unit were evaluated. Patients who underwent surgery due to colon perforation related to colonoscopy were retrospectively examined. Clinical data, surgical approaches, and postoperative outcomes were analyzed.

Results: A total of 18 patients were included in the study. Most perforations were located in the sigmoid colon. Primary repair and segmental resection were the most commonly performed surgical procedures. Patients who developed sepsis demonstrated increased intensive care requirements, prolonged hospital stay, and higher mortality rates.

Conclusion: Early diagnosis and appropriate surgical management are critical in the treatment of colonoscopy-related perforations. Consistent with the literature, the sigmoid colon was the most frequent site of perforation in our cohort. The presence of sepsis was associated with significantly worse clinical outcomes. These findings emphasize the importance of rapid clinical assessment and timely surgical decision-making in patients with suspected perforation.

Keywords: Colonoscopy, colonic perforation, surgical treatment

Silent but dangerous: Clinical, laboratory, and management characteristics of toxic megacolon cases - A single-center experience

Muhammed Hallaç[1], Bahattin Bayar[1], Muhammed Salih Süer[1], Sekan Demir[1], Faruk Yazıcı[1], Ender Ergüder[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Toxic megacolon is a life-threatening clinical condition that,although rare,requires early diagnosis and appropriate management due to its rapid progression and high risk of mortality. This study aimed to evaluate the demographic characteristics, clinical findings, laboratory dynamics, treatment approaches, and clinical outcomes of patients followed in our clinic with a diagnosis of toxic megacolon.

Material and Methods: In this retrospective observational study,four patients followed in our clinic with a diagnosis of toxic megacolon were evaluated. Demographic data, comorbidity burden (ASA score, Charlson comorbidity index), clinical findings (fever, tachycardia, hypotension, mental status, peritonitis), etiology, laboratory parameters (WBC, CRP_0-CRP_{24}, and ΔCRP, $lactate_0$-$lactate_{24}$, and Δlactate), timing of sepsis, treatments administered, intensive care unit requirement, complications, and mortality were recorded. Descriptive statistics were presented as median (interquartile range) or n (%).

Results: Four patients diagnosed with toxic megacolon were evaluated; 2 were female and 2 were male. The median age was 61.5 years, and the median BMI was 21.0 kg/m². The patients had a high-risk profile, with an ASA distribution of ASA-II in 25% and ASA-IV in 75%, while the Charlson comorbidity index varied among cases. At presentation, tachycardia and hypotension were not observed in any patient,and fever was present in only 25%; however, signs of peritonitis and altered mental status were noted in most cases. Imaging revealed marked colonic dilatation (median colon diameter: 9.25-cm) without free air. Laboratory evaluation showed elevated inflammatory markers, with considerable heterogeneity in 24-hour CRP and lactate dynamics among patients. Half of the patients were managed with emergency surgery and half with medical treatment; 50% required intensive care unit admission. Complications occurred in one patient (25%), and no mortality was observed.

Conclusion: This case series demonstrates that toxic megacolon may progress with severe clinical burden and a need for surgical intervention even in the absence findings such as fever, tachycardia, and hemodynamic instability. Although systemic inflammatory signs are highlighted in the literature as key diagnostic features of toxic megacolon,the relative absence of these findings in our study—contrasted with the predominance of peritonitis and altered mental status—is noteworthy. Furthermore, our observations suggest that short-term dynamic changes in inflammatory and perfusion markers (CRP and lactate), rather than their absolute values, may be more informative for clinical decision-making. This supports the importance of time-dependent monitoring strategies over static threshold-based assessments in the evaluation of toxic megacolon. The fact that half of the patients required emergency surgery and intensive care underscores the discrepancy between clinical "silence" and disease severity, which may increase the risk of delayed intervention in practice. In conclusion, the absence of classical systemic signs in patients with toxic megacolon should not create a false sense of clinical security. Altered mental status, signs of peritonitis, and dynamic laboratory trends should be regarded as decisive indicators for early and aggressive management. Our findings highlight the heterogeneous clinical spectrum of toxic megacolon and support the critical role of early recognition, close monitoring, and individualized treatment strategies in improving patient outcomes.

Feasibility of unsedated colonoscopy: A retrospective analysis of 296 patients

Güven Erdoğrul, Güvenç Diner, Boran Cihat Karakuş

University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: Colonoscopy is commonly performed with sedation in most centers. Although sedation improves patient comfort, it may lead to cardiopulmonary depression, hypotension, hypoxia, prolonged recovery time, and, rarely, serious complications. Therefore, unsedated colonoscopy has emerged as an alternative approach in selected patients. This study aimed to evaluate the procedural success and feasibility of unsedated colonoscopy.

Material and Methods: A total of 296 patients who underwent unsedated colonoscopy were retrospectively analyzed. Patient demographics, including age and sex, as well as indications for colonoscopy, were recorded. Successful completion of the procedure was defined as cecal intubation.

Results: The mean age of the patients was 50.79±12.44 years. Of the patients, 163 were male and 133 were female. The indications for colonoscopy were anemia (n=79), lower gastrointestinal bleeding (n=69), abdominal pain (n=44), constipation (n=23), positive fecal occult blood test (n=19), detection of a mass on digital rectal examination (n=16), weight loss (n=5), and other causes (n=41). Cecal intubation was successfully achieved in 255 patients (86.1%), while the procedure could not be completed in 41 patients (13.9%). Among patients in whom the procedure was incomplete, 26 were male and 15 were female. No major complications were observed in any patient.

Conclusion: The cecal intubation rate in unsedated colonoscopy was 86.1%, and no major complications were detected. With appropriate patient selection and adequate operator experience, unsedated colonoscopy is a safe and feasible procedure.

Is routine preoperative colonoscopy necessary before temporary stoma closure?

Abdullah Demirtaş, Duray Şeker

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Permanent or temporary stomas (ileostomy, colostomy) are frequently performed in general surgical practice for benign or malignant indications. Temporary stomas may be scheduled for closure after the recovery period or following adjuvant/systemic therapy. Prior to stoma closure, routine preoperative colonoscopic evaluation is commonly performed in many centers to assess colonic integrity, evaluate the colorectal anastomosis, and exclude recurrence or metachronous colorectal tumors. In this study, patients who underwent temporary stoma creation for any indication and subsequently had stoma closure following preoperative colonoscopic evaluation were retrospectively analyzed, and the necessity of routine colonoscopy prior to stoma closure was discussed, except for selected clinical criteria.

Material and Methods: A total of 147 patients who underwent stoma closure at University of Health Sciences Türkiye, Ankara Etlik City Hospital between January 2022 and July 2025 were identified. Thirty-one patients who underwent stoma closure without preoperative colonoscopic evaluation were excluded from the study. The demographic characteristics of the included patients (age and sex), indication for stoma creation (benign or malignant), type of stoma creation (emergency or elective), interval between stoma creation and closure, and the presence of pathologies that could preclude stoma closure detected during preoperative colonoscopy (such as anastomotic stricture or metachronous tumor) were retrospectively analyzed.

Results: A total of 116 patients who met the inclusion criteria were included in the study. The demographic and clinical characteristics of the patients are presented in Table 1, and conditions preventing stoma closure according to stoma indication are shown in Table 2. In the preoperative colonoscopic evaluation, no pathology preventing stoma closure was detected in 113 patients (97.4%), whereas only 3 patients (2.6%) had findings that contraindicated stoma closure. Of these patients, two had stomas created for benign indications and one for a malignant indication.

Conclusion: Stoma closure is generally performed before the expected time frame for local recurrence or development of metachronous secondary tumors following the primary surgery. Therefore, the clinical benefit of routine preoperative colonoscopic evaluation in asymptomatic patients remains controversial. In our study, the low rate of pathologies preventing stoma closure (2.6%) suggests that routine colonoscopy alters clinical management in only a limited subset of patients. However, colonoscopic evaluation should be selectively considered in patients with alarm symptoms, suspected anastomotic integrity issues, or in high-risk malignant patient groups. Routine preoperative colonoscopy rarely changes surgical decision-making in asymptomatic patients.

Low-grade mucinous neoplasms detected after appendectomy: A single-center retrospective evaluation

Sıddık Solak, Uğurcan Bulut, Muhammed Salih Süer, Serkan Demir, Alper Yavuz, Serhat Tokgöz

University of Health Sciences Türkiye, Health ScAnkara Etlik City Hospital, Ankara

Objective: A small proportion of patients undergoing surgery for acute appendicitis are histopathologically diagnosed with low-grade appendiceal mucinous neoplasms (LAMN). This study aimed to comprehensively evaluate the clinical, radiological, surgical, and histopathological characteristics of patients who underwent surgery with a preliminary diagnosis of acute appendicitis and were subsequently diagnosed with LAMN on postoperative pathological examination, and to discuss these findings in the context of the current literature.

Material and Methods: A total of 19 patients who underwent surgery with a preliminary diagnosis of acute appendicitis between October 2022 and October 2025 and were diagnosed with LAMN on pathological examination were retrospectively analyzed. Demographic characteristics, presenting symptoms, computed tomography (CT) findings, surgical technique, intraoperative macroscopic appearance, histopathological tumor size, surgical margin status, presence of extraluminal mucin, follow-up duration, and clinical outcomes were evaluated.

Results: The mean age of the patients was 60.7 years (range: 29-86), with 63% being female (n=12) and 37% male (n=7). Presenting complaints were consistent with acute appendicitis in 42% of cases, whereas 58% presented with other abdominal symptoms. On preoperative CT imaging, the mean appendiceal diameter was 21-mm; wall thickening was detected in 37% of cases, and a mucocele appearance was observed in 53%. Surgically, 53% of patients underwent open appendectomy and 47% underwent laparoscopic appendectomy. On pathological macroscopic examination, the mean tumor size was 7.1-cm, and positive surgical margins were observed in only 1 patient (5%). The presence of extraluminal mucin/pseudomyxoma peritonei was detected in 16% (n=3) of patients. The mean follow-up duration was 13 months. During follow-up, no recurrence was observed in 17 patients (89%), while 2 patients (11%) died.

Conclusion: LAMN is a neoplasm that may be incidentally detected among patients undergoing surgery for acute appendicitis, yet it is of critical importance in terms of clinical course and long-term prognosis. In our study, the presence of a mucocele appearance and increased wall thickness on preoperative CT imaging were identified as potentially valuable predictors in favor of LAMN. Surgical margin positivity and the presence of extraluminal mucin represent key determinants affecting prognosis and recurrence risk. Our findings demonstrate that histopathological examination following acute appendicitis surgery is indispensable not only for diagnostic purposes but also for prognostic assessment. Therefore, careful evaluation of surgical margins and the continuation of long-term oncological follow-up are essential in patients with LAMN.

Adjunctive botulinum toxin injection with surgical repair for recurrent rectovaginal fistulas

Fahri Yetişir[1], Kerim Güzel[2]

[1]*Department of General Surgery, Acıbadem Bayındır Private Hospital, Ankara*

[2]*Department of General Surgery, Near East University Faculty of Medicine, Nicosia, Cyprus*

Objective: Rectovaginal fistula is an abnormal connection between the rectum and the vagina. Through this connection, passage of flatus or stool from the rectum to the vagina may occur. Patient history and physical examination are usually sufficient for diagnosis. Although many surgical options have been described (e.g., sphincteroplasty, advancement flap, muscle interposition, fibrin glue, plugs), fistula closure remains challenging due to high surgical failure rates. To report the outcomes of a novel treatment approach combining surgical repair with botulinum toxin injection into the lateral internal anal sphincter for the management of recurrent rectovaginal fistula.

Material and Methods: Between 2013 and 2019, eight patients with recurrent rectovaginal fistula underwent a total of ten surgical repairs combined with injection of 100 units of botulinum toxin. Patient characteristics, fistula etiology, prior surgical history, fistula size, and treatment outcomes were analyzed (Figure 1).

Results: Eight patients with recurrent rectovaginal fistula were treated. Etiologies included obstetric trauma (n=3), radiotherapy and rectal surgery (n=2), vaginal reconstruction (n=2), and Crohn's disease (n=1). The median number of previous operations was 1.5 (range: 1-3). Fistula size ranged from 0.5×1 cm to 2×3 cm. Following the combined approach, successful fistula closure was achieved in all cases (100%) (Figure 2).

Conclusion: Botulinum toxin injection into the lateral internal anal sphincter can be successfully used as an adjunct to surgical repair in the treatment of recurrent rectovaginal fistulas.

Keywords: Rectovaginal fistula, botulinum toxin

Complication profile and associated clinical variables in oncoplastic breast surgery: A single-center retrospective study

Ayşegül Bekdemir, Ali Eren Durmuş, Hamdi Kaan Odabaşı, Ahmet Ağların, Oğuzkağan Batıkan, Tuba Göçmen

University of Health Sciences Türkiye, Bursa City Hospital, Bursa

Objective: Oncoplastic breast surgery is a multidisciplinary approach aimed at improving aesthetic outcomes while preserving oncologic safety. This single-center retrospective study evaluated the profile of postoperative complications and the clinical variables potentially associated with these complications in patients who underwent oncoplastic breast surgery at our institution between 2019 and 2026.

Material and Methods: This retrospective, single-center study included 16 patients who underwent oncoplastic breast surgery between 2019 and 2026. All procedures were performed by a multidisciplinary team consisting of general and plastic surgeons. Demographic characteristics (age, body mass index), comorbidities (smoking status, diabetes mellitus), surgical features (axillary surgery, implant use), neoadjuvant and adjuvant treatment details, and postoperative complications were recorded. Complications were assessed during the early postoperative period (within 3 months) and graded according to the Clavien-Dindo classification.

Results: All 16 patients were female (100%), with a mean age of 44.5 years and a mean body mass index of 26.83 kg/m². A history of smoking was present in 25% of patients.Surgical management was carried out by a multidisciplinary team in all cases. Sentinel lymph node biopsy and/or axillary dissection were performed in selected patients according to tumor characteristics and clinical stage. Neoadjuvant and adjuvant treatments were planned based on pathological findings and molecular subtype. Early postoperative complications occurred in 18.75% of patients. Most were classified as Clavien-Dindo grade II-IIIb and were successfully managed with medical or surgical intervention. Reoperation within the first year was infrequent, and implant loss was rare. No mortality was observed (0%). During follow-up, the rate of early local recurrence was low, while a limited number of patients developed late distant metastases. The mean follow-up duration was 34.5 months. Oncoplastic surgery was performed more frequently in 2021, 2023, and 2026. Higher body mass index, smoking, and performance of axillary surgery appeared to be associated with morbidity. Although patients receiving neoadjuvant or adjuvant therapy showed a trend toward higher complication rates, advanced statistical analysis was not feasible due to the limited sample size.

Conclusion: This single-center experience demonstrates that oncoplastic breast surgery can be performed safely with acceptable morbidity and zero mortality when a multidisciplinary approach is applied. Complications were generally manageable. Patient-related and surgical factors may influence morbidity. Larger multicenter prospective studies are required to validate these findings and better define risk factors.

Early clinical and biochemical outcomes of patients undergoing parathyroidectomy for parathyroid hyperplasia: A single-center experience

Murtaza Salih Kepez, Ahmet Berkay Arat, Muhammet Halil Duru, Mahmut Arif Yüksek, Ramazan Topcu

Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: In cases of secondary and tertiary hyperparathyroidism due to parathyroid hyperplasia, surgical treatment becomes a consideration when adequate control cannot be achieved despite medical therapy. Although biochemical improvement is expected following parathyroidectomy, early postoperative hypocalcemia may represent a significant cause of morbidity. The aim of this study was to evaluate the early postoperative clinical and biochemical outcomes of patients operated on at our center and to investigate factors associated with the development of postoperative hypocalcemia.

Material and Methods: Twenty-five patients who underwent parathyroidectomy with a diagnosis of parathyroid hyperplasia were retrospectively reviewed. Demographic characteristics, type of hyperparathyroidism, history of hemodialysis, medical treatments received, preoperative laboratory parameters (calcium, phosphorus, PTH, and ALP), as well as postoperative biochemical course and complications were recorded. Risk factors associated with the development of postoperative hypocalcemia were analyzed.

Results: The mean age of the patients was 56 years, and the majority were operated on for tertiary hyperparathyroidism. The mean preoperative PTH and ALP levels were 1.740 pg/mL and 389 U/L, respectively. A marked decrease in parathormone and phosphorus levels was observed after surgery. The mean calcium level on postoperative day 1 was 8.4 mg/dL. Hypocalcemia developed in six patients (24%), requiring calcium replacement therapy. Patients who developed hypocalcemia had higher preoperative PTH and ALP levels. No major surgical complications were observed.

Conclusion: Parathyroidectomy is an effective and safe treatment option for hyperparathyroidism due to parathyroid hyperplasia. However, postoperative hypocalcemia is frequently observed in patients with a high preoperative disease burden. Close biochemical monitoring and early replacement therapy are essential in these patients.

Keywords: Parathyroidectomy, hyperparathyroidism, hypocalcemia

Global scientific attention to the Israel-Gaza conflict: A bibliometric and thematic analysis of health and humanitarian research

Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Şener Balas[2]

[1]*Department of General Surgery, University Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Armed conflicts and humanitarian crises, particularly in the Middle East, have led to profound disruptions in civilian health and psychosocial well-being. In recent years, the Gaza region has become a focal point of such disruptions, prompting increasing academic attention. This study provides a comprehensive bibliometric analysis of the global scientific output related to war-affected civilian populations in the Middle East, with a special emphasis on Gaza and Palestine.

Material and Methods: We conducted a bibliometric analysis of 488 peer-reviewed articles published between 1961 and 2025, retrieved from PubMed database. Quantitative metrics such as annual scientific production, author productivity (Lotka's Law), institutional contributions, international collaborations, keyword co-occurrence, and thematic evolution were assessed using Bibliometrix (R package). Visualization techniques included co-authorship networks, thematic maps, treemaps, and trend analysis.

Results: Scientific interest in war-related civilian health surged significantly after 2023, reflecting the global academic response to escalating humanitarian crises in Gaza. A small group of highly productive authors and institutions (primarily based in Gaza, Israel, and Western academic centers) contributed disproportionately to the literature (Figure 1). Core themes include psychosocial trauma, gender disparities, child vulnerability, warfare-related epidemiology, and health service disruption. Keywords such as "humans," "female," "warfare," "child," "Middle East," and "mental health" emerged as dominant focal points (Figure 2). International collaboration rates reached 20.9%, with a noticeable rise in publications from high-impact journals.

Conclusion: The intersection of warfare, civilian suffering, and public health has generated a distinct, rapidly expanding body of research. This bibliometric study maps the scientific terrain of conflict-related health literature. These bibliometric patterns are consistent with humanitarian data from the United Nations and UNICEF, which indicate that women and children constitute a significant portion of civilian casualties in Gaza. Future studies must prioritize inclusive research agendas that center the voices of affected populations and address structural inequities in global health scholarship.

The ultimate killer in surgery: A sepsis-like syndrome or cytokine storm induced by surgery

Ali Cihat Yıldırım, Yalçın Sönmez, Sezgin Zeren

Department of General Surgery, Kütahya University of Health Sciences Faculty of Medicine, Kütahya

Objective: Surgical trauma triggers a cascade of immunological responses that can escalate into a cytokine storm—a life-threatening hyperinflammatory state characterized by massive elevations of pro- and anti-inflammatory mediators. This phenomenon shares pathophysiological features with sepsis-like syndrome and systemic inflammatory response syndrome (SIRS), contributing significantly to postoperative multiple organ dysfunction syndrome (MODS). Understanding the temporal dynamics of surgery-induced cytokine release and implementing damage control strategies are critical for improving patient outcomes, particularly in high-risk populations undergoing major abdominal or cardiac procedures. When we look backwards, the most common cause of mortality in our clinical surgical practice has often been sudden and unexpected intraoperative and early postoperative cytokine storms.

Material and Methods: This review synthesizes evidence from prospective observational studies, randomized controlled trials, and systematic reviews examining cytokine storm characteristics in surgical patients. Studies analyzed plasma cytokine levels (IL-1, IL-6, IL-8, IL-10, IL-16, TNF-α) at multiple time points using Luminex technology and ELISA. Patient cohorts included those undergoing cardiac surgery with cardiopulmonary bypass, abdominal surgery for intra-abdominal sepsis, and trauma patients requiring damage control surgery. Principal component analysis was employed to establish cytokine storm intensity curves. Therapeutic interventions including hemoadsorption (CytoSorb®), damage control surgery techniques, and targeted immunomodulation were evaluated.

Results: Cytokine storm response occurs within hours of surgical insult, with peak concentrations predating clinical deterioration markers. In severe cases, IL-6 levels reached 425.1 pg/mL (>1.200× normal), IL-10 reached 198.5 pg/mL (>1.800× normal), and IL-16 reached 623.0 pg/mL (>240× normal). Maximum cytokine storm intensity preceded peak Vasoactive-Inotropic Scores and Sequential Organ Failure Assessment scores, suggesting a critical intervention window. Damage control surgery—involving abbreviated initial operations followed by resuscitation and staged definitive repair—demonstrated reduced inflammatory burden compared to prolonged single-stage procedures. Hemoadsorption therapy showed promise in cytokine removal, though survival benefits remain inconclusive in randomized trials.

Conclusion: The early and predictable nature of surgery-induced cytokine storms presents opportunities for proactive intervention. Biomarkers such as IL-6, IL-10, and IL-16 may guide timing of immunomodulatory therapies within the critical 24-hour postoperative window. Damage control surgery philosophy aligns with this understanding by minimizing the "second hit" phenomenon—where prolonged operative stress compounds the initial inflammatory insult. Future therapeutic strategies should integrate cytokine storm biomarker monitoring with damage control principles, hemoadsorption technologies, and targeted anti-inflammatory interventions to mitigate progression from controlled inflammation to pathological sepsis-like states.

Keywords: Sepsis, sepsis-like syndrome, cytokine storm, damage control surgery

Clinical management of rectal foreign bodies: A single-center experience

Mehmet Mert Hıdıroğlu, Ahmet Yavuz

University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

Objective: Rectal foreign bodies are a rare clinical entity in general surgery but present distinctive diagnostic and therapeutic challenges. Cases associated with sexual preferences and social taboos often involve delayed presentation, difficulty obtaining a reliable medical history, and loss to follow-up, complicating clinical assessment and management. Additionally, variability in the type, size, and location of foreign bodies hinders the development of a standardized clinical approach. Although management algorithms prioritizing minimally invasive methods have been described, they do not fully address case heterogeneity, and clinical decision-making frequently relies on individual assessment. Therefore, the management of rectal foreign bodies remains a clinical problem with undefined standards. This study aims to contribute to the literature by sharing our clinical experience in managing rectal foreign bodies.

Material and Methods: Between January 2020 and January 2026, the demographic characteristics of patients treated for rectal foreign bodies, along with the diagnostic and therapeutic methods applied, were retrospectively reviewed using the hospital database.

Results: Between January 2020 and January 2026, 15 patients were treated in our clinic for rectal foreign bodies. The mean age was 41.2 years (22-66); 2 patients were female (13%) and 13 were male (87%). Upright plain abdominal radiography was performed in all patients, and abdominopelvic computed tomography was additionally obtained in 10 patients. Colon perforation with signs of peritonitis was detected in one patient, while no perforation was observed in the others. Foreign bodies were removed by digital rectal examination in 5 patients, anal examination under sedation in 1 patient, and rectosigmoidoscopy in 7 patients. In 2 patients, spontaneous passage occurred during intensive care follow-up due to concomitant drug-containing packages in the small intestine. Colon repair and colostomy were performed in the patient with perforation. Extracted foreign bodies were heterogeneous, including bottles, cucumbers, brushes, test tubes, and drug packages. Five patients were followed on an outpatient basis, nine were discharged the next day, and one on the seventh day. No mortality was observed.

Conclusion: Rectal foreign bodies, although rare, are associated with considerable uncertainty in clinical evaluation and management. In our study, most cases were safely managed with non-operative methods, while surgical intervention was required only in a limited number of complicated cases. However, delayed presentation, unreliable medical history, and case heterogeneity hinder the application of a standardized management strategy. Our single-center six-year experience supports prioritizing an individualized, stepwise, and minimally invasive approach in the management of rectal foreign bodies.

Evaluation of motorcycle accident cases admitted to our emergency clinic in 2025 in terms of ISS and NISS trauma scores

Barış Tüzün[1], Cansu Alyeşil Özturan[2], Tuncay Baran[3], Sumru Beril Çetintaş Atak[1], Murat Özdamar[1], Sude Sezer[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

[2]*Department of Emergency Medicine, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

[3]*Department of Orthopedics and Traumatology, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: Injury severity score (ISS) and new injury severity score (NISS), are anatomical scores calculated based on the abbreviated injury scale (AIS). The NISS scores multiple injuries in the same topographic region better than the ISS. The hypothesis of this study is that it does not show the same success in situations that can cause multiple orthopedic injuries, such as motorcycle accidents.

Material and Methods: In 2025, cases of motorcycle accidents brought to our hospital's emergency department were evaluated in terms of ISS and NISS scores, the clinic they were hospitalised, and need for intensive care. These scores were compared in cases admitted to the orthopedics and traumatology clinic (SPPS 27.0, Mann-Whitney U test).

Results: Of the 306 cases, 22 (7.2%) were admitted to the intensive care unit, 30 (9.8%) to the orthopedics and traumatology clinic, 13 (4.2%) to the thoracic surgery clinic, and 7 (2.3%) to other clinics. The mean ISS score was calculated as 6.57 (1-51) and the mean NISS score as 7.43 (1-51) in all cases. Both the ISS and NISS scores of the hospitalized cases were statistically significantly higher than those of the cases that did not require hospitalization (U=1776.5, p<0.001). The scores were also significantly higher in the cases admitted to the intensive care unit than in other cases (ISS U=180.5 p<0.001 and NISS U=171.5, p<0.001). However, no statistically significant difference was found between cases admitted to the orthopedics and traumatology clinic and cases admitted to other clinics (ISS U=226, p>0.05 and NISS U=230, p>0.05).

Conclusion: While ISS and NISS scores divide the body into 6 regions. ISS determines the highest score in each region and sums the squares of the top 3 regions. NISS, however, sums the squares of the top 3 pathologies regardless of topographical region. If there is multiple trauma in a single region, the ISS score may be lower than the NISS score overall. Therefore, we chose motorcycle accidents that can cause multiple fractures as our target group. Orthopedists make treatment decisions not only based on the severity of the pathology, but also considering age, the patient's general condition, the chosen treatment method, and even hospital conditions. For hospitals that want to measure themselves based on trauma scores, this situation can lead to misleading results. However, we did not obtain statistically significant results. Nevertheless, we believe that the anatomical scoring system NISS should not be used alone.better with one of the physiological trauma scores.

The effect of nursing education on anxiety levels in patients with thoracic tube insertion

Filiz Uçar Şenol

Department of Thoracic Surgery, Ondokuz Mayıs University Hospital, Samsun

Objective: Chest tube insertion is an invasive procedure that may increase fear, stress, and anxiety in patients. Nursing education provided before and after the procedure may improve patients' adaptation and psychological comfort. This study aimed to investigate the effect of nursing education on hospital anxiety levels in patients undergoing chest tube insertion.

Material and Methods: This study included 35 patients aged 18 years and older who were hospitalized in the Thoracic Surgery Department of Ondokuz Mayıs University Health Practice and Research Center and underwent chest tube insertion. Nursing education lasting 15-20 minutes was provided before and after the procedure. Pulse rate, respiratory rate, systolic and diastolic blood pressure, and body temperature were recorded, and the hospital anxiety assessment score (HAAS) was administered before and after the intervention. Data were analyzed using the SPSS statistical analysis program.

Results: The mean age of the patients was 57.6±16.6 years, and the mean length of hospital stay was 4.7±1.9 days. Of the patients, 40% were female and 60% were male. The mean body weight was 76.5±11.2 kg in female patients and 73.7±16.0 kg in male patients. All patients were mobilized, and 97.1% were fed with regimen 3. According to diagnoses, 65.7% of the patients had lung masses, 8.6% had pneumothorax, and 25.7% had other diagnoses (Table 1). No statistically significant differences were observed in vital signs before and after chest tube insertion ($p>0.05$). However, a statistically significant decrease in HAAS was found after nursing education ($p<0.05$) (Table 2).

Conclusion: Although chest tube insertion is an invasive procedure that increases anxiety, nursing education provided before and after the procedure significantly reduces anxiety levels without causing adverse changes in vital signs. Patient education should be considered a fundamental component of nursing care in surgical interventions.

National surgical congress proceedings: Trends from 2012 to 2024. What's the next one?

Ali Cihat Yıldırım, Yalçın Sönmez, Nebi Acar, Mehmet Fatih Ekici, Faik Yaylak, Sezgin Zeren, Ahmet Tekin

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Rapid developments and changes in medicine have also led to fundamental changes in surgical disciplines. Turkish surgery is among the countries that have quickly adapted to these developments. In this study, we aimed to examine the thematic changes in the topics of papers and sessions presented at the National Surgical Congresses (UCK) between 2012 and 2024.

Material and Methods: The analysis was conducted using a qualitative comparison method based on accessible abstracts and session titles from the 18th (2012), 19th (2014), 21st (2018), 22nd (2022), and 23rd (2024) UCK, which are available on our association's website. Since the data examined represents only selected sessions and abstracts, not the entire conference content, the results should be considered a sample reflecting the general trends of the conferences. Abstract titles and main session themes were examined to determine the shift in scientific focus over the years within major surgical categories such as endocrine, gastrointestinal/colorectal, and advanced technology.

Results: Four main trends were observed: expansion of disciplinary scope: while there was a strong emphasis on endocrine surgery in 2012 and 2018, as of 2014, the congress content covered all subspecialties of general surgery, including gastrointestinal, colorectal, HPB, and bariatric surgery. Gastrointestinal/colorectal surgery, in particular, has consistently occupied a significant place on the congress agenda. The pace of technological advancement: the field of minimally invasive surgery has evolved from traditional methods in 2012 to advanced techniques such as scarless surgery (TOETVA) in 2018 and robotic surgery in 2022. In 2022, experimental approaches such as 3D bioprinting and molecular biomarkers also held an important place. New areas of expertise: the congress began to include specialized areas such as wound and burn care and adrenal surgery, and in 2024, it highlighted breast surgery, cytoreductive, and complex surgery as main topics. Focus on surgical quality and management: non-clinical but critical topics such as the philosophy of surgical safety, ethics, and the human factor, which became prominent at the 2024 congress, demonstrate the importance modern surgical practice places on holistic management and patient safety.

Conclusion: UCKs have evolved from a sub-discipline focus to a comprehensive scientific platform combining advanced technology and interdisciplinary approaches. We can anticipate that topics at the 2026 congress will include new management approaches such as long-term outcomes of robotic surgery applications and error analysis, or topics at the intersection of technology and basic sciences such as the use of artificial intelligence in gastrointestinal surgical oncology.

One-year experience of gastric and colorectal ESD at a tertiary center: Indication diversity and early outcomes

Ozan Erek, Abdullah Kut

University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoglu City Hospital, İstanbul

Objective: Endoscopic submucosal dissection (ESD) is a minimally invasive technique that enables high en-bloc and R0 resection rates for superficial gastrointestinal neoplasms. In Western series, R0 resection rates are reported at 80-91% for gastric lesions and approximately 92% for colorectal lesions. This study aimed to present the spectrum of indications, histopathology, and early clinical outcomes of gastric and colorectal ESD procedures performed over one year at a tertiary center.

Material and Methods: Patients undergoing ESD for gastric or colorectal lesions between 2025 and 2026 were retrospectively analyzed. Demographic data, lesion location, procedural details, histopathology, resection margin status, and complications were recorded. Mucosal defects were closed with endoclips or, if large, left to heal under endoscopic follow-up. Major procedural complications were noted.

Results: A total of 12 patients (7 males, 5 females; mean age 66.2 years) underwent 13 ESD procedures. Five lesions (38.5%) were gastric and eight (61.5%) colorectal. Gastric lesions were located in the antrum (n=3), antrum-corpus junction (n=1), and corpus (n=1); histopathology included GIST (low-risk, 3 cm), hyperplastic polyp with low-grade dysplasia, neuroendocrine tumor (pending), submucosal lesion (possible leiomyoma), and chronic gastritis. Colorectal lesions were located in the cecum (n=3), ascending colon (n=2), transverse colon (n=1), hepatic flexure (n=1), and rectum (n=1); histopathology included tubular adenoma, tubulovillous adenoma, intramucosal carcinoma arising in serrated adenoma, and serrated adenoma. All colorectal lesions had negative lateral and deep margins. No major complications occurred, except one cecal perforation during polyp removal, successfully managed with endoscopic clipping and conservative care. Post-procedure imaging revealed pneumoperitoneum without contrast leakage. One patient required intraperitoneal air aspiration via 16 Fr catheter due to persistent distension; the patient subsequently recovered and was discharged.

Conclusion: Our series demonstrates high R0 resection rates and low complication rates, consistent with Western literature. Notably, gastric subepithelial lesions such as GISTs were successfully enucleated via ESD. R0 resection was also achieved in technically challenging colorectal locations, including the cecum and hepatic flexure, highlighting our center's technical proficiency. These findings suggest that the ESD learning curve can be overcome early, and high success rates may be achieved with experienced endoscopists even with fewer than the previously suggested 50-100 cases. Overall, one-year experience indicates that gastric and colorectal ESD can be performed safely and effectively across a broad spectrum of indications.

Keywords: Endoscopic submucosal dissection (ESD), gastric and colorectal lesions, early outcomes

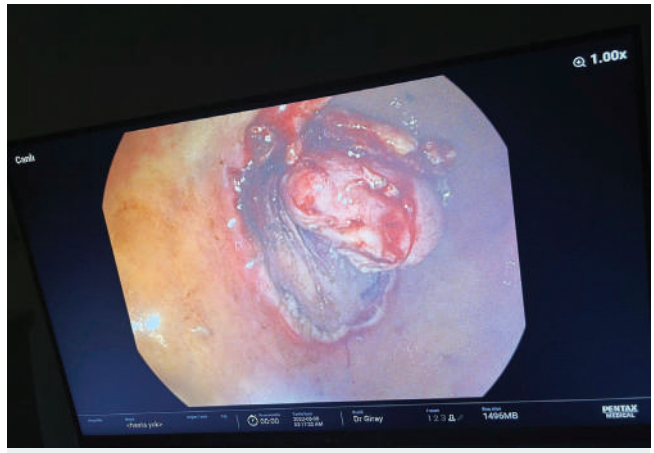

Figure 1. Enucleation was performed by endoscopic submucosal dissection at the level of the gastric incisura angularis.

Figure 2. ESD at the gastric antrum-corpus junction.

Demographic, clinical and histopathological characteristics of patients undergoing ESD

Parameter findings

Number of patients 12

Total ESD procedures 13

Gender7 Male (58.3%)/5 Female (41.7%)

Mean age 66.2 years

Lesion location stomach: 5 (38.5%)/colorectal: 8 (61.5%)

Gastric localizations antrum (n=3), antro-corporal junction (n=1), corpus (n=1)

Gastric histopathology GIST (low risk, 3 cm); hyperplastic polyp with low-grade dysplasia; neuroendocrine tumor?; submucosal lesion (leiomyoma?); chronic gastritis*

Colorectal localizations cecum (n=3), ascending colon (n=2), transverse colon (n=1), hepatic flexure (n=1), rectum (n=1)

Colorectal histopathology tubular adenoma; tubulovillous adenoma; traditional serrated adenoma with intramucosal carcinoma focus (high-grade dysplasia); serrated adenoma

Surgical margins (colorectal) negative (basal and lateral) in all lesions

Major complications none (no perforation or bleeding)

Mucosal defect management closure with endoclips or left for secondary healing in large defects.

Male breast cancer: A single-center retrospective descriptive study

Metin Yalçın, Gizem Nur Akay, Barış Rafet Karakaş, Kemal Eyvaz, Arif Aslaner

Department of General Surgery, University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Male breast cancer (MBC) accounts for approximately 1% of all breast cancers. Due to its low incidence, data on the clinical, pathological, and biological characteristics of the disease are limited. Diagnosis is often made at an advanced age, and delayed presentation and lack of awareness can negatively affect the prognosis. Because of its rarity, MBC is often managed according to the treatment principles of female breast cancer. This study aimed to define the demographic, surgical, and pathological characteristics of MBC patients operated on at a single center.

Material and Methods: This retrospective and descriptive study was conducted by reviewing the files of male patients who underwent surgery for breast cancer between 2019 and 2025. Patient age, preoperative imaging findings, presence of distant metastasis, surgical method used, histopathological diagnosis, and immunohistochemical characteristics (ER, PR, HER2/CERB, Ki-67) were recorded. Data were anonymized for analysis. In statistical analysis, continuous variables were presented as mean ± standard deviation or median, and categorical variables as number and percentage (%). Since the study is descriptive, no further statistical comparisons were made.

Results: The study included 10 MBC patients. The mean age of the patients was 66.7±11 years. Preoperative evaluation revealed no distant metastases in any patient. The most frequently used surgical method was modified radical mastectomy, and sentinel lymph node biopsy was performed in selected cases. Histopathological diagnosis in all patients was invasive breast carcinoma, NST (ductal type). Immunohistochemical examination showed: ER positivity: 100%, PR positivity: 100%, HER2 (CERB) positivity: 50%, and median Ki-67 value: 15%. These findings indicate that the vast majority of patients have hormone receptor-positive biology.

Conclusion: Our study revealed that MBC is a disease diagnosed at an advanced age and has a high hormone receptor positivity rate. Our findings are consistent with EMC series reported in the literature. The detection of ER and PR positivity in all patients supports endocrine therapy as a fundamental approach in the treatment of EMC. The HER2 positivity rate of 50% suggests that targeted therapies may also play an important role in this patient group. The dominance of modified radical mastectomy in the surgical approach is related to the limited size of male breast tissue and the frequent retroareolar location of tumors. Although MBC is rare, it mostly exhibits hormone receptor-positive biological characteristics. Early diagnosis and appropriate surgery, along with a multidisciplinary approach, can improve the prognosis in these patients.

Bibliometric analysis: AI and colorectal cancer surgery (2020-2026)

Ali Cihat Yıldırım, Sezgin Zeren, Yalçın Sönmez

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Artificial intelligence (AI) has rapidly emerged as a transformative technology in the field of colorectal cancer and surgery, offering new opportunities for early detection, diagnosis, treatment planning, and outcome prediction. As research in this interdisciplinary area accelerates, a comprehensive bibliometric analysis is essential to map the scientific landscape, identify influential authors, institutions, and journals, and highlight emerging trends and research hotspots. This study aims to systematically evaluate the global research output on AI applications in colorectal cancer and surgery, and impact of this dynamic and rapidly growing field.

Material and Methods: A bibliometric analysis was conducted using publication data exported from the Scopus database. The dataset comprised articles related to AI and colorectal cancer. Descriptive statistics were used to identify the most prolific authors, journals, and countries. Citation analysis was performed to determine the most influential articles. The top 10 authors, journals, and countries were identified based on publication counts. The most cited articles were ranked by total citation count.

Results: The most prolific authors in the field were Ichimasa, Katsuro and Kudo, Shinei, each contributing 13 publications, followed by Misawa, Masashi (10 publications), and Mori, Yuichi (8 publications). Several other authors, including Miyachi, Hideyuki and Kouyama, Yuta, also made significant contributions. The majority of articles were published in high-impact journals, with Frontiers in Oncology (12 articles) and European Journal of Surgical Oncology (10 articles) being the most frequent sources. "Artificial intelligence in colorectal cancer screening: A review" (2021), received 188 citations. Other highly cited works included "Transformer-based biomarker prediction from colonoscopy images" (2023, 170 citations) and "Artificial intelligence system to determine risk of colorectal cancer" (2021, 152 citations). China led in publication output with 171 articles, followed by the United States (157), United Kingdom (98), and Japan (90).

Conclusion: The bibliometric analysis reveals a rapidly expanding body of literature on AI in colorectal cancer and surgery, with a notable surge in publications over the past five years. This growth reflects the increasing recognition of AI's potential to enhance diagnostic accuracy, optimize surgical outcomes, and personalize patient care. Leading authors and institutions have contributed significantly to the field, and high-impact journals have provided platforms for disseminating key advancements. The shift in research focus from traditional image analysis to advanced deep learning and predictive modeling underscores the evolving landscape and the integration of AI into clinical workflows. However, challenges remain, including the need for standardized methodologies, validation in diverse populations, and addressing ethical and regulatory considerations.

Experience of laparoscopic colorectal surgery in a newly established general surgery clinic: Analysis of the first 26 cases

Sunguralp Farsak, Muhammet Gündal, Murat Kesen, Murat Akalın, Eyup Kebabçı, Cem Tuğmen

Bakırçay University, Çiğli Training and Research Hospital, İzmir

Objective: Laparoscopic colorectal surgery (LCS) is becoming the gold standard today due to shorter hospital stays, fewer postoperative complications, faster return to daily life, and oncological results similar to conventional colorectal surgery. In this study, we aimed to present the clinical, perioperative, and short-term postoperative outcomes of LCS cases performed in our clinic, accompanied by demographic data and in light of the current literature.

Material and Methods: The data of 26 patients who underwent laparoscopic surgery for colorectal malignancy and benign diseases in our clinic were retrospectively analyzed. Patients' demographic characteristics, stages, surgical features, operation times, lengths of hospital stay, and complication rates were analyzed.

Results: The study included 15 females (57.6%) and 11 males (42.4%), with a mean age of 64.1 years. The mean body mass index of the patients was 27.11 kg/m^2. The procedures performed were laparoscopic anterior resection in 9 patients (34.6%), laparoscopic right hemicolectomy in 8 patients (30.7%), laparoscopic low anterior resection in 5 patients (19.2%), total mesorectal excision in 1 patient, conventional right hemicolectomy after laparoscopic exploration in 2 patients, and conventional abdominoperineal resection after laparoscopic exploration in 1 patient. The mean operation time was 269 minutes, and the mean hospital stay was 6.6 days. The total number of complications was 2 (7.7%), and no mortality was observed. One patient's intraoperative small bowel injury was repaired primarily, and one patient was reoperated due to a postoperative intraabdominal collection. According to the pathology data, of the 26 patients, 6 (23%) were Stage I, 6 (23%) were Stage II, 12 (46%) were Stage III, and 2 patients were evaluated as having low-grade dysplasia.

Conclusion: LCS applications performed in our clinic are safely carried out with low complication rates and short hospital stays. From the perspective of a training clinic, the contribution of these standardized techniques to resident observation and education is significant.

Our clinical experience with wirsungojejunostomy types: A single-center experience

Önder Özcan, Kubilay Sertkaya, Ali Uluer, Mehmet Şah Benk, Oğuz Çatal, Samet Şahin, Semih Yazıcı, Yaman Kaya

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Whipple procedure-related wirsungojejunostomy anastomosis leakage due to malignancy is a serious complication that prolongs hospital stay and can even significantly increase mortality. This study aimed to evaluate the development and severity of postoperative leakage according to the types of wirsungojejunostomies performed in our clinic between January 2024 and January 2026; a retrospective study was conducted

Material and Methods: Thirty patients who underwent Whipple procedure at our clinic between these dates were retrospectively reviewed. Age, gender, diagnosis, type of wirsungojejunostomy anastomosis, and postoperative amylase level, as well as drain amylase level, were recorded. The Callery fistula risk score, used to determine the risk of leakage, and the ISGPS 2016 scores, used to determine the severity of leakage, were calculated retrospectively from patient data. The development of postoperative leakage/pancreatic fistula in patients was also recorded.

Results: The mean age of the patients was 60.5 years, and 20 patients (66.6%) were male. Postoperative leakage/fistula was present in 5 patients (16.66%). Kakita, Blumgart, Blumgart+Coverage, and Peng methods were used as wirsungojejunostomy types. Leakage risk was calculated retrospectively in patients using the ISGPS 2016 score, and leakage severity was calculated using the Callery fistula score. A parallel relationship was observed between the ISGPS 2016 risk classification and Callery fistula severity; leakage development was more frequent in patients in the high-risk group. According to the Callery leakage score, it was significantly lower in the Blumgart + Coverage group.

Conclusion: Different wirsungojejunostomy techniques applied in our clinic were compared in terms of postoperative fistula risk and severity. The WJ leakage rate was 16.66%, consistent with the rates in the literature. When evaluated according to anastomosis methods, patients who underwent Blumgart+Coverage were predominantly found to have a low- and moderate-risk profile according to the ISGPS 2016 classification, and no clinically significant leakage was observed. This finding demonstrates the protective effect of supporting the anastomosis line and covering the pancreatic surface. In patients who underwent Kakita and Blumgart techniques, leakage development was mostly at Grade A-B level, and Grade C fistulas were not observed. This suggests that these techniques offer acceptable results with appropriate patient selection. However, the higher proportion of patients with a moderate-risk profile in the Blumgart technique group indicates that pancreatic tissue and duct diameter are decisive factors in this technique. In conclusion, this study emphasizes the importance of an individualized surgical strategy based on patient and pancreatic characteristics, rather than a standard approach in the selection of the WJ technique.

Laparoscopic repair of giant diaphragmatic hernias: Evaluating the efficacy of the spider-web-like suturing technique combined with composite mesh reinforcement

Fahri Yetişir[1], Ertan Piri[2], Yasin Akın[3], Ramazan Tiken[3], Mete Yarlın Yetişir[4]

[1]*Clinic of General Surgery, Acıbadem Bayındır Private Hospital, Ankara*

[2]*Clinic of Anesthesia and Reanimation, A Life Private Hospital, Ankara*

[3]*Clinic of Radiology, A Life Private Hospital, Ankara*

[4]*Başkent University Faculty of Medicine, Ankara*

Objective: Giant diaphragmatic hernias (GDH) are rare but clinically significant, often leading to severe respiratory and gastrointestinal complications. Surgical repair is challenging, with high recurrence rates, especially in large defects where tension-free closure is difficult. This study evaluates the effectiveness of the spider-web-like suturing technique with composite mesh reinforcement in laparoscopic GDH repair.

Material and Methods: A retrospective analysis of nine patients who underwent laparoscopic GDH repair using the spider-web-like suturing technique between May 2016 and February 2021 was conducted. Patient demographics, preoperative symptoms, intraoperative findings, surgical parameters, and postoperative outcomes were analyzed. The technique involved reducing defect size with spider-web suturing before mesh placement to enhance mechanical support and prevent recurrence (Figure 1).

Results: The mean age was 51.2 years, and the mean hernia defect size was 12.1 cm. The procedure was successfully completed laparoscopically in all cases, with a mean surgical time of 191.1 minutes and hospital stay of 4.4 days. No surgery-related mortality or major complications were observed. Minor complications included transient abdominal distension (all patients) and temporary nausea/indigestion (2 patients). The mean follow-up was 37.7 months, with 89.4% symptom resolution and 93.3% patient satisfaction. No recurrence or mesh-related complications occurred.

Conclusion: The laparoscopic spider-web-like suturing technique with composite mesh reinforcement provides an effective, durable, and minimally invasive approach for GDH repair. It offers low recurrence risk, enhanced mesh stability, and improved patient outcomes (Figure 2). While initial results are promising, further studies with larger cohorts and longer follow-up periods are needed to confirm long-term efficacy.

Keywords: Bochdalek hernia, minimally invasive surgery, mesh fixation

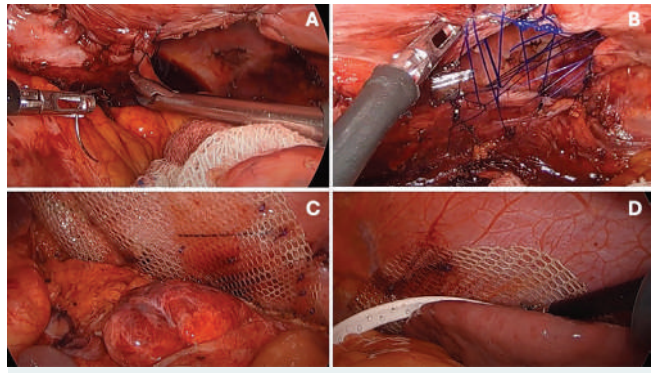

Figure 1. Stepwise repair of a giant diaphragmatic hernia using a spider-web suturing technique and composite mesh placement the giant diaphragmatic hernia was initially reduced by suturing its lateral edges to decrease the defect size. In the area where primary closure was not feasible, sutures were passed through opposing tissues in a spider-web-like fashion to create a structured closure. A composite mesh was then placed over the repaired area and secured for reinforcement. A) The defect is reduced by suturing from three different sides using V-Loc sutures. B) In the area where direct approximation is not possible, sutures are passed through opposing tissues, forming a spider-web-like structure to close the gap. C) A composite mesh is placed over the repaired area, ensuring it extends at least 2 cm beyond the defect, and is secured in place. D) The omentum and spleen are positioned over the repaired area and fixed to provide additional support and protection.

Figure 2. Comparison of preoperative abdominal computed tomography and postoperative chest X-ray images. A) In the preoperative CT scan, it is observed that the diaphragm hernia has allowed the colon, small intestine, stomach, omentum, spleen (white arrow), and kidney (black arrow) to pass into the thoracic cavity, occupying nearly the entire space. B) In the postoperative image, all abdominal organs are seen to be repositioned within the abdominal cavity, and the lung is fully expanded.

[P-128]

Topical etofenomate application in the treatment of anal fissures: Initial results

Emrah Uludağ

Kocaeli State Hospital, Kocaeli

Objective: In this study, we investigated the success rate in preventing painful defecation anxiety and improving the patient's overall comfort and relief by using an agent with analgesic, anti-edema, and anti-inflammatory effects in the treatment of anal fissures.

Material and Methods: Twenty consecutive patients were prospectively treated between September and December 2023. The indication was painful defecation and the presence of anal fissures on rectal examination. Topical etofenomat (72 mg/day, 4 times) and laxative suspension were used in cases with symptoms of chronic clinical constipation. Patients were seen 3 and 10 days after starting treatment. All were asked to answer a questionnaire from 0 to 5 (highest) indicating pain during defecation and rectal examination. The mean follow-up period was 3 months.

Results: Fourteen of the patients were women and six were men. The mean age was 34 (20-54). The pre-treatment pain score was 75% (5) in 15 patients and 25% (4) in 5 patients. Bleeding was present in 14 patients (70%), constipation in 12 patients (60%), and burning in 4 patients (20%) as accompanying symptoms. After 10 days of treatment, a significant reduction in pain score was observed in 16 patients. In 14 patients, the score was 0, meaning no pain, and in 2 patients, the score was 1, indicating regression of the pathology on physical examination. In two female patients, the pain score decreased from 4 to 3, while in the other two patients (both women), treatment was unsuccessful. In the vast majority of patients (80%), accompanying symptoms were also reduced (20%) or disappeared (60%). The only complication of treatment is perianal burning or itching (10%). One of these two patients had perianal maceration.

Conclusion: The data obtained from our study are preliminary and require further studies. On the other hand, local application of etofenomate accelerates fissure healing without any significant side effects and seems promising in the anamedical treatment of fissures.

Can bile leakage be prevented in complex and challenging biliary surgery?

Nurullah Aksoy, Nurullah Bilen, Aziz Bulut

Department of General Surgery, Gaziantep University Faculty of Medicine, Gaziantep

Objective: Laparoscopic cholecystectomy is one of the most commonly performed surgical procedures worldwide. However, bile leakage, stricture formation, intra-abdominal collections, cholangitis, and the need for reintervention may occur following cholecystectomy or other biliary tract surgeries. Due to its potent detergent effect on tissues, bile may cause severe inflammation, tissue destruction, and fibrosis, thereby complicating the treatment process. This issue becomes particularly critical in complex biliary cases requiring repeated interventions, where safe access to the biliary system poses a significant challenge. The concept of permanent access has traditionally been employed in situations necessitating long-term drainage and repeated interventions. This study aimed to evaluate the feasibility of a permanent access-like approach in the management of difficult biliary pathologies.

Material and Methods: One patient who developed a full-thickness common bile duct injury during cholecystectomy and two patients who developed anastomotic leakage following hepaticojejunostomy were included in the study. In all cases, the tissues were observed to be severely inflamed, edematous, and friable. Following Roux-en-Y hepaticojejunostomy, a catheter was placed across the anastomotic line and exteriorized through the abdominal wall by fixing it to the proximal (afferent) limb of the jejunal loop used for the anastomosis. In this manner, bile was diverted externally in the early postoperative period, thereby reducing pressure on the anastomotic site. During postoperative follow-up, biliary drainage was maintained via the permanent access-like route, and serial cholangiographic evaluations were performed. Technical success, complications, and clinical outcomes were retrospectively assessed.

Results: Active bile drainage through the catheter was observed in all three patients during the postoperative period, and no intra-abdominal bile leakage was detected. All patients were discharged on postoperative day 10. At three weeks, cholangiography performed via the catheter demonstrated no evidence of anastomotic leakage, and contrast passage to the distal intestine was confirmed in all cases. The catheter was subsequently clamped and removed in a controlled manner. Following catheter removal, normalization of stool color was observed in all patients. One patient developed a superficial wound infection, and one patient developed an incisional hernia. No episodes of cholangitis were observed.

Conclusion: In patients requiring long-term follow-up and repeated interventions after biliary tract surgery, permanent access is known to provide a safe and effective option that improves patient comfort. When applied in appropriately selected patients and in experienced centers, the combination of catheter placement and a permanent access approach may represent a valuable surgical option in the management of complex biliary diseases.

Enteral and parenteral nutrition management in surgical intensive care patients: An integrative review

Ayça Elmaderesi Aydın, Onur Turhan, Emine Bayat

Hacettepe University Hospital, Ankara

Objective: Malnutrition in surgical intensive care units is a significant clinical problem that increases morbidity, mortality, and cost, as well as leading to delayed wound healing, increased risk of infection, loss of muscle strength, and prolonged hospital stay. Intensive care patients undergoing surgical procedures face significant physiological changes due to metabolic stress response. Conditions such as surgical stress, trauma, and sepsis cause rapid loss of body energy stores, negative nitrogen balance, and impaired immune function. The aim of this review is to synthesize, in light of current literature, the assessment of nutritional status in surgical and critically ill patients, the indications, contraindications, timing, and comparison of nutrition, and the importance of evidence-based nursing care in this process.

Material and Methods: This study used an integrative review method. Literature searching was conducted in the Google Scholar database using the keywords "enteral nutrition," "parenteral nutrition," "surgical patient," "intensive care," and "nursing care." Turkish studies published between 2010 and 2025, with full text available, were evaluated without any limitations regarding study type. Twelve studies were included in the review. The studies examined consisted of systematic reviews, meta-analyses, and clinical trials.

Results: The studies show that the malnutrition rate can reach up to 50% in intensive care patients undergoing surgical procedures. Therefore, nutritional support is an integral part of the treatment process. Any patient who stays in the intensive care unit for more than 48 hours should be considered at risk of malnutrition. Enteral nutrition should always be the first choice for patients with a functional gastrointestinal system; however, parenteral nutrition is life-saving when the gastrointestinal system is unusable or enteral nutrition is insufficient. Enteral nutrition preserves the mucosal integrity of the gastrointestinal system, is more physiological, reduces the risk of infection, and is less expensive than parenteral nutrition. In critically ill patients who are hemodynamically stable and have gastrointestinal function, it is recommended to start nutrition within the first 24-48 hours. Post-surgical accelerated recovery protocols also support avoiding prolonged fasting and initiating early nutrition.

Conclusion: In surgical and intensive care patients, nutritional support is a crucial part of treatment, not only to close the calorie deficit but also to manage the metabolic response and accelerate recovery. While the "use it if the gut is working" principle remains valid, parenteral support should be used when the targeted energy intake cannot be achieved. The success of nutritional management depends on early initiation, correct route selection, regular monitoring, and evidence-based nursing care.

Keywords: Enteral nutrition, parenteral nutrition, surgical patient, intensive care, nursing care

Temporary grafting as a barrier to protect brachial vein burn developed as a result of electrical arc burn

Mehmet Özyıldız[1], Barış Tüzün[1], Gamzenur Güney[2], Murat Burç Yazıcıoğlu[2]

[1]*Department of General Surgery Burn Center, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: In fourth-degree burns caused by high-voltage arc fires, subcutaneous tissues, muscles, and even internal organs have been observed to be affected. Vascular burns are rare complications and are difficult to detect and treat.

Material and Methods: A 46-year-old male patient was electrocuted and fell from a height after contact with a high-voltage power line. He was referred to our emergency clinic from a secondary healthcare center three hours after the trauma. The characteristics of his burns, the treatment applied, and the results were retrospectively evaluated.

Results: The patient had grade 3 and 4 burns covering most of the right upper extremity, grade 3 burns in the right axilla, and grade 3 burns covering almost the entire lateral aspect of the right thorax and abdomen. Compartment syndrome was detected in the right hand and forearm. Emergency decompression surgery was performed. Exploration was carried out to the axilla using a Lazy-S incision. Widespread necrosis was detected in all muscles of the volar surface of the forearm and debrided. An adventitial burn was observed in a 1 cm area 10 cm from the axilla in the proximal brachial vein. To prevent traumatization and injury to this area during dressing changes, the entire brachial vein was closed with a temporary split-thickness graft. In the subsequent period, after escharectomies, all burn areas were closed with partial-thickness grafts in 2 sessions starting from the 15th day. Advanced electromyographic examination of the patient showed near-complete loss of radial, ulnar, and median nerve conduction in the right arm. At six months, there were no remaining skin defects or open wounds, and although right upper extremity function had partially improved, it remained severely plegic. Venous Doppler examination of the right upper extremity revealed no pseudoaneurysm, and venous flow was normal.

Conclusion: Decompression surgery performed within the first 6 hours and by a burn center team yields the best results. In this case, we wanted to report that multiple compartments were affected, numerous muscles, tendons, and vascular structures were involved, therefore the incision (Lazy-S is preferred in our center) was kept wide, and the exposed venous structure was protected with a temporary partial-thickness skin graft. Synthetic barriers can also be used as an alternative. However, we found the skin graft suitable to allow visualization of the area where frequent debridement may be necessary. Temporary partial-thickness skin grafts can be used to protect exposed vascular structures for evaluation of necrosis and underlying tissues.

Experience with 120 TAPP cases in a secondary care center

Tugberk Tok, Ahmet Furkan Mazlum

Karadeniz Ereğli State Hospital, Zonguldak

Objective: Laparoscopic transabdominal preperitoneal (TAPP) repair is a widely accepted approach for inguinal hernia treatment. This study presents early outcomes from 120 TAPP procedures performed in a secondary care hospital.

Material and Methods: Between October 2024 and July 2025, a total of 120 TAPP cases performed by a consistent surgical team at Zonguldak Karadeniz Ereğli State Hospital were retrospectively analyzed. All patients underwent standardized procedures using polypropylene mesh, absorbable tackers for fixation, and continuous closure of the peritoneum with 3/0 V-Loc suture. Hernia defects were left open.

Results: Patients ranged from 20 to 75 years of age, with 108 males. The mean BMI was 32. Comorbidities included hypertension (40%), diabetes mellitus (26%), COPD (8%), and coronary artery disease (32%). Among the cases, 104 were primary and 16 were recurrent hernias. The average operation time was 40 minutes. One case experienced epigastric artery injury requiring drainage. Postoperatively, 2 patients developed atelectasis and 6 developed seromas, 2 of which required interventional drainage. No wound infection, mesh infection, ileus, or chronic pain was observed. VAS scores were 6 on day 1 and 2 on day 10.

Conclusion: Our experience shows that TAPP repair can be safely and effectively performed even in a secondary care hospital. Low complication rates and high patient satisfaction were achieved through consistent surgical technique and team standardization. Peritoneal closure and leaving hernia defects open were found to be safe strategies.

Effects of preoperative parameters and compliance with the weight loss process on post sleeve gastrectomy weight loss

Eyüp Can İşlek[1], Muhammet Kadri Çolakoğlu[2], Oya Topaloğlu[2], Erdal Birol Bostancı[2]

[1]*Kurtalan State Hospital, Siirt*

[2]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

Objective: Obesity is a chronic disease that is increasingly prevalent and poses a significant risk of morbidity and mortality. Individuals with a body mass index (BMI) of 30 kg/m² or higher are classified as obese, and obesity is associated with health issues such as diabetes, cardiovascular diseases, and hypertension. Bariatric surgery is considered one of the most effective methods for achieving sustained weight loss. Sleeve gastrectomy is a commonly performed procedure that reduces stomach volume, thereby limiting food intake and providing metabolic benefits. However, surgical success is not solely dependent on the procedure itself but also on patients preoperative parameters and adherence to preoperative education. The aim of this study is to evaluate the effects of preoperative patient parameters and compliance with preoperative education on postoperative weight loss in patients undergoing sleeve gastrectomy.

Material and Methods: This retrospective study includes 113 patients who underwent sleeve gastrectomy at Ankara Bilkent City Hospital Obesity Center between December 2019 and December 2023. Inclusion criteria included patients aged 18 years and older who underwent sleeve gastrectomy and completed the follow-up process. Patients who underwent other bariatric surgical procedures or revision surgery were excluded from the study. The evaluation parameters included age, gender, preoperative and postoperative weight, BMI, waist to hip ratio, blood pressure, HbA1c, and lipid profile.

Results: The mean age of the patients was 42.22±11.55 years, with 83.2% being female and 16.8% male. Comorbid conditions such as diabetes (29.2%) and hypertension (18.6%) were identified. The average weight loss at postoperative 3 months was -28.37±12.48 kg for male patients and -22.45±8.85 kg for female patients (p=0.035). The total weight loss at postoperative 12 months was -42.32±15.81 kg for males and -35.30±12.69 kg for females (p=0.020). A moderate, positive, and statistically significant relationship was found between total and excess weight loss in the preoperative 3 months and excess weight loss at postoperative 3 and 12 months (p<0.005). The results indicate that as preoperative 3 month weight loss increases, postoperative 3 month and 12 month weight loss also increases.

Conclusion: This study demonstrates that preoperative patient parameters and compliance with preoperative education have a significant impact on postoperative weight loss in patients undergoing sleeve gastrectomy. Male patients experienced greater weight loss than females. Furthermore, adherence to preoperative education and preparation was found to support postoperative weight loss. These findings provide guidance for patient selection criteria and preoperative education processes in bariatric surgery applications.

Keywords: Obesity, sleeve gastrectomy, weight loss

Endoscopic submucosal dissection for gastrointestinal polypoid lesions: A single-center experience

Barış Dağdemir, Emre Bozlakoğlu, Hilmi Yazıcı, Vural Argın, Asım Cingi

Surgical Endoscopy Unit, Marmara University Pendik Training and Research Hospital, İstanbul

Objective: Endoscopic submucosal dissection (ESD) is a curative and organ-preserving treatment modality that can be applied as an alternative to surgery in superficial gastrointestinal neoplastic lesions. This study aimed to evaluate the clinical and pathological outcomes of ESD procedures performed at our center and to assess procedure-related complications.

Material and Methods: Patients who underwent ESD at the Surgical Endoscopy Unit of Marmara University Pendik Training and Research Hospital between September 2024 and January 2026 were retrospectively analyzed. A total of 20 patients were included. Lesion localization, size, en-bloc and R0 resection rates, complications, and histopathological results were evaluated. One patient whose pathology report was not yet available was excluded from the study.

Results: The mean age of the patients was 65 years. Seventeen lesions (85%) were colorectal and three (15%) were gastric in origin. Lesion size was ≤20 mm in seven patients (35%) and >20 mm in thirteen patients (65%). En-bloc resection was achieved in 16 patients (80%), and R0 resection in 18 patients (90%). Bleeding occurred in four patients (20%); three were early and one was delayed. All bleeding episodes were successfully managed with endoscopic clip application. Perforation was observed in three patients (15%). In two patients, perforation was recognized intraoperatively and closed with endoscopic clips. One of these cases involved a 3 cm sessile lesion in the sigmoid colon, in which a wall defect developed during deep dissection. In one patient, no obvious perforation was detected during the procedure; however, minimal free air was identified on postoperative CT. This patient was managed conservatively following clip application, and no emergency surgery was required. Histopathological examination revealed tubular adenoma in seven patients, tubulovillous adenoma in six, sessile serrated lesion in four, and T1 adenocarcinoma in three patients. Among the gastric lesions, one patient had a well-differentiated neuroendocrine tumor (Grade 1) located in the corpus, with lymphovascular and perineural invasion and positive deep and lateral margins. One of the two patients with non-R0 resection had invasive adenocarcinoma in the sigmoid colon (pT1, Grade 3, lymphovascular invasion positive, lateral margin positive) and underwent laparoscopic anterior resection; no residual tumor was detected in the surgical specimen. The other patient is under multidisciplinary evaluation. No recurrence was observed during early follow-up.

Conclusion: ESD performed at our center achieved high R0 resection rates, and procedure-related complications such as bleeding and perforation were largely managed endoscopically. In cases of non-curative resection, ESD played an important role in guiding further treatment decisions.

Keywords: ESD, polypoid lesions, en-bloc resection

[P-135]

Clinical value of RDW in predicting the presence of lymphoma: A retrospective study

Betül Kübra Aydın Mucuk

Gazi University Faculty of Medicine, Ankara

Objective: Lymphoma is a malignancy characterized by frequently non-specific clinical and laboratory manifestations, necessitating histopathological assessment for a definitive diagnosis. In clinical practice, there is a critical need for readily accessible parameters to predict which patients require prioritization for invasive diagnostic interventions. The objective of this study is to evaluate the clinical utility of specific hematological and biochemical parameters, derived from routine laboratory investigations, in predicting the presence of lymphoma among patients undergoing evaluation for suspected malignancy.

Material and Methods: Patients who underwent axillary lymph node sampling after being referred from the hematology clinic with suspected lymphoma between February 2024 and February 2026 were included in the study. Based on histopathological diagnosis, patients were divided into two groups: Those diagnosed with lymphoma and those who were not. Age and gender data, along with lymphocyte count, neutrophil-to-lymphocyte ratio (NLR), red cell distribution width (RDW), lactate dehydrogenase (LDH), albumin, and systemic immune-inflammation index (SII) values, were retrospectively analyzed. Data were analyzed using SPSS version 23.0. In descriptive statistics, categorical variables were presented as numbers and percentages, while continuous variables were expressed as mean ± standard deviation or median (interquartile range). Differences in categorical variables between groups were analyzed using appropriate chi-square tests, and differences in continuous variables were assessed using the Mann-Whitney U test. Statistical significance was set at $p<0.05$.

Results: A total of 27 patients were included in the study. The mean age of the patients was 54.5±18.1 years, and 51.9% were male. It was determined that 40.7% (11 patients) were diagnosed with lymphoma. No statistically significant differences were observed between the groups with and without a lymphoma diagnosis in terms of age ($p=0.394$), gender ($p=0.532$), lymphocyte count ($p=0.294$), NLR ($p=0.080$), LDH ($p=0.162$), albumin ($p=0.080$), and SII ($p=0.121$). The median RDW value was 16.20 (15.50-18.60) in the lymphoma group and 14.45 (12.70-15.93) in the non-lymphoma group. RDW values were found to be statistically significantly higher in the lymphoma group compared to the non-lymphoma group ($p=0.039$).

Conclusion: These findings suggest that routine blood parameters may guide clinicians in evaluating suspected lymphoma. Specifically, the association between RDW and lymphoma presence indicates its potential as a simple, cost-effective supportive marker in clinical decision-making. However, these results should not be used independently for diagnosis and warrant validation through larger, prospective studies.

Retrospective analysis of colorectal cancer surgery before, during, and after the COVID-19 pandemic (2018-2025)

Mert Şotik, Sinan Efe Yazıcı, Sermet Terzi, Erdinç Çetinkaya

Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara

Objective: This study aimed to evaluate the impact of the COVID-19 pandemic on colorectal cancer diagnosis and surgical treatment processes by comparing emergency/elective surgery rates and disease stage at presentation across the pre-COVID, COVID, and post-COVID periods.

Material and Methods: In this retrospective single-center study, the periods were defined as follows: Pre-COVID (March 2018-February 2020), COVID (March 2020-April 2022), and post-COVID (May 2022-December 2025). Patients aged ≥18 years with histopathologically confirmed colon cancer who underwent elective or emergency surgery and whose data were accessible were included. Patients with rectal cancer were excluded. Emergency versus elective surgery rates, disease stage [early stage (Stage I-II) vs advanced stage (Stage III-IV)], and presence of metastatic disease were compared across the three periods.

Results: A total of 446 colorectal cancer cases were analyzed (pre-COVID: n=130, COVID: n=101, post-COVID: n=215). Emergency surgery rates during the pre-COVID, COVID, and post-COVID periods were 17.69% (n=23), 11.88% (n=12), and 13.49% (n=29), respectively, with no statistically significant difference between periods (p=0.38). The proportion of patients presenting with advanced-stage disease was 59.2% (n=77) in the pre-COVID period, 58.4% (n=59) during COVID, and 48.8% (n=105) in the post-COVID period, with no statistically significant difference (p=0.10). Similarly, metastatic disease rates were 11.5% (n=15), 12.9% (n=13), and 8.8% (n=19) across the respective periods, and the difference was not statistically significant (p=0.50).

Conclusion: No statistically significant differences were observed among the three periods regarding advanced-stage diagnosis, metastatic disease rates, or emergency surgical presentation in colorectal cancer patients at our center. However, compared with the pre-COVID and COVID periods, a decreasing trend in advanced-stage presentation and metastatic disease rates was observed in the post-COVID period. Multicenter studies are needed to better clarify the impact of the pandemic on colorectal cancer diagnosis and treatment processes.

Time-dependent effects of botulinum toxin and glyceryl trinitrate on postoperative pain after excisional hemorrhoidectomy: A systematic review and meta-analysis

Mert Yiğit Akdoğan, Furkan Uğur, Ahmet Berkay Arat

Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: Postoperative pain following excisional hemorrhoidectomy remains a significant clinical problem, adversely affecting patient comfort, recovery, and return to daily activities. Internal anal sphincter spasm is considered a major contributing factor, along with other multifactorial mechanisms. Chemical sphincter relaxation strategies, including botulinum toxin and topical glyceryl trinitrate (GTN), have been proposed to reduce postoperative pain. However, their time-dependent efficacy has not been clearly established. This study aimed to evaluate and compare the effectiveness of botulinum toxin and GTN in postoperative pain control using a systematic review and meta-analysis.

Material and Methods: This systematic review and meta-analysis was conducted in accordance with PRISMA 2020 guidelines. PubMed was systematically searched for randomized controlled trials evaluating botulinum toxin or topical GTN for pain control after excisional hemorrhoidectomy. Studies involving stapled hemorrhoidopexy or Doppler-guided techniques were excluded. Pain outcomes were standardized to a 0-10 visual analog scale. Mean differences (MD) with 95% confidence intervals (CI) were calculated using a random-effects model for postoperative days 1, 3, and 7.

Results: Nine randomized controlled trials were included in the systematic review, and eight studies comprising 452 patients were eligible for meta-analysis. On postoperative day 1, GTN significantly reduced pain compared to controls (MD -0.72, 95% CI -1.18 to -0.26; p=0.002; I^2=48%), whereas botulinum toxin showed no significant effect (MD -0.21, 95% CI -0.58 to 0.16; p=0.26). On postoperative day 3, both GTN (MD -0.64, 95% CI -1.09 to -0.19; p=0.005; I^2=52%) and botulinum toxin (MD -0.68, 95% CI -1.12 to -0.24; p=0.003; I^2=46%) significantly reduced pain scores. On postoperative day 7, botulinum toxin demonstrated a greater and more consistent analgesic effect (MD -1.12, 95% CI -1.63 to -0.61; p<0.001; I^2=34%), while GTN was not statistically significant (MD -0.38, 95% CI -0.82 to 0.06; p=0.09). Headache was the most common adverse event with GTN, occasionally leading to discontinuation. Botulinum toxin was not associated with increased serious adverse events.

Conclusion: Chemical sphincter relaxation demonstrates time-dependent effects on postoperative pain following excisional hemorrhoidectomy. GTN provides superior pain relief in the early postoperative period, whereas botulinum toxin offers more sustained analgesia in later stages. Considering its single-dose administration and favorable safety profile, botulinum toxin may represent a more durable analgesic option. Further high-quality randomized controlled trials are required to determine optimal treatment strategies.

Placement of markers and the impact on surgical outcomes in node-positive breast cancer patients prior to neoadjuvant therapy

Tuba Sönmez[1], Atahan Uzun[2]

[1]*Darende Hulusi Efendi State Hospital, Malatya*

[2]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

Objective: Accurate surgical management of the axilla after neoadjuvant chemotherapy (NACT) is crucial to prevent unnecessary axillary lymph node dissections (ALND). This study aimed to evaluate the impact of marker (clip) placement in biopsy-proven metastatic axillary lymph nodes prior to NACT on surgical and oncological outcomes.

Material and Methods: A total of 192 patients who underwent surgery after NACT at our tertiary breast surgery center between 2019 and 2024 were retrospectively analyzed. Patients were divided into two groups based on whether a marker was placed in the axillary lymph node. Surgical approach [sentinel lymph node biopsy (SLNB)/ALND], number of excised lymph nodes, pathological response, and surgery-related complications were compared between groups. Statistical analyses were performed using SPSS version 21.0, and p values <0.05 were considered statistically significant.

Results: Among the 192 patients, marker placement in the axillary lymph node was performed in 124 patients. In the marker group, the sensitivity (33.7%) and negative predictive value (14.7%) of SLNB were higher. In contrast, specificity was higher in the non-marker group (58.3%). No significant difference was observed between patients undergoing SLNB and ALND in terms of surgical complications such as reoperation and lymphedema. Univariate analysis identified advanced nodal stage (N2) (p=0.011) and older age (p=0.016) as factors significantly associated with the need for ALND.

Conclusion: Removal of the marker-placed lymph node during axillary evaluation after NACT improves the accuracy of axillary staging and enhances the reliability of SLNB. Marker placement is an effective method that may reduce the need for ALND in appropriately selected patients. However, the decision to avoid axillary dissection in patients with high nodal burden should be made with caution.

Immediate breast reconstruction concurrent with mastectomy: Our clinical experience

Rona Cansu Kavar Ağcabay, Mehmet Arda Yıldırım, Tarık Buğra Naralan, Nuri Emrah Göret, Eyüp Kebabçı

Bakırçay University, İzmir

Objective: Approximately one in eight women worldwide will be diagnosed with breast cancer during their lifetime. Preserving psychosocial well-being is particularly important for patients with a history of mastectomy due to breast cancer or an increased risk of developing breast cancer. Reconstructive options include autologous reconstruction and implant-based techniques. Although autologous reconstruction was more commonly preferred before the 2000s, implant-based reconstruction has become markedly more popular in recent years. This study aimed to report the clinical outcomes of patients who underwent immediate breast reconstruction at the time of mastectomy.

Material and Methods: Thirty-two patients who underwent immediate implant-based breast reconstruction in the subpectoral plane concurrently with mastectomy between January 2024 and January 2026 were retrospectively reviewed.

Results: The mean age of female patients was 42.8 years (range, 29-55). The mean body mass index was 19.60 kg/m^2 (range, 14.56-25.62). The mean length of hospital stay was 6.84 days. Subcutaneous mastectomy and reconstruction were performed in 32 breasts: unilateral in 29 patients (90.6%) and bilateral in 3 patients (9.4%). The mean breast specimen weight was 511.4 g. The mean implant volume was 399.1 cc (range, 250-600). No complications occurred in 22 of 32 patients. Complications were observed in 10 patients, including one patient who underwent bilateral subcutaneous mastectomy and reconstruction. Among the 10 breasts with complications, partial skin necrosis occurred in 3, bleeding in 1, wound dehiscence in 5, and pneumothorax in 1 patient. Patients with wound complications were treated with debridement and primary closure. Among molecular subtypes, the most common were luminal A (n=11) and luminal B (n=9).

Conclusion: Our single-center experience suggests that immediate subpectoral implant-based reconstruction at the time of mastectomy is a feasible option and that complications are largely manageable. Appropriate patient selection, careful assessment of mastectomy flap quality, and multidisciplinary follow-up are critical to reducing complications. Immediate reconstruction is often preferred, particularly by patients with greater cosmetic concerns. Some studies have identified immediate mastectomy plus reconstruction as a factor associated with reduced psychiatric comorbidity. Given the multitude of parameters involved—together with the cancer treatment process and patient adherence—it is evident that optimal treatment selection requires a multidimensional evaluation.

A rare and aggressive malignancy: Clinical, surgical, and pathological analysis of our adrenocortical carcinoma cases

Muhammed Metin Yüksel[1], Duray Şeker[1], Serkan Demir[1], Muhammed Salih Süer[1], Faruk Yazıcı[2], Serhat Tokgöz[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Adrenocortical carcinoma (ACC) is a rare but highly aggressive endocrine malignancy characterized by a distinct biological behavior and poor prognosis. This study aimed to evaluate the demographic, clinical, surgical, and pathological characteristics, along with adjuvant therapy, recurrence, and follow-up outcomes of patients who underwent adrenalectomy and were histopathologically diagnosed with ACC in our clinic.

Material and Methods: Eleven patients who underwent adrenalectomy and were diagnosed with ACC based on pathological reports were retrospectively analyzed. Demographics, clinical presentation, hormonal functional status, radiological and surgical findings, and pathological parameters (Weiss score, Ki-67, mitosis, invasion status, and ENSAT staging) were recorded. Additionally, adjuvant mitotane therapy, recurrence, follow-up duration, and mortality data were collected. Continuous data were mean ± standard deviation or median (min-max), while categorical variables were expressed as frequencies and percentages.

Results: The study included 11 patients (mean age: 50.3 ± 13.7 years; 54.5% male). Mean BMI was 30.2 ± 8.2 kg/m^2 and ASA III rate was 54.5%. Incidentalomas were found in 63.6%. Functional tumors comprised 63.6%, with cortisol excess (Cushing's) as the primary presentation (36.4%); no virilization or feminization occurred. Hyperaldosteronism, hypokalemia, and hypertension rates were 9.1%, 9.1%, and 27.3% (Table 1A). Median operative time was 180 (95-300) minutes. Complication rate was 18.2%; none were Clavien-Dindo $\ge$III. Median hospital stay was 6 (3-12) days (Table 2B). Pathology showed capsular invasion in 54.5% and vascular invasion in 45.5%. R0 resection rate was 72.7% (Table 3B). Median tumor diameter was 90 (45-180) mm. Median Ki-67 was 25% (10-55) and mitotic activity was 16/50 HPF (5-40) (Table 3A). Per ENSAT staging, 45.5% were Stage III and 18.1% Stage IV (Table 3C). Adjuvant mitotane was given to 45.5%. Over a median 21 (3-27) month follow-up, recurrence and mortality rates were 18.2% and 9.1%.

Surgical management, treatment, and clinical outcomes in adrenal myelolipomas: A single-center experience

Muhammed Metin Yüksel[1], Serkan Demir[1], Muhammed Salih Süer[1], Faruk Yazıcı[2], Duray Şeker[1], Melih Akıncı[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*
[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Adrenal myelolipomas are rare, benign adrenal tumors that are mostly detected incidentally. Clinical uncertainty regarding the surgical approach can occur because they can reach large sizes, their imaging findings can overlap with malignant adrenal tumors, and they rarely lead to complications such as intratumoral hemorrhage. In this study, we aimed to evaluate the detailed clinical, radiological, hormonal, and surgical outcomes of patients in our clinic whose diagnosis of adrenal myelolipoma was histopathologically confirmed following adrenalectomy.

Material and Methods: Seven patients undergoing adrenalectomy with histopathologically confirmed adrenal myelolipoma were retrospectively reviewed. Clinical analysis included demographics, comorbidities, detection mode, tumor laterality/size, CT density, intratumoral hemorrhage, and hormonal status. Surgical indications, operative approach, operative time, postoperative complications, and follow-up outcomes were recorded. Data were analyzed using descriptive statistics.

Results: Mean patient age was 56.4±11.9 years, with a male predominance (71.4%). Most myelolipomas were detected incidentally (85.7%) (Table 1). Laterality was equally distributed between right and left sides (42.9% each), with one bilateral case (14.3%). Mean tumor diameter was 67.9±18.6 mm; 71.4% were giant myelolipomas (>6 cm). Mean CT density was -32.1±11.4 HU, consistent with adipose content. Intratumoral hemorrhage occurred in one patient (14.3%), necessitating surgery due to symptoms (Table 2). Hormonal evaluation revealed only one functional tumor (14.3%). Primary surgical indications were size (57.1%), symptoms (14.3%), hemorrhage (14.3%), and suspicious imaging (14.3%). Surgical approaches included laparoscopic (57.1%), open (28.6%), and robotic (14.3%) adrenalectomy. Mean operative time was 112±26 minutes. No major complications (Clavien-Dindo ≥3) occurred. Over a median follow-up of 21 months (3-39), no recurrence or mortality was recorded (Table 4).

Conclusion: Literature indicates that adrenal myelolipomas are typically non-functional, incidental benign lesions, with surgery recommended for tumors >6 cm, symptomatic cases, intratumoral hemorrhage, or malignancy suspicion. Notably, our series achieved adrenalectomy without major morbidity, recurrence, or mortality, despite a predominance of giant myelolipomas. The successful use of minimally invasive techniques confirms that laparoscopic and robotic approaches are safe and effective for large lesions in experienced centers. This study demonstrates that while tumor size is the primary determinant for surgery, symptoms, hemorrhage, and suspicious imaging findings are critical complementary indications, providing real-world guidance for clinical management (Table 5).

Clinicopathological evaluation of Hürthle cell thyroid lesions: A case series

Ahmetcan Atmaca, Muhammed Salih Süer, Serkan Demir, Gamze Kızıltan, Melih Akıncı

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Hürthle cell thyroid neoplasms lead to uncertainties in clinical management due to the difficulty of distinguishing adenoma from carcinoma using preoperative cytological and radiological methods. In this study, we aimed to evaluate the clinical, radiological, and pathological features of patients with Hürthle cell lesions who underwent surgical treatment in our clinic and to identify distinctive findings suggestive of carcinoma.

Material and Methods: Four patients who underwent total thyroidectomy in our clinic and whose final pathology was reported as Hürthle cell neoplasm were retrospectively reviewed. Demographic data, preoperative ultrasonography findings (TI-RADS classification), fine-needle aspiration biopsy results (Bethesda classification), surgical and pathological features, adjuvant treatment approaches, and follow-up outcomes were evaluated. Pathological examination particularly analyzed the presence of capsular invasion, vascular invasion, and extrathyroidal extension. Additional parameters such as thyroid function tests, ultrasonographic morphological features, and lymph node status were described based on clinical records.

Results: All patients included in the study were female, with a median age of 54 years (range: 47-69). Preoperative ultrasonography revealed TI-RADS category 4 nodules in all cases, with nodule sizes ranging from 8 to 56 mm. Fine-needle aspiration biopsy results ranged from Bethesda categories 2 to 6, with cytological findings overlapping between benign and malignant groups. Final pathological evaluation identified Hürthle cell carcinoma in 2 patients and Hürthle cell adenoma in 2 patients. Vascular invasion was observed in all patients with Hürthle cell carcinoma, whereas no vascular invasion, capsular invasion, or extrathyroidal extension was detected in adenoma cases. Capsular invasion and extrathyroidal extension were observed exclusively in the carcinoma group. Preoperative thyroid function tests, when available, indicated a euthyroid state in all patients. Ultrasonographic assessment showed that all nodules were solid, and no distinct morphological differences were identified between benign and malignant cases. No lymph node involvement was detected based on clinical and imaging findings. All patients in the carcinoma group received adjuvant radioactive iodine therapy. Follow-up duration ranged from 3 to 96 months, during which recurrence was observed in one carcinoma case. No mortality was observed during the study period.

Conclusion: In conclusion, this case series highlights the limited ability of preoperative ultrasonographic and cytological methods to reliably distinguish adenoma from carcinoma in Hürthle cell thyroid lesions. Our findings emphasize that postoperative pathological features, particularly vascular invasion and other invasive criteria, represent the most consistent and reliable indicators of malignancy. Despite the limited number of patients, these results support a pathology-based approach in clinical decision-making and follow-up strategies and underscore the need for careful long-term surveillance, especially in patients with Hürthle cell carcinoma.

Parathyroid surgery: A single-center, single-surgeon experience (53 cases)

Ali Sarı, İbrahim Kurtoğlu

Kastamonu Training and Research Hospital, Kastamonu

Objective: Parathyroid surgery is the definitive treatment for primary hyperparathyroidism and is increasingly performed in general surgical practice. Primary hyperparathyroidism is one of the most common causes of hypercalcemia, particularly affecting elderly patients and women. With appropriate patient selection and a standardized surgical approach, high success rates with low complication risk can be achieved. This study aimed to present the demographic characteristics, preoperative imaging findings, pathological diagnoses, and early postoperative clinical and biochemical outcomes of patients who underwent parathyroid excision at our center.

Material and Methods: A retrospective analysis was conducted of 53 patients who underwent parathyroid surgery at a single center by a single surgeon. Demographic data, comorbidities, preoperative biochemical parameters [serum calcium and parathyroid hormone (PTH) levels], preoperative imaging results (ultrasonography and/or scintigraphy), pathological diagnoses, early postoperative laboratory findings, complications, reoperation rates, and length of hospital stay were evaluated. Intraoperative intact PTH monitoring could not be performed due to technical limitations, and frozen section examination was not routinely used. The study was designed as a descriptive analysis.

Results: Of the patients, 77.4% (n=41) were female and 22.6% (n=12) were male. Most patients were elderly, and a considerable proportion had at least one comorbidity. The mean preoperative serum calcium and PTH levels were 11.1 mg/dL and 273.6 pg/mL, respectively. Preoperative imaging successfully localized the parathyroid lesion in 90.6% of patients (n=48). Pathological examination revealed parathyroid adenoma in 92.5% (n=49) and parathyroid carcinoma in 7.5% (n=4). Single-gland excision was performed in 81.1% of cases (n=43), while multigland excision was required in 18.9% (n=10). Despite the absence of intraoperative PTH monitoring and routine frozen section analysis, significant biochemical improvement was observed. On postoperative day one, mean serum calcium and PTH levels decreased to 8.9 mg/dL and 38.0 pg/mL, corresponding to reductions of approximately 20% and 85%, respectively. Most patients experienced no postoperative complications, and hospital stay was generally limited to one day.

Conclusion: Parathyroid surgery at our center achieved high rates of successful preoperative localization, marked early postoperative biochemical improvement, and low complication rates. Even without intraoperative intact PTH monitoring and routine frozen section examination, effective and predictable outcomes were obtained with careful surgical exploration and appropriate patient selection.

Keywords: Parathyroid surgery, parathyroid hormone, serum calcium

Outcomes of percutaneous cholecystostomy in high-risk patients with acute cholecystitis: A single-center experience

Veysi Gökyer, İbrahim Doğan, Mehmet Kadir Bartın, Sebahattin Çelik

Department of General Surgery, University of Health Sciences Türkiye, Van Training and Research Hospital, Van

Objective: Emergency surgery in high-risk patients with acute cholecystitis is associated with substantial morbidity and mortality. In this patient population, percutaneous cholecystostomy (PC) has been proposed as an alternative or bridge-to-surgery treatment option. This study aimed to evaluate the clinical outcomes of PC in high-risk patients with acute cholecystitis.

Material and Methods: In this retrospective study, 53 patients with acute cholecystitis who underwent PC at our institution were analyzed. Demographic characteristics, diagnoses, Tokyo severity grades, ASA scores, Charlson comorbidity index (CCI), indications for cholecystostomy, need for intensive care, length of hospital stay, 30-day mortality, recurrent cholecystitis episodes, and rates of elective cholecystectomy were recorded.

Results: The mean age of the 53 patients was 75.2±11.8 years, and 64.2% were male. Regarding diagnosis, 83.0% had acute cholecystitis and 17.0% had perforated cholecystitis. According to the Tokyo classification, 77.4% of patients were classified as grade III. In terms of surgical risk, 71.7% were ASA III and 28.3% were ASA IV. The mean CCI was 5.9±2.1. The most common indication for PC was high surgical risk (67.9%), followed by sepsis (20.8%) and need for intensive care (11.3%). Overall, 41.5% of patients required intensive care unit follow-up. The median length of hospital stay was 12 days (IQR: 7-18). The 30-day mortality rate was 7.5%. During follow-up, 83.0% of patients did not experience recurrent cholecystitis. Only 18.9% of patients subsequently underwent elective cholecystectomy.

Conclusion: PC is an effective and safe treatment option in high-risk patients with acute cholecystitis, with relatively low 30-day mortality rates. Particularly in elderly patients with significant comorbidities, this approach may serve as an alternative to emergency surgery and often remains the definitive treatment in a substantial proportion of patients.

Pancreatic osteoclast-like giant cell undifferentiated carcinoma: A rare case treated with surgical resection

Aziz Bulut, Nurullah Bilen, Nurullah Aksoy, Beyza Kent Aslan, Sacid Çoban

Gaziantep University Faculty of Medicine, Gaziantep

Objective: Undifferentiated pancreatic carcinoma with osteoclast-like giant cells (UC-OGC) is an extremely rare histological subtype among pancreatic malignancies, accounting for less than 1% of all pancreatic tumors. This study aimed to present a case of UC-OGC treated surgically.

Material and Methods: Patient data were retrospectively obtained from the database of Gaziantep University Hospital.

Results: A 72-year-old male patient presented to the emergency department with abdominal pain. Ultrasound revealed a suspicious lesion in the pancreas, and the patient underwent further investigation. A mass was detected in the pancreatic corpus during the evaluation for pancreatic cancer. Dynamic contrast-enhanced upper abdomen CT scan revealed a heterogeneous hypodense mass measuring approximately 48×45×40 mm in the pancreatic corpus, extending superoposteriorly and containing cystic-necrotic areas. There was approximately 5 mm dilation in the tail section of the pancreatic duct. The lesion was in close proximity to the celiac trunk and its branches, as well as the portal and splenic veins, and its borders with the right diaphragmatic crus could not be clearly distinguished. A PET-CT scan performed for staging purposes revealed a hypermetabolic lesion measuring 4.72×3.60 cm in the pancreatic corpus with an SUV_{max} of 14.75 and a centrally hypometabolic (consistent with necrosis). Additionally, a suspicious soft tissue lesion measuring 1.3 cm with low FDG uptake was observed. Tru-cut biopsy results revealed findings consistent with an UC-OGC; carcinosarcoma could not be definitively ruled out. The patient underwent neoadjuvant chemotherapy. A PET-CT scan performed after treatment showed a slight increase in the size of the lesion and metabolic stability (5.37×4.29 cm, SUV_{max} 15.2). Surgical treatment was then planned, and the patient underwent distal pancreatectomy and splenectomy. No complications developed in the postoperative period, and the patient was discharged without any problems.

Conclusion: UC-OGC is a rare pancreatic malignancy and differs from classic pancreatic ductal adenocarcinoma in terms of clinical and histopathological features. Radiologically, it is usually seen as large masses with a necrotic and heterogeneous structure. The effectiveness of chemotherapy is limited, and a better prognosis is reported in cases where surgical resection is feasible. UC-OGC is rare but should be considered in the differential diagnosis. Preoperative biopsy may be helpful in the diagnostic process, and surgical resection is the primary treatment option in suitable patients.

Evaluation of clinical features, diagnosis, treatment, and surgical outcomes in cases of hydatid cysts with atypical localization: A retrospective study

Mehmet Zafer Sabuncuoğlu[1], İsa Sözen[2], Bilal Turan[2], Serdar Acar[2], İsa Karaca[2], Ahmet Burak Erdoğan[2]

[1]*Department of General Surgery, Akdeniz University Faculty of Medicine, Antalya*

[2]*Department of General Surgery, Süleyman Demirel University Faculty of Medicine, Isparta*

Objective: This study aimed to evaluate the clinical features, diagnostic challenges, and surgical outcomes of hydatid cysts with atypical localization based on a single-center retrospective case series.

Material and Methods: This was a retrospective study of patients who underwent surgery for pathologically confirmed hydatid cysts in locations outside the liver, spleen, and pancreas between 2014 and 2024. Postoperative recurrence, intraoperative and postoperative complications, and the need for reoperation were evaluated. All patients were assessed with ultrasonography and/or computed tomography according to standard diagnostic protocols for hydatid disease, and albendazole was used as adjuvant therapy regardless of cyst localization.

Results: Ten patients (mean age 44.5±17.7 years; 8 females, 2 males) were included. Cysts were localized in musculoskeletal tissues (n=5, 50%), retroperitoneum (n=3, 30%), adrenal gland (n=1, 10%), and adnexal region (n=1, 10%). Total cyst excision was performed in eight patients (80%), while cystotomy and drainage were required in two patients (20%). Postoperative recurrence was observed in two patients (20%), one following excision of a gluteal cyst and one after retroperitoneal cyst drainage; both patients underwent reoperation. No intraoperative or postoperative complications and no mortality were observed during the follow-up period.

Conclusion: This case series demonstrates that hydatid cysts with atypical localization present with diverse anatomical involvement and may be associated with a risk of postoperative recurrence, particularly in non-radical surgical procedures. Careful preoperative evaluation and complete surgical excision, when feasible, may reduce the need for reoperation in these patients.

Classic inflammatory findings may be absent in perforated appendicitis: A diagnostic pitfall

Kanan İsmayilzada[1], Babek Tabandeh[1], Koray Topgül[2], Ramazan Dönmez[1]

[1]*Medicana Ataşehir Hospital, İstanbul*

[2]*Medicana International İzmir Hospital, İzmir*

Objective: Perforated appendicitis is a common surgical cause of acute abdominal pain, and its diagnosis often requires the combined evaluation of clinical findings, laboratory tests, and imaging results. Although inflammatory markers such as leukocytosis and C-reactive protein (CRP) are frequently used as supportive tools, they are not always reliable predictors. Ultrasonography, particularly in the early stages, may fail to detect perforation and yield false-negative results. Recent studies suggest that perforated appendicitis without accompanying classical inflammatory findings may complicate the diagnostic process and increase the risk of delayed treatment. This study aims to evaluate the diagnostic pitfalls of perforated appendicitis cases in which classical inflammatory findings are absent.

Material and Methods: This retrospective study reviewed patients who underwent surgery for acute appendicitis at Medicana Ataşehir Hospital between May 2021 and August 2025. The diagnosis of perforated appendicitis was confirmed based on intraoperative findings and pathological reports. Among patients with perforation, those without fever and leukocytosis were identified. Demographic characteristics, symptom duration, laboratory parameters (CRP, white blood cell count, and neutrophil-to-lymphocyte ratio), and ultrasonography findings were evaluated. Perforated appendicitis cases with and without classical inflammatory findings were compared.

Results: A total of 286 patients operated on for acute appendicitis were evaluated. Among them, 32 patients were confirmed to have perforated appendicitis based on surgical and pathological findings. In 8 patients (25%), neither fever nor leukocytosis was present. In this subgroup, the median CRP level was 4.9 mg/dL, and the median symptom duration was 72 hours. Ultrasonography failed to detect perforation in 5 patients (62.5%). A summary of the findings and the diagnostic process is presented in Figure 1.

Conclusion: Perforated appendicitis without accompanying classical inflammatory findings such as fever and leukocytosis represents a significant diagnostic pitfall in clinical practice. Our findings demonstrate that normal body temperature and white blood cell counts do not reliably exclude perforated appendicitis. In patients with prolonged symptom duration and subtle inflammatory markers, clinical suspicion should be maintained even when imaging findings are unremarkable, and a comprehensive diagnostic approach is essential. Among 286 patients operated on for acute appendicitis, 32 cases were confirmed as perforated appendicitis based on intraoperative and pathological findings. In 8 patients (25%), neither fever nor leukocytosis was present. In this subgroup lacking classical inflammatory findings, ultrasonography failed to detect perforation in 62.5% (5/8) of cases. The median CRP level was 4.9 mg/dL, and the median symptom duration was 72 hours. This schematic highlights that normal body temperature and white blood cell counts do not reliably exclude perforated appendicitis.

Gastrointestinal introduction of drug-filled plastic capsules: A single-center experience and clinical management in light of literature recommendations

Berk Topaloğlu, İbrahim Doğan

University of Health Sciences Türkiye, Van Training and Research Hospital, Van

Objective: Gastrointestinal introduction of drug-filled plastic capsules is a high-risk clinical scenario due to potential complications such as obstruction, perforation, and rupture-related toxicity. Current recommendations generally support close observation and conservative elimination in patients without toxicity or complications, while advocating surgical management when symptoms or suspected complications are present. In the setting of gastric retention, the optimal timing of intervention remains patient-specific and debated. Here, we present the diagnostic workup and treatment outcomes of patients managed at a single center.

Material and Methods: Seven consecutive patients brought to the hospital under law-enforcement supervision with multiple drug-filled capsules identified within the gastrointestinal tract were retrospectively reviewed. Recorded variables included demographics, diagnostic modality, the method used to confirm complete capsule clearance from the gastrointestinal tract, number of capsules, signs of toxicity, laxative use, time to passage, duration of in-hospital observation, management strategy, and complications.

Results: The median age of the seven patients was 39 years (27-48), and six were male. The number of capsules ranged from 7 to 93. Diagnosis was established by computed tomography (CT) in all patients. Clearance was confirmed by CT in four patients and by colonoscopy in two patients. No patient developed clinical signs of toxicity. Six patients were managed conservatively, and all patients in the conservative group received laxatives. In this group, capsule passage occurred within 1-2 days. One patient underwent surgical treatment due to marked gastric retention on presentation accompanied by abdominal pain; 52 capsules were removed via gastrotomy. The median duration of in-hospital observation was 2 days (range 1-5). No complications were observed in any patient. In the patient operated on due to abdominal pain with marked gastric retention on CT, a total of 52 capsules were extracted via gastrotomy.

Conclusion: When this series is interpreted alongside the literature, management appears to be best guided by risk stratification. Close observation and conservative treatment should be prioritized in patients without toxicity or acute abdominal findings. Surgical treatment should be considered in the presence of toxicity, marked gastric retention, obstruction, or perforation.

Keywords: Body packing, conservative management, emergency surgery

Clinical, laboratory, and imaging characteristics of negative and uncomplicated cases in acute appendicitis: Single-center real-life data

Semih Yolcu, Serkan Ademoğlu, Ferudun Kaya, Ercan Korkut

University of Health Sciences Türkiye, Gaziantep City Hospital, Gaziantep

Objective: Acute appendicitis is one of the most common causes of acute abdomen requiring emergency surgical intervention. Variability in clinical presentation and the limitations of imaging modalities may complicate the differentiation of negative and uncomplicated appendicitis in daily practice, potentially leading to increased rates of negative appendectomy and unnecessary surgical interventions. A better understanding of the clinical, laboratory, and imaging characteristics of negative and uncomplicated appendicitis may improve diagnostic accuracy and help reduce unnecessary surgeries. This study aimed to compare the clinical, laboratory, and imaging findings of patients with negative and uncomplicated appendicitis.

Material and Methods: This single-center retrospective study included patients who underwent surgery with a diagnosis of acute appendicitis. Patients with pathological findings consistent with negative appendicitis (normal appendix or reactive/lymphoid hyperplasia) and uncomplicated appendicitis were included. Patients with complicated appendicitis and those with incomplete data were excluded from the analysis. Demographic characteristics, preoperative laboratory parameters (white blood cell count, C-reactive protein, albumin levels, and neutrophil-to-lymphocyte ratio), and imaging findings obtained by ultrasonography and computed tomography were evaluated. Group comparisons were performed using appropriate statistical tests, and a p-value of <0.05 was considered statistically significant.

Results: A total of 82 patients were included in the study, of whom 13 had negative appendicitis and 69 had uncomplicated appendicitis. The proportion of normal or equivocal findings on computed tomography was significantly higher in the negative appendicitis group compared with the uncomplicated group (33.3% vs. 7.5%; $p=0.034$). Although white blood cell count, C-reactive protein levels, and neutrophil-to-lymphocyte ratio tended to be lower in patients with negative appendicitis, these differences did not reach statistical significance ($p>0.05$ for all). No significant difference was observed in albumin levels between the groups.

Conclusion: Computed tomography findings are more frequently reported as normal or equivocal in patients with negative appendicitis, indicating persistent diagnostic uncertainty in this subgroup. While clinical and laboratory parameters alone may not be sufficiently discriminative, careful interpretation of imaging findings may help reduce negative appendectomy rates. These results support the importance of a multidisciplinary diagnostic approach in patients with suspected acute appendicitis.

Keywords: Acute appendicitis, negative appendectomy, imaging modalities

Traumatic diaphragmatic injuries: Diagnosis, surgical approach, and retrospective analysis of clinical outcomes

Zeynep İlayda Işık[1], Serkan Demir[1], Salih Süer[1], Şener Balas[1], Alper Yavuz[1], Faruk Yazıcı[2]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*
[2]*Etimesgut State Hospital, Ankara*

Objective: Traumatic diaphragmatic injuries (TDI), although uncommon, are clinically significant due to diagnostic challenges and the high rate of associated thoracoabdominal injuries. This study aimed to retrospectively evaluate the demographic characteristics, mechanisms of trauma, diagnostic processes, associated injuries, surgical management, and clinical outcomes of patients operated for TDI at the General Surgery Department of University of Health Sciences Türkiye, Ankara Etlik City Hospital between November 2022 and December 2025.

Material and Methods: This single-center retrospective case series included patients operated for TDI during the study period. Data were obtained from electronic medical records. Demographics, trauma mechanism and type, time to admission, time to diagnosis and delayed diagnosis (>24 hours), imaging modalities and CT findings, associated injuries, side of injury and defect size, surgical timing, approach and repair technique, and clinical outcomes were recorded. Continuous variables were presented as median (IQR), and categorical variables as number and percentage.

Results: Twenty-one patients were analyzed. The median age was 29 years (IQR: 23-42), and 95.2% were male. Penetrating trauma accounted for 76.2% of cases, most commonly stab wounds (52.4%), while 23.8% resulted from blunt trauma. Injuries involved the left hemidiaphragm in 81.0% and the right in 19.0%. Most patients (95.2%) presented in the acute phase; the median time from trauma to diagnosis was 3 hours (IQR: 2-6), with delayed diagnosis in 14.3%. CT identified diaphragmatic injury in 42.9% of patients, whereas 19.0% were missed on initial imaging. Associated injuries were present in 90.5%, predominantly thoracic (81.0%) and abdominal (76.2%). Solid organ injury occurred in 42.9%, hollow viscus injury in 28.6%, and abdominal organ herniation in 28.6%. All patients underwent emergency surgery. Laparotomy was the most common approach (81.0%), and primary suture repair was performed in all cases. The median defect size was 4 cm (IQR: 2-7), and median operative time was 90 minutes (IQR: 90-120). All patients required ICU admission; median ICU stay was 7 days (IQR: 2-8), and median hospital stay was 14 days (IQR: 7-18). No reoperations or mortality were observed. Median follow-up was 4 months (IQR: 1-11).

Conclusion: TDI represents a critical trauma entity characterized by diagnostic difficulty and a high incidence of associated injuries. Despite widespread CT use, a subset of injuries was missed on initial imaging, underscoring the importance of clinical suspicion. Systematic evaluation for diaphragmatic injury is essential, particularly in penetrating thoracoabdominal trauma.

Pneumatosis intestinalis: A mysterious radiological finding or an early harbinger of surgical necessity? Our experience with 28 cases

Ayşe Doğru, Mustafa Şentürk, Zuhal Ak

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: Pneumatosis intestinalis (PI) is a radiological finding defined by the presence of gas within the bowel wall. It may appear in a linear or cystic pattern within the submucosal or subserosal layers of the intestine. PI is not pathognomonic for a single disease entity and may be encountered in a wide clinical spectrum ranging from benign, self-limiting conditions to life-threatening acute mesenteric ischemia requiring emergency surgical intervention.The aim of this study was to retrospectively evaluate the role of this clinical-radiological marker, whose pathogenesis is not yet fully understood, in predicting the need for surgical intervention.

Material and Methods: Patients in whom PI was detected on radiological imaging at Necmettin Erbakan University Faculty of Medicine Hospital over the last five years were retrospectively reviewed. Patients younger than 18 years of age and those who were not evaluated by a general surgery specialist were excluded from the analysis. Demographic data, presenting symptoms, laboratory parameters (lactate, CRP, WBC), computed tomography findings, and surgical outcomes were analyzed.

Results: A total of 28 patients diagnosed with PI were included in the study. The mean age was 60.8±18.4 years (range, 23-92), with a median age of 58.5 years. Regarding sex distribution, PI was observed in both genders without a marked predominance, demonstrating a heterogeneous distribution. Among the 28 patients, 13 (46.4%) were managed conservatively with medical treatment, whereas 13 patients (46.4%) underwent surgical intervention. However, two additional patients for whom surgical intervention was indicated could not undergo surgery: one patient died before the operation due to hemodynamic instability, and another patient refused surgical treatment. Therefore, while surgical indication was established in 15 patients, 13 were ultimately operated on indications for surgery. The main reasons for surgical decision-making were: • Mesenteric ischemia • Bowel necrosis • Perforation • Internal herniation • Progresive mechanical ileus. Surgical decisions were primarily based on clinical findings consistent with an acute abdomen and radiological suspicion of bowel ischemia. Patients with surgical indication demonstrated significantly higher leukocyte levels. CRP levels also tended to be higher in this group, whereas lactate levels showed a similar distribution between groups.

Conclusion: PI alone is not an absolute indication for surgery; however, in our series, it was associated with a substantial rate of significant surgical pathology. When evaluated together with clinical and laboratory parameters, PI may serve as an early warning sign of serious conditions such as bowel ischemia and perforation. Therefore, careful clinical assessment and timely surgical decision-making are of critical importance in patients diagnosed with PI.

Rare complication of pleural drainage catheter: Iatrogenic splenic vein cannulation and management

Zeynep Nur Yurdakul[1], Mehmet Sefa Çamöz[1], Gözde İğdeci Tut[1], Yiğit Dilaver[1], Behzat Fatih Demirci[1], Teymur Hajılı[1], Sabiha Nur Özmen[2], Hikmet Pehlevan Özel[1]

[1]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*
[2]*Amasya Sabuncuoğlu Şerefeddin Training and Research Hospital, Amasya*

Objective: While subdiaphragmatic organ injuries during pleural effusion drainage have been described in the literature, direct cannulation of a vascular structure by a pleural catheter (pleurocan) is extremely rare. This report discusses the surgical management of a case in which a catheter, placed for pleural effusion, traversed the splenic parenchyma and was malpositioned directly into the splenic vein.

Material and Methods: A 69-year-old female patient, hospitalized in the oncology department for chemotherapy due to metastatic ovarian cancer, was consulted following pleurocan catheterization for pleural effusion. The consultation was prompted by the drainage of approximately 1000 cc of hemorrhagic fluid, accompanied by acute hypotension (90/50 mmHg) and tachycardia (130 bpm). Laboratory findings revealed a hemoglobin level of 8.2 g/dL. A non-contrast chest CT, performed to check the catheter position, demonstrated that the drainage catheter had advanced into the abdomen through the left 9th-10th intercostal space, traversed the entire splenic parenchyma, and extended to the level of the splenic hilum. Due to hemodynamic instability and potential vascular injury, the patient was taken for emergency surgery.

Results: During exploration, no hemorrhagic fluid was detected within the abdominal cavity. It was observed that the catheter had passed through the diaphragm, entered the spleen via the lateral-posterior aspect, emerged from the splenic hilum medially, and advanced into the splenic vein. The spleen was mobilized by sharp dissection from its surrounding ligaments. The splenic artery and vein were skeletonized. The artery was ligated and divided. The catheter was palpated within the vein; it was then removed in a controlled manner, followed by the ligation and division of the vein. Subsequently, the spleen was removed from the abdomen. The diaphragm was repaired primarily, and a new pleural drainage catheter was inserted. The patient, who experienced no postoperative complications, was transferred back to the oncology department on the 5th day.

Conclusion: This case highlights that pleural interventions, though rare, can lead to life-threatening complications such as major vascular cannulation following parenchymal passage. Rapid imaging and timely surgical intervention are essential to reducing mortality and morbidity.

Nursing care for the use of abdominal binder after major abdominal surgery and abdominal hernia surgery

İrem Sezer, Aydanur Kürklü, Suat Can Ulukent, Baki Ekçi

University of Health Sciences Türkiye, Başakşehir Çam ve Sakura City Hospital, İstanbul

Objective: Approximately 400 abdominal hernia surgeries are performed annually in the General Surgery-3 unit of University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, where we are employed. Nursing care provided to these patients during the preoperative and postoperative periods primarily encompasses the use of surgical abdominal binders, respiratory exercises, early mobilization, nutritional management, wound care, and discharge education. Within the scope of binder use, nurses conduct comprehensive physical and psychosocial assessments, provide patient education and practical support, and take an active role in ensuring appropriate application while preventing potential complications. The aim of this study is to present our clinical experience regarding nursing care in patients using abdominal binders following surgery.

Material and Methods: Abdominal binders are initiated within the first 24 hours postoperatively, in conjunction with the mobilization process. The duration of use generally ranges between 2-6 weeks, depending on the type of surgery performed. In this context, the patient's height, weight, waist circumference, and, if present, the presence and location of a stoma should be carefully assessed. By comprehensively evaluating these characteristics, nurses facilitate the selection of the appropriate binder. During the first postoperative mobilization, the binder is applied while the patient is in a supine position or slightly turned to the right or left lateral position, ensuring full support of the abdominal region. While fastening the binder straps, nurses pay particular attention to maintaining adequate respiratory function, avoiding excessive compression of the body, preventing impairment of regional blood circulation, and ensuring that existing drains are not compromised.

Results: Patients are instructed to wear the surgical binder during each mobilization period for 2-6 weeks, depending on the type of surgery, and to loosen or remove the straps when resting in the supine position after mobilization. Furthermore, in accordance with the physician's recommendations, patients are advised not to wear the binder while bathing and during wound care following discharge.

Conclusion: Incorrect use of abdominal binders may lead to skin irritation, pressure injuries, and impairments in circulation and respiratory function. In conclusion, in surgeries requiring abdominal incisions, the use of an abdominal binder in accordance with physician recommendations necessitates comprehensive nursing roles, including patient assessment, implementation support, complication prevention, and management. The effective execution of these roles based on scientific principles and collaboration with patients and their families throughout the process contributes significantly to the improvement of postoperative care quality.

Successful management of congenital transmezocolic internal hernia in adult patients with second-look surgery

Abdülaziz Emek[1], Ozan Can Tatar[2], Orhan Tatlı[1], Ahmet Oktay Yirmibeşoğlu[1], Nihat Zafer Utkan[1]

[1]*Kocaeli University School of Medicine, Kocaeli*
[2]*University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: Rectovaginal fistula (RVF) is a clinical condition resulting from the formation of an abnormal tract between the rectum and the vagina, leading to serious hygiene problems, infections, and a significant loss of quality of life. RVFs secondary to pelvic radiotherapy constitute the most difficult subgroup to treat due to poor vascularization and fibrosis. The success rate of primary surgical repair in these cases is low. Fecal diversion is often preferred as the first-line approach. However, spontaneous closure after diversion is rare. This report presents a case of radiation-related RVF that completely closed after fecal diversion and mucosal support therapy.

Material and Methods: The clinical findings, imaging methods, surgical approach, and follow-up results of a 59-year-old female patient with a history of neoadjuvant chemoradiotherapy were retrospectively evaluated.

Results: The patient presented approximately one year after radiotherapy with complaints of fecal leakage from the vagina and foul-smelling discharge. Imaging revealed a RVF extending from the anterior rectal wall to the vagina. Colonoscopy confirmed a large fistula 15 cm proximal to the anal verge. Primary repair was considered high-risk due to the previously irradiated area, fistula width, and suspicion of widespread disease, so fecal diversion was planned. During laparotomy, colon mobilization was not possible due to a "frozen pelvis" appearance, so a loop ileostomy was performed. The vaginal leakage completely resolved in the postoperative period. Omental biopsies were reported as benign. Long-term mesalazine and sucralfate enema therapy was administered to support the radiation-damaged mucosa. The sixth-month follow-up colonoscopy showed complete closure of the fistula and epithelialization. The ileostomy was closed at eight months. No fistula recurrence or additional complications were detected during the 24-month follow-up.

Conclusion: In the treatment of radiation-induced RVF, fecal diversion, when used in conjunction with mucosal support therapy in appropriate patients, may allow for permanent fistula closure. This case demonstrates that conservative approaches may be an alternative to surgical reconstruction in selected cases.

Keywords: Rectovaginal fistula, radiation damage, fecal diversion, ileostomy, mucosal support therapy

Colonoscopy findings in diverticular disease: Are polyps and colorectal malignancy actually increasing?

Banu Karapolat[1], Faruk Aksoy[1], Altan Aydın[1], Aydın Aktaş[1], Halil Afşin Taşdelen[1], Maksude Esra Kadıoğlu[2], Ahmet Yüğrük[1], Selim Altındaş[1], İsmet Çelik[1], Ekrem Koç[1], Coşkun Aydın[1], İrfan İnci[1], Mustafa Sarı[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

[2]*Department of Radiology, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

Objective: Diverticular disease is a common clinical condition in the colonoscopy patient population. The relationship between diverticular disease and colonic polyps and colorectal malignancy remains unclear. In particular, data on the relationship between the location of the diverticulum in the colon, the clinical stage of the disease, and the prevalence of polyps and malignancy are limited. This study aimed to evaluate the age and gender distribution, colonic location, polyp prevalence, Hinchey classification, and colorectal malignancy frequency in patients diagnosed with diverticular disease.

Material and Methods: This retrospective study included 79 patients of whom 48 underwent by colonoscopy. Patients' age and gender information, diverticulum location (right colon, left colon, total colon), Hinchey classification, presence of polyps detected by colonoscopy, and malignancy status were recorded. The presence of polyps was assessed as a binary variable (present/absent). Missing data were coded as NA and excluded from the relevant subgroup analyses. The Hinchey classification was evaluated only in patients diagnosed with acute diverticulitis. Patients with colorectal malignancy were excluded from the polyp prevalence analysis. Continuous variables were presented as median (minimum-maximum), and categorical variables were presented as number and percentage. The chi-square test was used to compare categorical variables.

Results: Of the patients included in the study, 49 (62.0%) were female and 30 (38.0%) were male. The median age was 58 years (range 32-92). In terms of colonic location, left-sided colon involvement was observed in the vast majority of cases. Colonic polyps were detected in 9 (18.8%) of the 48 patients with available polyp data. No statistically significant relationship was found between the presence of polyps and gender or colonic location ($p>0.05$). The majority of patients were in the Hinchey 1A-1B group, while Hinchey ≥2 cases were rare. No significant relationship was found between complicated diverticulitis and the presence of polyps. Colorectal malignancy was rarely detected in patients who underwent colonoscopy.

Conclusion: The prevalence of colonic polyps in patients with diverticular disease is similar to that in the general population, and cases are predominantly localized in the left colon. The presence of complicated diverticulitis does not pose an additional risk for polyp development. Colorectal malignancy was observed at a low rate in patients with diverticulitis who underwent colonoscopy. These findings suggest that diverticular disease and the development of colonic polyps and colorectal malignancy may be largely independent processes.

Frequency of neoplastic lesions in appendectomy specimens: A single-center experience with 749 cases

Yunus Emre Aydoğdu, Berkay Aksu, Salih Raşit Mizan, Ufuk Karabacak, Murat Derebey, İsmail Alper Tarım

Department of General Surgery, Ondokuz Mayıs University Health Practice and Research Hospital, Samsun

Objective: Acute appendicitis is one of the most common indications for emergency surgical intervention, with a reported lifetime incidence of approximately 7-8%. In patients presenting with typical clinical symptoms, the diagnosis is generally established using imaging modalities, followed by appendectomy. However, histopathological examination of appendectomy specimens is of great importance not only for identifying inflammatory conditions but also for detecting rare yet clinically significant neoplastic lesions.

Material and Methods: In this study, pathology reports of 749 patients who underwent surgery for acute appendicitis at the Department of General Surgery, Ondokuz Mayıs University Faculty of Medicine, between January 2017 and January 2026 were retrospectively reviewed. Histopathological findings were categorized, and the frequency of neoplastic lesions was evaluated.

Results: Among the 749 cases, the most common histopathological diagnosis was acute appendicitis, observed in 477 patients (63.68%). This was followed by necrotizing appendicitis in 174 cases (23.63%), lymphoid hyperplasia in 32 cases (4.27%), and perforated appendicitis in 16 cases (2.13%).Neoplastic lesions were identified in 12 cases (1.6%). The distribution of these lesions was as follows: low-grade mucinous neoplasm (6 cases), high-grade mucinous neoplasm (1 case), adenocarcinoma (2 cases), tubulovillous adenoma (1 case), and grade 2 neuroendocrine tumor (2 cases). Non-neoplastic pathologies accounted for 98.4% of all cases.The most frequently detected pathology in appendectomy specimens was acute appendicitis, which is consistent with the rates of 60-70% reported in the literature. Complicated forms such as necrotizing and perforated appendicitis together constituted approximately 25-30% of cases. Although appendiceal neoplasms are rare, they are clinically significant. Mucinous neoplasms and neuroendocrine tumors often mimic the clinical presentation of acute appendicitis in the preoperative period. The neoplasm rate of 1.6% observed in our study is consistent with the range of 0.5-2% reported in the literature.

Conclusion: Although acute appendicitis remains the most common diagnosis in appendectomy specimens, neoplastic lesions are detected at a non-negligible rate. These findings support the clinical necessity of routine histopathological examination of all appendectomy specimens, as early diagnosis contributes to appropriate treatment and follow-up planning.

What has changed in the surgical management of T1a papillary thyroid carcinoma over the last 10 years?

Işık Çetinoğlu, Hatice Oymak, Zerin Şengül, Mehmet Taner Ünlü, Ozan Çalışkan, Ahmet Faruk Yener, Nurcihan Aygün, Mehmet Uludağ

University of Health Sciences Türkiye, Şişli Hamidiye Etfal Training and Research Hospital, İstanbul

Objective: Papillary thyroid carcinoma (PTC) is the most common differentiated thyroid cancer. Its incidence has steadily increased over the past 50 years, and approximately half of surgically treated cases are tumors ≤1 cm (T1a, micro-PTC). Although lymph node metastasis is present at diagnosis in 9-42% of these tumors, prognosis is generally excellent. Management options for T1a tumors range from active surveillance to total thyroidectomy and therapeutic neck dissection. We aimed to evaluate whether there has been a change in the surgical management of T1a tumors in our clinic over the past decade.

Material and Methods: We retrospectively reviewed patients who underwent surgery for PTC with T1a (<1 cm) tumors between January 2016 and December 2025. Patients with lymph node metastasis underwent therapeutic central and/or lateral neck dissection. Patients were divided into two groups: 2016-2020 (group 1) and 2021-2025 (group 2). Surgical extent was compared between the two periods.

Results: A total of 178 patients (147 females, 31 males) were included: 52 in group 1 and 126 in group 2. Initial surgery in group 1 vs. group 2 was lobectomy in 21 (40.4%) vs. 76 (60.3%), total thyroidectomy in 25 (48.1%) vs. 46 (36.5%), and total thyroidectomy with central ± lateral neck dissection in 6 (11.5%) vs. 4 (3.2%), respectively (p=0.0142). Completion thyroidectomy after lobectomy was performed in 6 (11.1%) and 5 (4.1%) patients in groups 1 and 2, respectively (p=0.0803). After completion procedures, final surgical distribution was lobectomy in 17 (32.7%) vs. 72 (57.1%), total thyroidectomy in 28 (53.8%) vs. 50 (39.7%), and total thyroidectomy with central ± lateral neck dissection in 6 (11.5%) vs. 4 (3.2%) (p=0.0046).

Conclusion: A significant shift in the surgical management of T1aN0M0 tumors has occurred over the last decade. During the first 5-year period, total thyroidectomy (± neck dissection) was the most common procedure, accounting for nearly 60% of cases. In the second period, approximately 60% of patients underwent lobectomy, making it the preferred initial surgical approach. The rate of neck dissection for lymph node metastasis decreased from 10% to 3%, likely reflecting a move away from prophylactic dissection and an increase in incidentally detected small tumors.

Invasive lobular breast cancer progressing to aggressive metaplastic carcinoma

Abdülaziz Emek[1], Ozan Can Tatar[2], Orhan Tatlı[1], Enes Şahin[1], Nihat Zafer Utkan[1]

[1]*Kocaeli University Faculty of Medicine, Kocaeli*
[2]*University of Health Sciences Türkiye, Kocaeli City Hospital, Kocaeli*

Objective: Breast cancer is a malignancy exhibiting heterogeneous biological characteristics, with treatment response and prognosis varying significantly according to histopathological subtypes. Metaplastic breast carcinoma (MBC) is a rare subtype, accounting for less than 1% of all breast cancers, which is usually aggressive, triple-negative, and resistant to chemotherapy. The sequential development of different histopathological breast cancer types in the same patient is quite rare and complicates clinical management. This case presents aggressive MBC developing after a history of invasive lobular breast cancer.

Material and Methods: The clinical course, imaging findings, surgical interventions, and histopathological results of a 44-year-old female patient who developed different breast cancer subtypes at different times were retrospectively evaluated.

Results: The patient was initially operated on due to a mass developing in the left breast. Pathological evaluation revealed HER2-positive invasive breast carcinoma, and adjuvant chemotherapy, trastuzumab, and radiotherapy were administered. During follow-up, a rapidly growing mass in the right breast was surgically removed, and invasive lobular carcinoma was diagnosed. Adjuvant chemotherapy was initiated. However, eight months after right mastectomy, while adjuvant treatment was ongoing, a rapidly progressing mass invading the pectoral muscle developed at the mastectomy site. No distant metastases were detected on imaging. Following a multidisciplinary team decision, the lesion was en bloc excised along with the pectoral muscle segment. Pathological examination revealed findings consistent with MBC with a triple-negative phenotype, containing widespread squamous differentiation, and the surgical margins were negative.

Conclusion: Although MBC is rare, it exhibits aggressive biological behavior and chemoresistant properties. This case highlights the possibility of biological transformation in breast cancer and the necessity for re-biopsy and multidisciplinary evaluation in cases of recurrence or progression. An aggressive surgical approach in the absence of distant metastasis may offer an important treatment option for local control.

Reasons for conversion from breast-conserving surgery decision to primary mastectomy in multidisciplinary tumor boards: Pandemic impact and temporal trends

Yusuf Can Elmas, Fazilet Erözgen, Anıl Orhan, Erkan Okumuş, Aykut Eren Çiçek, Mustafa Aktaş, Berke Baş, Mustafa Nusret Önal, Türkan İkizceli, Esen Gül Uzuner

University of Health Sciences Türkiye, Haseki Training and Research Hospital, İstanbul

Objective: Reasons for conversion from breast-conserving surgery decision to primary mastectomy in multidisciplinary tumor boards: pandemic impact and temporal trends.

Material and Methods: In this single-center retrospective analysis, cases initially recommended for BCS by the MTB but who subsequently underwent primary mastectomy were evaluated annually. The "pandemic impact" period was defined as 2021-2022, and the "post-pandemic" period as 2023-2025. Reasons for conversion were categorized as physician-based (extra-board re-evaluation: concerns regarding negative surgical margins, cosmetic considerations) and patient-based [preference for mastectomy following counseling: perceived higher efficacy of mastectomy, difficulty accessing radiotherapy (RT), fear of RT/hospital contact, and the desire to minimize hospital visits by opting for a single-session procedure]. Ethical committee exemption was obtained for the study.

Results: Between 2021 and 2025, a total of 369 BCS decisions were made, and primary mastectomy was performed in 77 cases (20.9%). While the annual number of BCS decisions increased from 62 to 84 (a 35.5% increase), the conversion rate from BCS to mastectomy was 37.1% (23/62) in 2021, 25.0% (17/68) in 2022, 22.7% (17/75) in 2023, 12.5% (10/80) in 2024, and 11.9% (10/84) in 2025. The conversion rate was significantly higher during the pandemic impact period (30.8%, 40/130) compared to the post-pandemic period (15.5%, 37/239) ($p<0.001$). Throughout the entire study period, 33.8% (26/77) of conversions were physician-based, while 66.2% (51/77) were patient-based. The most common physician-based reason was concern regarding negative surgical margins (19/26), followed by cosmetic reasons (7/26). In the pandemic impact period, fear of RT/hospital contact and RT access difficulties were the predominant patient-based factors; in the post-pandemic period, although the overall conversion rate decreased, patient-related factors remained the primary driver.

Conclusion: The conversion rate from a BCS recommendation to primary mastectomy was found to be significantly higher during the pandemic impact period. In the post-pandemic era, while BCS decisions increased, the conversion rate markedly decreased. We conclude that the standardization of patient counseling and implementation of measures to facilitate access to radiotherapy may further reduce the conversion rates from BCS to mastectomy in the future.

Multidisciplinary team (MDT)-tumor board practices and the need for digital solutions in Türkiye

Mert Ercan[1], Murat Güner[2], Erdinç Kamer[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir*

Objective: The annual number of newly diagnosed cancer cases in Türkiye is reported to be approximately 240.000 (Turkish Statistical Institute), and these cases,together with other complex clinical conditions,are evaluated within multidisciplinary team meeting (MDT/tumor boards); however, MDT/tumor board practices vary across institutions, and the need for digitalization in terms of recording,data management, and sustainability is increasing. Systematic evaluation of MDT practices in Türkiye remains limited.

Material and Methods: This cross-sectional survey study included 167 physicians representing 26 medical specialties and 23 different tumor board types from 30 cities across Türkiye. Participants were digitally administered a 42-item online questionnaire (Google Forms) covering MDT experience, tumor board workflow, recording-consent-data security practices, and attitudes toward digital MDT solutions.

Results: Of the 167 participating physicians, 63.47% were male and 36.53% female, with 68.26% aged 31-50 years. Overall, 69.46% had ≥5 years of post-specialty experience, and 83.24% worked in tertiary care institutions. Regarding MDT experience, 66.02% reported ≥4 years and 33.53% ≥10 years. According to participant reports, 82.63% of MDT meetings are still conducted face to face, and 46.10% of decisions are recorded on paper forms. Presentation materials and patient files are commonly stored on personal computers (31.70%), messaging platforms (24.00%), and email attachments (21.60%), with 63.47% reporting file loss or version confusion. The proportion reporting that no specific patient consent is obtained for MDT discussions was 73.65%, while 71.26% indicated the absence of a written procedure for communicating decisions to patients. Only 22.75% considered MDT processes to be fully compliant with "KVKK/GDPR". Additionally, 44.31% reported frequent impact on personal time, and 32.93% on working hours. Despite this, MDT participation was not institutionally documented in 47.31% of cases; 94.01% reported no financial benefit, and 80.24% rated academic prestige/publication contribution as none or rare. Artificial intelligence was not used in MDT processes by 89.20% of participants. The main barriers to digitalization were lack of technical infrastructure (67.10%), insufficient digital tool usage habits (61.10%), and institutional integration challenges (52.70%). The most prioritized features of a digital MDT system were single-panel access to all patient data (77.80%), automated and standardized decision recording (73.70%), PACS integration (71.30%), and "HBYS/e-Nabız" integration (59.90%). A total of 84.40% agreed that digital MDTs would improve standardization, accessibility, and institutional sustainability, and 78.40% believed they would contribute to the national healthcare system. Digital solutions for MDT preparation and implementation (Table 1) and the anticipated innovations and benefits of a digital MDT software (Table 2) were rated as highly important and beneficial. Finally, 92.80% stated they would use a digital MDT system (definitely 53.30%, if needed 39.50%), and 74.85% were willing to participate voluntarily in pilot, testing,or design phases.

Conclusion: This study demonstrates that MDT practices in Türkiye are widespread but require further development in terms of standardization, data security, and recording systems; however, there is strong acceptance and high willingness to participate in digital, integrated, and artificial intelligence-supported MDT solutions. The findings indicate that digital MDT solutions hold significant transformative potential.

Evolution of educational resources: A comparative analysis of laparoscopic cholecystectomy videos over two decades

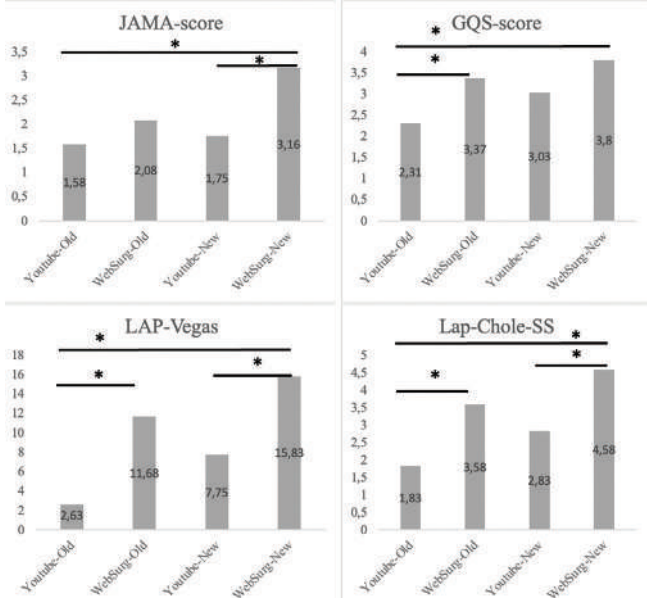
Muhammed Salih Süer, Lara Kavasoğlu, Serkan Demir, Şener Balas

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Laparoscopic cholecystectomy (LAP chole) is one of the most commonly performed surgeries worldwide. With the rise of online platforms like YouTube and WebSurg, surgical videos have become popular educational tools. However, the quality of these videos varies, raising concerns about their reliability. This study evaluates the changes in the quality of laparoscopic cholecystectomy videos over two decades and compares the educational value of YouTube and WebSurg videos.

Material and Methods: Twenty-four videos were analyzed and divided into four groups: older YouTube, older WebSurg, newer YouTube, and newer WebSurg. Six videos from each group were selected based on relevance and popularity. Three independent surgeons assessed them using standardized scoring systems, including the JAMA benchmark score, global quality score (GQS), LAP-VEGaS, and a new LAP chole-specific score (SS). Video characteristics such as duration, uploader type, and viewer engagement were also considered. Statistical comparisons were made between the groups.

Results: The analysis showed that although newer videos were longer, the difference was not statistically significant (p=0.74). Newer videos had significantly better image quality (p<0.001). WebSurg videos consistently outperformed YouTube videos across all evaluation criteria (Table 1). WebSurg scored higher in the JAMA benchmark (2.62 vs. 1.66), GQS (3.58 vs. 2.63), LAP-VEGaS (13.7 vs. 6.58), and LAP chole-SS (4.08 vs. 2.33) (Table 2).



Conclusion: In conclusion, WebSurg provides higher-quality, peer-reviewed content, making it more reliable for surgical education, while YouTube offers accessibility but often lacks educational rigor.

Upper and lower gastrointestinal endoscopy: Indications and findings according to age groups in a tertiary center

Canan Aral Orhan, Esra Akça Çalışkan, Cenk Özkan, Hüseyin Kadıoğlu

University of Health Sciences Türkiye, Kanuni Sultan Süleyman Training and Research Hospital, İstanbul

Objective: Upper and lower gastrointestinal endoscopy are essential diagnostic tools for evaluating gastrointestinal symptoms. Endoscopic indications and findings may vary according to age, influencing diagnostic yield and clinical decision-making. This study aimed to evaluate age-related differences in indications and findings of both upper and lower gastrointestinal endoscopy and to explore whether clinically relevant findings increase before the current colorectal cancer screening age.

Material and Methods: A retrospective analysis was conducted on patients who underwent upper and/or lower gastrointestinal endoscopy between 2025 and 2026 in a tertiary care center. Patients were stratified into age groups (<40, 40-49, 50-59, and ≥60 years). Demographic characteristics, indications for endoscopy, and endoscopic findings were recorded. Upper and lower gastrointestinal endoscopy results were analyzed separately and comparatively according to age groups using descriptive and comparative statistical methods.

Results: A total of 325 endoscopic procedures were included, comprising 167 upper and 156 lower gastrointestinal endoscopies. Dyspeptic symptoms were the most common indications for upper gastrointestinal endoscopy across all age groups. Antral gastritis was the most frequent upper endoscopic finding. Lower gastrointestinal endoscopy was most commonly performed for rectal bleeding, altered bowel habits, anemia, and abdominal pain. Normal or near-normal findings were more frequent in younger patients, whereas pathological findings increased with age, particularly in patients aged 50 years and older. Although colorectal cancer screening is generally recommended from the age of 50, analysis of patients aged 40-49 years did not reveal a statistically significant increase in pathological endoscopic findings compared with other age groups (p=0.66), indicating no clear evidence to support lowering the screening age to 40 in this cohort.

Conclusion: Endoscopic findings demonstrate a progressive age-related increase rather than a sharp rise in the 40-49 age group. While pathological findings become more prevalent after the age of 50, the current data do not support lowering the colorectal cancer screening age to 40. An age-based and indication-driven approach to gastrointestinal endoscopy remains essential for optimizing diagnostic yield.

The role of nurses in preventing post-liver transplantation complications

Merve Yücel, Emel Barutçu Hançar

Hacettepe Adult Hospital, Ankara

Objective: Liver transplantation is a life-saving treatment for end-stage liver disease. However, early postoperative complications such as infection, acute rejection, bleeding, vascular thrombosis, and biliary complications remain major causes of morbidity and mortality. Nurses play a pivotal role in the early detection, monitoring, and prevention of these complications.

Material and Methods: This study was designed as an evidence-based literature review. Recent national and international studies were analyzed to identify common postoperative complications and related nursing interventions. Key nursing responsibilities, including hemodynamic monitoring, infection control practices, immunosuppressive therapy management, fluid and electrolyte balance assessment, early mobilization, and patient education, were systematically evaluated.

Results: Findings indicate that structured and protocol-driven nursing care significantly reduces preventable postoperative complications. Continuous monitoring of vital signs and laboratory parameters enables early detection of acute rejection and graft dysfunction. Strict adherence to aseptic techniques lowers infection rates, while comprehensive patient education enhances medication adherence and long-term graft survival.

Conclusion: Nurses play a critical role in preventing early complications after liver transplantation. The integration of standardized nursing protocols into postoperative care pathways improves patient safety, reduces complication rates, and enhances overall transplant outcomes.

Keywords: Liver transplantation, nursing care, postoperative complications

The role of four-dimensional computed tomography in preoperative localization in primary hyperparathyroidism

Serkan Erkan[1], Tevfik Avcı[1], Murathan Erkent[2], Ahmet Çakcak[2], Çiğdem Yalçın[3], Neşe Torun[4], Eda Melek Ertörer[5], Hakan Yabanoğlu[1]

[2]*Department of General Surgery, Başkent University Faculty of Medicine, Ankara*

[3]*Department of Radiology, Başkent University Adana Dr. Turgut Noyan Practice and Research Center, Adana*

[4]*Department of Nuclear Medicine, Başkent University Adana Dr. Turgut Noyan Practice and Research Center, Adana*

[5]*Department of Endocrinology and Metabolic Diseases, Başkent University Adana Dr. Turgut Noyan Practice and Research Center, Adana*

Objective: Accurate preoperative localization is of critical importance in the surgical management of primary hyperparathyroidism (PHPT). Ultrasonography (USG) and sestamibi scintigraphy are first-line imaging modalities. However, in cases where first-line imaging is negative or discordant, four-dimensional computed tomography (4D-CT) has gained increasing importance. In this study, the concordance between imaging modalities and surgical findings was analyzed in PHPT patients who underwent 4D-CT and subsequent surgery.

Material and Methods: Demographic and clinical characteristics of 23 patients diagnosed with PHPT were retrospectively recorded. Patients included in the study had a diagnosis of PHPT, had not undergone prior surgery, had non-localizing findings on first-line imaging or discordance between imaging modalities, and underwent 4D-CT imaging preoperatively. Surgical findings were accepted as the gold standard, and the localization success and complete concordance rates of the imaging methods were evaluated accordingly. Intraoperative rapid parathyroid hormone (PTH) measurement and nerve monitoring were utilized in all cases. Focused parathyroidectomy or four-gland exploration was performed depending on the case.

Results: Of the patients (19 females, 4 males), the mean age was 46.8±14.5 years. The mean preoperative serum calcium level was 10.81±0.83 mg/dL, and the mean PTH level was 279.4±437.1 pg/mL. All patients underwent preoperative USG, scintigraphy, and 4D-CT imaging. According to surgical findings, the most common adenoma location was the right inferior gland (39.1%). The localization success rate of USG was 87% (20/23), with a complete localization accuracy of 78.3% (18/23). 4D-CT achieved localization in 65.2% (15/23) of cases, with a complete surgical concordance rate of 39.1% (9/23). Scintigraphy achieved localization in 30.4% (7/23) of cases, with a complete concordance rate of 17.4% (4/23). In cases with marked discordance between USG and scintigraphy, 4D-CT provided additional anatomical information in some patients and contributed to surgical planning, particularly in ectopically located glands. However, 4D-CT did not demonstrate sufficient concordance with surgical findings in all discordant cases. Among the imaging modalities, USG showed the highest concordance with surgical findings.

Conclusion: Although the overall success rate of 4D-CT was low in our study, it appears to serve a complementary role, particularly in selected patients with negative or discordant conventional imaging findings. According to the literature, we attribute our relatively low imaging success rate with 4D-CT to the learning curve associated with this technique. Despite inadequate imaging results, pathological foci were identified and successfully excised in 21 patients. These findings support the importance of a stepwise imaging approach in the management of PHPT.

"Diagnosis, surgical approach, and clinical outcomes in adult intussusception: A single-center experience"

Muhammed Hallaç, Alper Yavuz, Muhammed Salih Süer, Bahattin Bayar, Serkan Demir, Ender Ergüder, Şener Balas

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Adult intussusception is a challenging clinical entity in terms of diagnosis and management due to its rarity, high rate of malignancy in the etiology, and variable clinical course. In this study, the demographic characteristics, clinical and radiological findings, surgical approaches, and clinical outcomes of adult patients with intussusception presenting to the emergency department were evaluated.

Material and Methods: Thirty-eight adult patients diagnosed with intussusception after presenting to the Emergency Department at the General Surgery Department, University of Health Sciences Türkiye, Ankara Etlik City Hospital were retrospectively reviewed. Demographic data, duration of symptoms, clinical and radiological findings, surgical decision-making processes, pathological diagnoses, and postoperative outcomes were analyzed.

Results: Median age was 50 years (IQR: 31.5-57.8), and 55.3% were male. The most common presenting symptom was abdominal pain (94.7%), followed by nausea-vomiting (71.1%) and obstipation (50.0%). Fever (15.8%) and hypotension (10.5%) were noted, while a palpable abdominal mass on physical examination was recorded in 5.3% of patients. Computed tomography (CT) was used for diagnostic evaluation in all patients, and a preoperative diagnosis of intussusception was achieved in 97.4% of cases. The most frequently identified type of intussusception was enteroenteric (83.8%). CT findings included the target/donut sign in 97.4%, an invaginated segment longer than 3 cm in 81.6%, obstruction in 51.4%, and free fluid in 39.5% of patients. Diagnostic delay (>48 hours) was present in 52.6% of cases. The median time from symptom onset to diagnosis was 59 hours (IQR: 12-81). Of the 38 patients, 27 (71.1%) underwent surgical intervention, the vast majority under emergency conditions (96.3%). The most common surgical indications were bowel obstruction (37.0%), acute abdomen/peritonitis (25.9%), signs of ischemia (18.5%), and suspicion of malignancy (18.5%). Bowel resection was performed in 55.6% (15/27) of surgically treated patients. Among those who underwent resection, 93.3% received segmental small bowel resection and 6.7% underwent right hemicolectomy. The stoma formation rate was 3.7%. Pathological examination of resected specimens revealed malignancy in 33.3% (5/15) of cases. In the postoperative period, at least one complication occurred in 18.5% of patients. The most common complications were surgical site infection (7.4%) and sepsis (7.4%). No anastomotic leakage was observed. A total of 40.7% of patients required intensive care unit follow-up, with a median ICU stay of 0 days (IQR: 0-1). The 30-day mortality rate was 2.6%, and overall mortality was 7.4%. The median follow-up duration was 12 months (IQR: 7.5-20.5).

Conclusion: The literature indicates that adult intussusception is often detected electively or incidentally. In our study, the fact that all cases presented through the emergency department reflects a distinct patient population with a more severe clinical course. The malignancy rate of 33.3% in surgically treated and resected cases is consistent with the literature and underscores that the possibility of malignancy must be carefully considered in clinical decision-making for emergent adult intussusception. The central role of CT in diagnosis was confirmed, as CT was used in all patients with a preoperative diagnostic rate of 97.4%. Radiological parameters such as the target/donut sign, invaginated segment length, and findings of obstruction or ischemia significantly guided surgical decision-making. In conclusion, adult intussusception presenting to the emergency department is associated with a high need for surgery and a substantial malignancy risk, requiring integrated clinical, radiological, and pathological evaluation for timely surgical management.

Global research trends in robotic versus laparoscopic low anterior resection for rectal cancer: A bibliometric analysis

Faruk Yazıcı[1], Serkan Demir[2], M Salih Süer[2], Şener Balas[2]

[1]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara,*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Low anterior resection (LAR) is a cornerstone procedure in rectal cancer surgery, with minimally invasive techniques increasingly replacing open approaches. While laparoscopic LAR has demonstrated favorable perioperative and oncological outcomes, technical limitations in challenging pelvic anatomy have encouraged the adoption of robotic platforms. With the maturation and wider availability of robotic technology, comparative studies between robotic and laparoscopic LAR have increased. However, beyond clinical outcome comparisons, the global research structure and collaborative patterns of this literature have not been systematically evaluated. This study aimed to perform a bibliometric analysis of publications comparing robotic and laparoscopic low anterior resection, focusing on temporal trends, core journals, and leading contributors.

Material and Methods: This bibliometric analysis evaluated PubMed-indexed literature comparing robotic and laparoscopic low anterior resection for rectal cancer. A systematic search of titles and abstracts was conducted using the terms "low anterior resection" OR "LAR" AND "robotic" AND "laparoscopic," without restrictions on publication year, article type, or language. Publications published between 2006 and 2026 were included and exported in MEDLINE format. Analyses were performed using the Bibliometrix package and Biblioshiny interface. Evaluated indicators included annual scientific production, life cycle analysis, core journals identified by Bradford's law, corresponding author countries, and collaboration patterns based on co-authorship and geographic networks.

Results: A total of 198 publications across 77 journals were included, authored by 1,248 unique researchers. All publications were multi-authored, with a mean of 7.7 authors per document, indicating a highly collaborative research environment. Scientific production remained limited until 2012, followed by steady growth after 2013 and a marked increase from 2020 onward. Life cycle analysis demonstrated that the field has entered a maturity phase, reaching approximately 75% of its projected saturation level. Journal analysis revealed a concentrated dissemination pattern, with a small group of core journals accounting for a disproportionate share of publications. Japan was identified as the leading contributing country, followed by South Korea, China, and the United States, with predominantly regional research networks. Thematic assessment indicated a shift from feasibility-oriented laparoscopic studies toward robotic-focused and outcome-driven research. Annual number of publications comparing robotic and laparoscopic low anterior resection for rectal cancer between 2006 and 2026. Scientific output remained limited until 2012, followed by a steady increase after 2013 and a marked surge from 2020 onward. Life cycle analysis of publications comparing robotic and laparoscopic low anterior resection. The model demonstrates that the research field has reached approximately 75% of its projected saturation level, indicating a maturity phase of scientific production. Leading journals publishing studies on robotic versus laparoscopic low anterior resection, demonstrating a concentrated dissemination pattern in a limited number of core surgical journals.

Conclusion: This bibliometric analysis demonstrates that research comparing robotic and laparoscopic low anterior resection has evolved into a mature and expanding field. Although bibliometric data cannot establish clinical superiority, observed research trends suggest that robotic platforms are increasingly perceived as potential solutions to the limitations of conventional laparoscopy in complex pelvic surgery. These findings support the need for future multicenter and cost-effectiveness-focused studies to define the role of robotic technology in routine rectal cancer practice.

Can axillary positivity be predicted by hemogram parameters in breast cancer patients with axillary positivity at the time of diagnosis?

Arzu Akan[1], Semra Günay[2], Sezen Koyuncu[1], Orhan Yalçın[3]

[1]*University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul*

[2]*Okan University, İstanbul*

[3]*University of Health Sciences Türkiye, Taksim Training and Research Hospital, İstanbul*

Objective: This study aimed to evaluate the predictive value of hemogram parameters for axillary metastasis in patients diagnosed with breast cancer who had synchronous axillary lymph node metastasis at the time of diagnosis.

Material and Methods: This retrospective study was conducted among patients diagnosed with breast cancer who presented to the breast/endocrine surgery outpatient clinic of University of Health Sciences Türkiye, Prof. Dr. Cemil Taşcıoğlu City Hospital between June 2023 and May 2025. Patients were divided into two groups according to axillary lymph node (ALN) status at diagnosis as ALN-negative and ALN-positive. Hemogram parameters at initial presentation were evaluated, and lymphocyte, neutrophil, and platelet counts were recorded. Based on these values, the neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), and lymphocyte-to-monocyte ratio (LMR) were calculated.

Results: Of the 203 patients included in the study, 101 were ALN-positive and 102 were ALN-negative. Lymphocyte counts were significantly higher in ALN-positive patients ($p<0.001$), whereas no significant differences were observed in monocyte, platelet, or neutrophil counts. Similarly, NLR, PLR, and LMR values were found to be statistically significant ($p<0.001$). Ultrasonography, mammography, and magnetic resonance imaging (MRI) showed a strong positive association with ALN positivity ($p<0.05$), while no association was found between tumor type and axillary positivity ($p=0.805$). ALN biopsy results were also found to be significantly higher in identifying ALN positivity ($p<0.001$).

Conclusion: We concluded that hemogram parameters may be effective in predicting axillary lymph node positivity in breast cancer patients, particularly in situations where radiological methods and biopsy procedures are not accessible.

Quality and safety of AI-generated patient education in general surgery: A pilot study

Fatih Gürsoy, Şaban Alhattab

Düzce University, Düzce

Objective: Artificial intelligence (AI)-generated patient education materials are increasingly used to support perioperative counseling in general surgery. However, concerns remain regarding the accuracy, safety, readability, and clinical appropriateness of AI-generated information. This pilot study aimed to evaluate the quality, safety, and readability of AI-generated patient education content for common general surgical conditions.

Material and Methods: In this cross-sectional pilot study, patient education texts were generated using a large language model for 10 common general surgery topics, including appendicitis, cholelithiasis, hernia, colorectal cancer, and postoperative care. Three general surgery specialists independently evaluated the materials using validated assessment tools, including DISCERN, global quality score (GQS), and a safety checklist focusing on misinformation and missing critical warnings. Readability was assessed using flesch reading ease and grade-level metrics. Inter-rater reliability was analyzed using intraclass correlation coefficients (ICC).

Results: A total of 50 AI-generated education texts were evaluated. The mean DISCERN score was 61.4±8.2, indicating moderate-to-high quality, while the mean GQS was 3.8±0.7. Safety assessment identified minor omissions in 18% of materials, primarily related to complication warnings and red-flag symptoms, whereas critical misinformation was rare (4%). Readability analysis showed that most texts were written at a grade level above recommended patient education standards (mean grade level: 10.6±1.3). Inter-rater agreement was good to excellent (ICC=0.82).

Conclusion: AI-generated patient education materials in general surgery demonstrate acceptable overall quality and safety but frequently exceed recommended readability levels and may omit key safety information. Human supervision remains essential before clinical implementation. Larger studies are needed to establish standardized frameworks for AI-assisted patient education

Our clinical experience with laparoscopic splenectomy

Burak Güneş[1], Burak Yavşan[1], Mehmet Fatih Ebiloğlu[2], Ahmet Bozdağ[2]

[1]Clinic of General Surgery, Elazığ Fethi Sekin City Hospital, Elazığ

[2]Department of General Surgery, Fırat University Faculty of Medicine, Elazığ

Objective: Laparoscopic splenectomy is considered the gold standard for elective splenectomy in benign hematological diseases, as it provides less postoperative pain, shorter hospital stay, and faster recovery compared with open surgery. This study aimed to evaluate the outcomes of laparoscopic splenectomy performed at our clinic.

Material and Methods: Forty-four patients who underwent laparoscopic splenectomy for benign hematological diseases between 2015 and 2022 were retrospectively analyzed. Demographic characteristics, indications for splenectomy, length of hospital stay, conversion to open surgery, transfusion requirements, and postoperative complications were evaluated.

Results: The patients' ages ranged from 19 to 87 years; 26 were female and 18 were male. Immune thrombocytopenic purpura was the most common indication (79.5%). Conversion to open surgery occurred in one patient. The median length of hospital stay was 4 days. No significant associations were found between age, sex, spleen size, preoperative platelet count, or hematological diagnosis and complication rate, mortality, length of hospital stay, or conversion rate. However, complication rates were significantly higher in patients requiring perioperative transfusion ($p<0.05$). Low preoperative hemoglobin levels and high preoperative leukocyte counts were also significantly associated with increased complication rates ($p<0.05$).

Conclusion: Laparoscopic splenectomy is a safe and effective procedure for benign hematological diseases. Careful assessment of preoperative hematological parameters is essential to reduce postoperative complications.

Keywords: Immune thrombocytopenic purpura, laparoscopic splenectomy

The organ-preserving role of endoluminal surgical techniques in large colorectal polyps: Initial experience of our center

Burak Dinçer, Onur Can Güler

Department of Surgical Oncology, University of Health Sciences Türkiye, Ankara Oncology Training and Research Hospital, Ankara

Objective: With the implementation of advanced endoluminal techniques such as endoscopic mucosal resection (EMR) and hybrid EMR/endoscopic submucosal dissection (ESD), large colorectal polyps and superficially spreading lesions that were previously considered unresectable can now be removed without the need for organ resection. This approach reduces the rate of colorectal resections performed for benign lesions and prevents the morbidity and mortality associated with major colorectal surgery. In this study, we aimed to present our initial experience with EMR and hybrid EMR/ESD procedures performed at our center.

Material and Methods: Patients who underwent endoluminal surgical techniques at our center between 2024 and 2025 were included in the study. Demographic, clinical, endoscopic, pathological, and follow-up data were retrospectively evaluated.

Results: A total of nine patients were included. The median age was 63 years (range: 51-77), and six patients (66.7%) were male. The median lesion size was 26 mm (range: 17-37), with five lesions located in the rectum. According to the Paris classification, seven lesions were type 0-IIa, one was type 1sp, and one was type 1p. Based on the Kudo pit pattern classification, five lesions were type 3 and four were type 4. En bloc resection was achieved in five patients, while piecemeal resection was performed in four patients. Post-polypectomy bleeding occurred in only one patient and was successfully managed with endoscopic clipping. No perforation was observed. Histopathological examination revealed tubulovillous adenoma in seven patients and villous adenoma in two patients. High-grade dysplasia was identified in three patients (33.3%); all three lesions were resected en bloc with negative surgical margins. During a median follow-up of 17 months (range: 13-21), no recurrence was detected.

Conclusion: Endoluminal surgical techniques enhance organ-preserving management in colorectal polyps and superficially spreading lesions. Their wider adoption, given the low complication rates, may reduce the need for colorectal resections performed for benign disease.

Keywords: Endoscopic mucosal resection, endoscopic submucosal dissection

1331 iatrogenic perforation in consecutive colonoscopies: A single-center experience of five cases

Ali Çiftçi[1], Hamdi Taner Turgut[1], Uğur Buğan[2], Abdullah Güneş[1], Murat Burç Yazıcıoğlu[1], Ceyhun Mestçi[1]

[1]*Clinic of General Surgery, Kocaeli City Hospital, Kocaeli*

[2]*Clinic of Gastroenterology Surgery, Kocaeli City Hospital, Kocaeli*

Objective: Colonoscopy is a widely used and generally considered safe procedure for the diagnosis and treatment of colorectal diseases. However, perforation is one of the rare but potentially serious complications. This study aimed to evaluate the incidence of iatrogenic perforations and the results of surgical management in 1331 consecutive colonoscopy procedures performed at our center.

Material and Methods: 1331 colonoscopies performed during the specified period were retrospectively reviewed. Five patients who developed perforation after the procedure were included in the study. Patients were evaluated in terms of demographic characteristics, accompanying comorbidities, perforation localization, time of diagnosis (during the procedure or in the postoperative period), surgical approach applied, need for intensive care, length of hospital stay, and 30-day mortality.

Results: Perforation occurred in five patients out of a total of 1331 colonoscopy procedures, and the perforation rate was calculated as 0.37%. The average age of the patients was approximately 68 years, and the majority of cases were in the elderly age group. Most perforations were found in the distal colon, particularly in the rectosigmoid region; one case involved a perforation at the level of the splenic flexure. The diagnosis was made during the procedure in some patients, while in others it was diagnosed based on acute abdominal symptoms that developed after the procedure. All patients were treated surgically. Primary repair was preferred in hemodynamically stable cases with limited intra-abdominal contamination. Laparoscopic approach was safely applied in appropriate cases. A temporary stoma was required in one patient with a more clinically complicated course. No mortality was observed during the 30-day follow-up period.

Conclusion: Although rare, colonoscopic perforation is a potentially serious complication. The perforation rate in our series was consistent with the literature. Successful clinical outcomes were achieved with early diagnosis and timely surgical intervention. When appropriate patient selection is made, primary repair stands out as a safe and effective treatment option, especially for perforations located in the distal colon.

Laparoscopic repair of iatrogenic colon perforations occurring during colonoscopy

Turgut Anuk[1], Ahmet Başak[2]

[1]*Department of General Surgery, Yalova University Faculty of Medicine, Yalova*

[2]*Clinic of General Surgery, Erzurum City Hospital, Erzurum*

Objective: Colonoscopy is a diagnostic procedure commonly performed for suspected colonic pathologies. The incidence of iatrogenic perforation during colonoscopy ranges between 0.03% and 0.8%. In this study, we aimed to present the management of patients who developed perforation during colonoscopy.

Material and Methods: Iatrogenic perforation occurred in three patients during colonoscopy procedures. The mean age of the patients was 57.6 years; two were male and one was female. None of the patients had a history of previous abdominal surgery. Colonoscopy was performed in one patient due to abdominal pain and constipation, while in the other two patients it was performed for diagnostic purposes following a positive fecal occult blood test. The perforations were detected intraoperatively by direct visualization of intraperitoneal perforation, and the patients were taken for emergency surgery. Laparoscopic exploration revealed no intra-abdominal contamination. Perforation sites were located in the sigmoid colon in two patients and at the rectosigmoid junction in one patient. The perforation size ranged between 2 and 3 cm. Primary repair was performed laparoscopically using 3/0 Vicryl sutures. A pelvic drain was placed, and the procedure was concluded. During follow-up, no anastomotic leakage was observed. A liquid diet was initiated on postoperative day 3, and all patients were discharged uneventfully on postoperative day 5.

Results: Iatrogenic colon perforations occurring during colonoscopy may present as an acute abdomen requiring emergency surgery if not recognized promptly. However, early detection during the procedure allows timely intervention. Depending on the size of the perforation, surgical repair, resection, or ostomy creation may be preferred based on the patient's comorbidities and the degree of contamination.

Conclusion: In our case series, early-detected perforations were successfully managed with laparoscopic intervention. In similarly presenting cases, laparoscopic management should be considered as the first-line approach.

Keywords: Colonoscopy, laparoscopic repair, perforation

Is surgery always necessary in adult intussusception?

Sena Çağla Özden, Erkan Okumuş, Berk Yılmaz, Özlem Zeliha Sert

University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, İstanbul

Objective: Adult intussusception is a rare clinical entity that differs from pediatric cases due to the higher likelihood of underlying pathological causes. Although surgery has traditionally been recommended in adult patients, the widespread use of advanced imaging techniques has led to increased detection of transient and self-limiting small bowel intussusceptions. This has raised questions regarding the necessity of routine surgical intervention. The aim of this study was to evaluate the need for surgery in adult intussusception based on localization and to assess the risk of malignancy, particularly in colonic cases.

Material and Methods: Adult patients who were hospitalized after being diagnosed with intussusception on imaging studies following emergency department or outpatient clinic admission over the past 10 years were retrospectively reviewed. In patients with multiple admissions, the admission requiring surgery was included; if none required surgery, the admission with the most complete data was selected. Patients were compared according to operative and non-operative management. Intussusceptions were classified as small bowel or colonic. Histopathological findings were evaluated in surgically treated patients.

Results: A total of 90 patients were included in the study. Surgical treatment was performed in 38 patients (42%), while 52 patients (58%) were managed non-operatively. The rate of surgical intervention was significantly higher in colonic intussusceptions compared to small bowel intussusceptions (64% vs. 32%, p=0.028). Colonic intussusceptions were associated with a 3.7-fold increased risk of requiring surgery (OR: 3.7, 95% CI: 1.1-12.4). Malignant pathology was identified in 1 patient (2.6%) who underwent surgery, and malignancy was observed exclusively in the colonic intussusception group.

Conclusion: Surgical management of adult intussusception should not be routine for all patients but rather individualized according to the location of the intussusception. While a substantial proportion of small bowel intussusceptions can be safely managed conservatively, the potential presence of underlying malignancy in colonic intussusceptions should always be considered, favoring a surgical approach.

Keywords: Adult intussusception, colonic intussusception, surgical management, malignancy

[P-215]

Bibliometric analysis of the sacral neuromodulation literature in pelvic floor disorders

Serkan Demir[1], Faruk Yazıcı[2], M Salih Süer[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut State Hospital, Ankara*

Objective: This study aimed to bibliometrically evaluate the scientific output, historical evolution, thematic trends, and global research dynamics of sacral nerve stimulation (SNS) and sacral neuromodulation in the context of pelvic floor disorders and pelvic floor dysfunction.

Material and Methods: This bibliometric study included publications indexed in PubMed between 2001 and 2026. The search strategy combined "sacral nerve stimulation" or "sacral neuromodulation" with "pelvic floor disorders" or "pelvic floor dysfunction." Retrieved records were analyzed for annual scientific output, author and institutional contributions, country-level productivity, journal distribution, keyword frequencies, trending topics, and patterns according to Lotka's and Bradford's laws. Analyses were performed using the bibliometrix package.

Results: A total of 56 publications were identified across 42 journals, with contributions from 257 authors. The literature was predominantly multi-authored, with a mean of 4.95 authors per document; the international collaboration rate was 10.71% (single-author publications: n=4). Annual output was low and irregular between 2001 and 2010, followed by a marked increase after 2015, with a clear concentration during 2018-2025. Country-level productivity was mainly driven by the United States, Chile, China, Norway, Portugal and France, reflecting a progressive global dissemination of the field. At the institutional level, pelvic floor innovation centers and university hospitals predominated, with core production concentrated in a limited number of centers. Journal distribution conformed to Bradford's law, clustering in journals focused on colorectal surgery, urogynecology, gastroenterology, and neuromodulation. Keyword and trend analyses identified humans, female, electric stimulation therapy/methods, and treatment outcome as dominant terms, with a temporal shift from technique-oriented themes toward clinical outcomes and quality-of-life-focused research; author productivity followed Lotka's law.

Conclusion: This bibliometric analysis indicates that sacral nerve stimulation and sacral neuromodulation have become an increasingly studied and maturing research area in pelvic floor disorders. The literature remains concentrated in specific countries and high-volume centers, yet recent years show broader global expansion with growing contributions from diverse regions. The predominantly multi-author and interdisciplinary structure suggests a clinically driven, collaboration-based research ecosystem. The original contribution of this study is its holistic characterization of scientific production in this field—not only quantitatively, but also through thematic trajectories, journal dynamics, and temporal shifts in research focus. The observed transition from technique- and pathophysiology-oriented approaches toward treatment outcomes and quality-of-life–centered evaluations clearly reflects ongoing clinical integration. By clarifying the structure and developmental pathways of the literature, this work provides a practical framework for researchers, clinicians, and policymakers and serves as a strategic reference for planning future multicenter, prospective, and standardized studies.

Rectal cancer patients: The effect of distal resection margin on local recurrence and survival

Yunus Emre Gayberi

Department of General Surgery, Mersin University Faculty of Medicine, Mersin

Objective: To evaluate the impact of distal circumferential surgical margin (distal resection margin; DRM) length on local recurrence and survival in patients undergoing curative resection for rectal cancer, and to provide clinical data to inform ongoing debates on the optimal distal margin.

Material and Methods: This retrospective cohort study included 186 patients who underwent surgery with curative intent for rectal cancer at Mersin University Faculty of Medicine, Department of General Surgery, between 2010 and January 2025. Patients were stratified into three groups according to the distal margin length reported in the pathology report: ≤1 cm (n=43), 1-2 cm (n=51), and >2 cm (n=92). Clinical, intraoperative, pathological, and postoperative variables were recorded. Survival analyses were performed using the Kaplan-Meier method, and groups were compared with the log-rank test. Factors associated with mortality and recurrence were assessed using univariable and multivariable Cox regression analyses.

Results: The mean age was 63.72±9.63 years and 57.0% of patients were male. The overall local recurrence rate was 6.5% (n=12). There were no statistically significant differences among DRM groups in 60-month overall survival (OS) or disease-free survival (DFS) (all p>0.05); 60-month DFS rates were 81.3% in the ≤1 cm group, 80.4% in the 1-2 cm group, and 81.5% in the >2 cm group. Anal verge distance and stoma formation rates differed significantly between groups, whereas no meaningful differences were observed in other demographic, clinical, or pathological variables. In mortality analyses, postoperative complications and lymphovascular invasion increased the risk of mortality; perineural invasion was associated with mortality in univariable analysis.

Conclusion: In this cohort, distal resection margin length (≤1 cm, 1-2 cm, >2 cm) did not significantly affect local recurrence or 60-month survival outcomes. These findings suggest that, particularly when oncologic resection quality is ensured (R0/CRM-negative resection and appropriate surgical technique), individualized decision-making based on tumor biology and clinical context may be more rational than a single rigid distal margin threshold.

Keywords: Rectal cancer, distal resection margin, local recurrence, survival

[3]*Clinic of General Surgery, Büyükçekmece Mimar Sinan State Hospital, İstanbul*

[4]*Clinic of General Surgery, Mamak State Hospital, Ankara*

Objective: The widespread adoption of screening programs has led to a significant increase in the early diagnosis of rectal cancer. In addition, staging tools and treatment modalities for rectal cancer have greatly advanced. Consequently, there is growing interest in multimodal organ-preserving strategies, including the use of local excision and chemoradiotherapy in patients with early rectal cancer. In our study, we aimed to evaluate the correct and incorrect decisions regarding local excision in patients who underwent transanal resection (TAR).

Material and Methods: Patients who underwent transanal resection for a mass in the distal rectum between November 2023 and August 2024 were included in the study. The patients' demographic data, such as age, gender, height, and weight, comorbidities, preoperative radiological and endoscopic images, and pathology results were recorded. Patient positions, duration, complications, pathology results, and follow-up data during surgery were recorded.

Results: Three patients were included in the study. Two patients were male and one was female. The mean age was 61.3 years. Two patients were ASA 3 and one was ASA 2. The patients' BMIs were 29.1, 27.9, and 25.2, respectively. The follow-up periods of the patients were 21, 35, and 30 months. The distances of the lesions from the dentate line were 1 cm, 2 cm, and 3 cm. The sizes were 5x6 cm for the small lesion and 4x3 cm for the other lesion. The CEA values of the patients were 1.7, 20.1, and 8. The biopsy results of 2 patients were reported as tubulovillous adenoma, and the biopsy of 1 patient was reported as intramucosal carcinoma. Preoperative endosonography did not reveal muscularis propria invasion in 2 patients, and there was suspicion of muscularis propria invasion in 1 patient. CT and MR imaging were performed for this patient. LAP was not detected on CT imaging. The patients' surgery durations were 70, 50, and 120 minutes. Postoperative pathology results: Adenocarcinoma (biopsy result: Tubulovillous adenoma) was detected in 1 patient, and adenocarcinoma invading the muscularis propria (biopsy result: Intramucosal carcinoma) was detected in 1 patient. Low anterior resection was performed on this patient. No malignancy was detected in the surgical pathology specimen. The other two patients underwent colonoscopic follow-up.

Conclusion: When deciding on local excision for rectal masses, radiological and endoscopic examinations and pathology specimens should be evaluated by experienced multidisciplinary teams. Correct decisions based on preoperative data can protect patients from unnecessary surgery, while incorrect assessments negatively affect patients' definitive surgical processes after local excision.

Magnetic compression therapy for a patient with colorectal anastomotic stricture

Servet Karagül, Emine Yıldırım, Cüneyt Kayaalp

İstanbul Atlas University, İstanbul

Objective: We aimed to present the outcomes of a patient who developed colorectal anastomotic stricture following colorectal surgery and was treated using magnetic compression therapy.

Material and Methods: A 70-year-old male patient presented with difficulty in gas and stool passage and abdominal distension. He had a history of Hartmann's procedure performed approximately two years earlier for rectosigmoid adenocarcinoma causing intestinal obstruction. Synchronous liver metastases had also been detected, and the patient was under medical oncology treatment. His colostomy had been closed approximately nine months prior, and three months after closure, an anastomotic stricture was identified. Despite one endoscopic stent placement and five balloon dilatation procedures, the stricture could not be resolved. Rectoscopic examination revealed a tight stricture approximately 10 cm from the anal verge, preventing passage of the colonoscope. The patient underwent surgery, during which a loop ileostomy was created. Under colonoscopic guidance, magnets were placed across the anastomotic stricture. At three-week follow-up rectoscopy, restoration of luminal patency was observed, and the magnets were removed. The patient was discharged with a plan for subsequent ileostomy closure.

Results: The patient underwent surgery, during which a loop ileostomy was created. Under colonoscopic guidance, magnets were placed across the anastomotic stricture. At three-week follow-up rectoscopy, restoration of luminal patency was observed, and the magnets were removed. The patient was discharged with a plan for subsequent ileostomy closure.

Conclusion: Magnetic compression therapy may be successfully applied in selected cases of colorectal anastomotic stricture.

The relationship between tumor regression and clinicopathological parameters in breast cancers treated with neoadjuvant systemic therapy

Sude Sezer Özkul, Sumru Beril Çetintaş Atak, Mevlüt Yordanagil, Abdullah Güneş

Clinic of General Surgery, Kocaeli City Hospital, Kocaeli

Objective: Neoadjuvant systemic therapy is accepted as the standard approach in locally advanced breast cancers and in tumors that are sensitive to targeted therapies according to their biological subtype. However, the response to treatment varies depending on the biological characteristics of the tumor. In this study, we aimed to evaluate the relationship between tumor regression and clinicopathological parameters in breast cancer patients who received neoadjuvant systemic therapy.

Material and Methods: A total of 35 breast cancer patients who underwent surgery following neoadjuvant systemic therapy at our institution were retrospectively evaluated. Tumor regression after neoadjuvant therapy was analyzed according to the Miller-Payne classification. Patients were divided into two groups based on treatment response: Miller-Payne grades 1-3 were defined as poor response, and grades 4-5 as good response. Histopathological type, tumor grade, ER, PR, HER2 status, Ki-67 proliferation index, luminal subtype, clinical T stage, lymph node status, perineural invasion, and lymphovascular invasion parameters obtained from biopsy and resection specimens were evaluated. Categorical variables were analyzed using the chi-square test, and continuous variables were analyzed using the Mann-Whitney U test. ROC analysis was performed for Ki-67 to determine the optimal cut-off value.

Results: A significant association was found between tumor grade, luminal subtype, histopathological type, and response to neoadjuvant systemic therapy ($p=0.047$, $p<0.001$, and $p<0.001$, respectively). ER positivity was observed in 71% of patients, PR positivity in 45%, and HER2 positivity in 37%, and all were significantly associated with a good response to neoadjuvant systemic therapy ($p=0.006$, $p<0.001$, and $p=0.002$, respectively). The Ki-67 value (cut-off 35%) demonstrated an AUC of 0.70 in ROC analysis for predicting response to neoadjuvant therapy, and the optimal cut-off value was determined as 35%. At this threshold, sensitivity was 58.8% and specificity was 88.9%. No significant association was found between tumor regression and clinical T stage, MRI tumor size, age, or lymphovascular invasion.

Results: Tumor response to neoadjuvant systemic therapy is closely associated with the biological characteristics of the tumor. In particular, hormone receptor status, HER2 expression, proliferation index, and luminal subtype are key determinants in predicting tumor regression. The impact of anatomical staging parameters on treatment response appears to be limited. These findings support the importance of biology-driven approaches in the planning of neoadjuvant therapy.

[3]*Clinic of General Surgery, University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

[4]*Department of of General Surgery, University of Health Sciences Türkiye, Sincan Training and Research Hospital, Ankara*

Objective: Male breast cancer is a rare malignancy accounting for approximately 1% of all breast cancers; therefore, available data remain limited. Although it shares biological similarities with female breast cancer, diagnosis is often established at a more advanced stage, and prognostic factors are not clearly defined. Tumor size, lymph node involvement, histological grade, and immunohistochemical markers are considered important determinants of prognosis. However, data regarding predictors of recurrence in male breast cancer are insufficient. This study aimed to evaluate our institutional experience and investigate the association between clinicopathological characteristics and recurrence.

Material and Methods: This retrospective study included patients who underwent surgery for histopathologically confirmed male breast cancer between 2023 and 2025 at Ankara Bilkent City Hospital. Demographic data, comorbidities, preoperative tumor markers, surgical procedure, tumor size, lymph node status, lymphovascular and perineural invasion, and immunohistochemical parameters (ER, PR, HER2, Ki-67) were recorded. Tumors were staged according to the AJCC 8th edition. The Nottingham prognostic index (NPI) was calculated. Patients were followed for disease-free survival (DFS) and categorized as disease-free or recurrence/metastasis/death. Statistical analyses were performed using appropriate parametric or non-parametric tests and the chi-square test, with $p<0.05$ considered significant.

Results: A total of 20 male breast cancer patients were evaluated. The mean age was 60.7 ± 15 years, and the mean tumor size was 2.6 ± 1.1 cm. Sixty percent were T2 stage, and nodal positivity was observed in 60%. The mean number of lymph nodes removed was 13.7 ± 4.8, while the median number of metastatic nodes was 1 (0-17). All tumors were invasive ductal carcinoma, and 60% were grade 2. Lymphovascular invasion was present in 85% and perineural invasion in 50%. Modified radical mastectomy was performed in 75%. Estrogen receptor positivity was frequent, whereas HER2 positivity was 25%. The mean Ki-67 index was approximately 30%. Most patients were classified as intermediate risk according to the Nottingham Prognostic Index. Mean disease-free survival was 14 months (6-36), and recurrence/metastasis/death occurred in 20%. Although tumor size and metastatic lymph node number were higher in recurrent cases, differences were not statistically significant ($p>0.05$).

Conclusion: Male breast cancer predominantly presents as hormone receptor-positive disease with an intermediate prognostic profile. None of the evaluated clinicopathological parameters significantly predicted recurrence. However, increased tumor size and nodal burden may be associated with recurrence. Larger multicenter studies are needed to clarify prognostic factors.

Insulinoma: Clinicopathological characteristics and surgical management -a case series-

Turgay Sayın[1], Burçak Cavnar Helvacı[2], Muhammed Salih Süer[1], Muhammed Metin Yüksel[1], Serkan Demir[1], Duray Şeker[1], Ahmet Oğuz Hasdemir[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Department of Endocrinology and Metabolism, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: This study aims to evaluate the clinical and pathological characteristics of patients treated for insulinoma and discuss the surgical outcomes in light of the current literature.

Material and Methods: We retrospectively reviewed six insulinoma patients operated on between 2023 and 2025. Demographic, clinical, surgical, and histopathological data were extracted from institutional databases. Long-term outcomes and symptom resolution were assessed via telephone follow-up.

Results: The mean age of the patients was 52,17±15,63 years, with an equal gender distribution (3 females, 3 males). The mean body mass index (BMI) was 26.38±1.46 kg/m². All patients presented with syncope as the primary reason for emergency admission, and whipple's triad (WT) was observed in all cases. The mean blood glucose level at admission was 31.83±10.42, and all six patients exhibited elevated C-peptide levels. The Prolonged Fasting test was positive in four patients. Preoperative localization was achieved in all cases via imaging. Surgical intervention consisted of laparotomy in five patients and a laparoscopic approach in one. In all laparotomy cases, intraoperative ultrasound (IOUS) was utilized for definitive lesion localization. The primary factor influencing operative time was the duration of intraoperative localization. While the lesion was identified through direct surgical exploration in three patients, IOUS was required for localization in the remaining three. The mean tumor size was 17.5±7.37 mm. Surgical procedures included distal pancreatectomy for distal lesions (n=1), Whipple procedure (pancreaticoduodenectomy) for a lesion in the pancreatic head adjacent to the wirsung duct (n=1), and enucleation for the remaining four cases. The patient who underwent the Whipple procedure required a 131-day hospitalization due to postoperative complications, whereas the mean hospital stay for other patients was 5 days. Histopathological analysis revealed WHO NET grade 1 in three patients, grade 2 in two, and grade 3 in one. The Ki-67 proliferation index was below 5% in five patients, while it was 20% in the patient who underwent distal pancreatectomy. During the follow-up period (23.17±11.57 months), all patients achieved complete symptomatic relief with no evidence of recurrence.

Conclusion: Surgical resection is definitive, though intraoperative localization remains challenging. We emphasize the necessity of intraoperative ultrasonography (IOUS). Despite high morbidity reported in the literature—such as citing a 53% fistula and 7% hemorrhage rate for proximal lesions—our series remained recurrence-free. One patient required re-intervention for a post- Whipple fistula. Persistent hypoglycemia post-resection should prompt investigation for multiple adenomas or MEN syndromes. High Ki-67 indices and poor differentiation necessitate rigorous long-term surveillance.

Surgical approach to chronic pancreatitis cases: Analysis of a single-center study

Firdevs Melike Onuktav, Oğuzhan Aydın, Yusuf Yunus Korkmaz, Özgür Bostancı, Erdem Kınacı

Department of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Chronic pancreatitis is a clinical condition characterized by severe pain, with its etiology primarily categorized into biliary and non-biliary causes. This study aims to evaluate patients diagnosed with chronic pancreatitis who underwent surgical intervention at our center, comparing surgical approaches in relation to postoperative hospital stay, complication rates, and postoperative pathological findings.

Material and Material: Patients operated on between June 2020 and December 2025 were retrospectively analyzed. Surgical methods were classified into the frey procedure, laparoscopic frey procedure, laparoscopic beger procedure, classic Whipple procedure, pylorus-preserving Whipple (PPPD), and robotic puestow procedure. Data regarding etiology, body mass index (BMI), ASA score, age, gender, length of hospital stay, postoperative complications, and surgical indications were recorded to evaluate the clinical impact of surgical treatment.

Results: Eighteen patients were included in the study. Six patients had a confirmed preoperative diagnosis of chronic pancreatitis, with biliary and non-biliary etiologies equally represented. The remaining 12 patients underwent a Whipple procedure due to an inability to exclude malignancy in the presence of distal common bile duct stricture (n=3), pancreatic head cysts (n=2), and pancreatic head masses (n=7). Patient histories revealed recurrent attacks of abdominal pain. Regarding etiology, 6 of the patients who underwent the Whipple procedure presented with biliary pathology. Surgical techniques included classic Whipple in 9 (50%) patients, PPPD in 3 (16.6%), laparoscopic beger in 1 (5.5%), laparoscopic frey in 2 (11.1%), frey in 2 (11.1%), and robotic puestow in 1 (5.5%). The mean age was 52, mean BMI was 21.6, mean hospital stay was 16 days, median ASA score was 2, and the mean preoperative attack frequency was 5. The postoperative complication rate was 33.3% (n=6), with pancreatic fistula being the most common cause. The median number of attacks was 2 in the complication group and 5 in the non-complication group. Notably, the final pathology for all 12 patients who underwent radical resection due to suspected malignancy was consistent with chronic pancreatitis. Pain recurrence was observed in one patient operated on for non-biliary chronic pancreatitis.

Conclusion: While drainage methods suffice, Whipple remains necessary if malignancy is suspected. Preoperative attack frequency predicts complications, requiring meticulous patient and technique selection to optimize clinical outcomes

Objective: Liver metastases resulting from malignancies other than colorectal and endocrine tumors (non-colorectal non-endocrine liver metastases; NCNELM) are characterized by heterogeneous biological behavior and generally poor prognosis. However, in cases with appropriate patient selection, surgical resection remains one of the most important curative treatment options capable of providing long-term survival. This retrospective study aimed to analyze the demographic, clinicopathological, and operative characteristics of patients with NCNELM who underwent surgery, and to evaluate perioperative outcomes and survival data in conjunction with the existing literature.

Material and Methods: Patients who underwent liver resection in a separate session from the primary tumor surgery between June 1, 2020, and October 31, 2025, at our clinic due to NCNELM were retrospectively analyzed. The demographic data, comorbidities, operative findings, primary tumor and metastasis characteristics, postoperative clinical course, and histopathological results of the patients were evaluated.

Results: The median age of the 18 patients was 53.5 years (range 31-74), and 13 (72.2%) were female. Ten patients (55.6%) had at least one comorbidity. The distribution of primary tumors was as follows: Breast (n=7, 38.9%), lung (n=3, 16.7%), sarcoma (n=2, 11.1%), stomach (n=2, 11.1%), pancreas (n=1, 5.6%), small intestine (n=1, 5.6%), ovary (n=1, 5.6%), and ocular origin (n=1, 5.6%). Surgical procedures performed included segmentectomy in 12 patients (66.7%) and bisegmentectomy in 6 patients (33.3%). The R0 resection rate was 83.3% (n=15). Postoperatively, one patient (5.6%) developed an intra-abdominal abscess, and two patients (11.1%) developed wound infections. No mortality was observed within 90 days postoperatively.

Conclusion: Surgical resection stands out as a safe and feasible treatment option in patients with non-colorectal non-endocrine liver metastases who are appropriately selected. The high rate of R0 resection achieved in our series, together with low morbidity rates and the absence of 90-day mortality, supports the perioperative safety and reliability of the surgical approach. Despite the heterogeneous tumor biology, these results suggest that surgery may provide a potential survival benefit in selected patients. Therefore, an aggressive surgical approach should be considered for appropriate candidates with NCNELM following multidisciplinary evaluation.

Epidemiological distribution and clinical correlations of pathological findings in cholecystectomy specimens: A single-center experience with 509 patients

Osman Sıbıç, Oğuzhan Hakan Topgül, Bahar Canbay, Sena Çağla Özden, Anıl Orhan, Gamze Çıtlak, Ahmet Zahit Kaan, Yusufcan Elmas

University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, İstanbul

Objective: Cholecystectomy is one of the most frequently performed operations in general surgery. The aim of this study is to determine the distribution of gallbladder pathology results in patients who underwent cholecystectomy and to evaluate its relationship with clinical parameters.

Material and Methods: A retrospective analysis was conducted on 509 consecutive cholecystectomy patients who underwent surgery at the general surgery clinic of University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, between 2020 and 2025. Demographic data, type of surgery (laparoscopic/open), operation time, length of hospital stay, and postoperative complications were recorded. Histopathological results were classified as chronic cholecystitis, acute cholecystitis, cholesterolosis, adenomyomatosis, polyp, dysplasia, and incidental malignancy. Categorical variables were analyzed using the chi-square test, and continuous variables were analyzed using the Mann-Whitney U or Kruskal-Wallis test.

Results: The study included 509 patients who underwent cholecystectomy. Of these patients, 327 (64.2%) were women and 182 (35.8%) were men, with a median age of 50 years (IQR: 40-60). The most frequently detected pathology was chronic cholecystitis (87.8%) in 447 patients, followed by acute cholecystitis (3.7%), adenomyomatosis (2.8%), and cholesterol polyp (2.4%). Dysplasia was observed in 14 patients (2.8%) in the study group. The incidence of incidental gallbladder malignancy was 0.8%. Among non-malignant causes, the longest operation time was 112 minutes (IQR: 61-149) in the acute cholecystitis group, and the length of hospital stay was statistically longer than in the other groups, similar to the acute pancreatitis group ($p<0.05$). No association was found between the presence of malignancy and dysplasia and continuous variables ($p<0.05$). Patients with malignancy were older, but no statistically significant difference was found ($p=0.606$).

Conclusion: The vast majority of cholecystectomy specimens consist of benign inflammatory pathologies. However, the occurrence of incidental malignancy, albeit at a low rate, highlights the importance of routine histopathological evaluation of all specimens.

Complementary surgery in incidental gallbladder cancers: A single-center experience from 2018-2025

Batuhan Öğüt, Emre Atmaca, İzzet Berk Cansız, Çağlar Tufan, Yasemin Özdemir Dündar, Kemal Eyvaz, Arif Aslaner

University of Health Sciences Türkiye, Antalya Training and Research Hospital, Antalya

Objective: Gallbladder cancer (GBC), although rare, is clinically significant due to its aggressive course and frequent late diagnosis. Most cases are incidentally detected after cholecystectomy performed with a preliminary diagnosis of benign disease. Complementary surgery is recommended in stages T1b and above due to the risk of residual disease and regional lymph node metastasis. This study evaluated incidental GBC cases detected in cholecystectomy specimens after 2018 and the pathological results of the complementary surgeries performed.

Material and Methods: Cholecystectomies performed in our center between 2018 and 2025 were retrospectively reviewed. A total of 8.886 cholecystectomies were performed during this period [8.162 laparoscopic (91.9%)], 724 open [(8.1%)]. Cases with malignancy were identified by reviewing pathology records. Tumors were staged according to the AJCC 8th edition TNM classification. The primary surgical type, T stage, complementary surgical content (liver bed/segment IVb-V resection and regional lymph node dissection), and complementary pathology findings were analyzed.

Results: Between 2018 and 2025, gallbladder malignancy was detected in 9 patients (incidence ≈0.10%). 5 of the patients were female (55.6%), and 4 were male (44.4%). The mean age was 68.7±8.0, and the median age was 70 (57-80). The majority of cases were T2 or higher stage (T1b: 1; T2/T2a: 7; T3: 1). All 8 patients with information on complementary surgery underwent liver bed/segment resection along with regional lymph node dissection. Metastatic lymph nodes were detected in 3 of the patients who underwent lymph node dissection (37.5%); One patient had N2 disease (≥4 metastatic nodes). Complementary pathology samples revealed residual tumor or microscopic malignant involvement in 3 patients (37.5%).

Conclusion: Incidental gallbladder cancer (GBC) is rare but clinically significant. The rates of lymph node metastasis and residual disease detected during complementary surgery in T2 and higher cases strongly support the critical oncological importance of liver bed resection and regional lymph node dissection.

Clinical characteristics, diagnostic process, and treatment outcomes of bezoar ileus cases: A single-center retrospective analysis

Uğurcan Bulut[1], Muhammed Salih Süer[1], Serkan Demir, Faruk Yazici[2], Ender Ergüder[1], Şener Balas[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Although rare, bezoar ileus represents an important cause of acute abdomen and mechanical intestinal obstruction. This study aimed to retrospectively evaluate the demographic characteristics, clinical findings, diagnostic methods, treatment approaches, and clinical outcomes of patients diagnosed with bezoar ileus and managed at the Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital.

Material and Methods: Patients who presented to the emergency department between October 2022 and November 2025 and were followed, treated, or surgically managed with a diagnosis of bezoar ileus were retrospectively analyzed. Demographic data, comorbidities, clinical symptoms, laboratory findings, imaging modalities, bezoar characteristics, applied treatment modalities, and postoperative outcomes were recorded. Continuous variables were presented as median (IQR) and mean ± standard deviation, whereas categorical variables were expressed as number and percentage.

Results: A total of 22 patients were included in the study. The median age was 60 years (48.2-68.5), and 59.1% were female. All patients were admitted. The most common presenting symptoms were abdominal pain (90.9%), nausea/vomiting (90.9%), and abdominal distension (81.8%). The median symptom duration was 3.5 days (2.0-5.0). Computed tomography was the most frequently used imaging modality, and a preoperative diagnosis of bezoar was established in 68.2% of patients, while 27.3% were initially diagnosed with non-bezoar-related causes. The majority of bezoars were phytobezoars (86.4%), and the common location was the ileum (72.7%). Conservative treatment was attempted in 45.5% of patients; however, 81.8% ultimately required emergency surgery. Open surgery was performed in all surgically treated patients, with enterotomy and bezoar extraction being the most commonly applied procedure (77.8%). Bowel resection was required in 18.2% of patients. The postoperative complication rate was 27.3%, with postoperative ileus being the most frequent complication. No mortality was observed, and the recurrence rate during follow-up was 9.1%.

Conclusion: Our series demonstrates that bezoar ileus represents an important cause of mechanical intestinal obstruction, particularly in elderly patients with a high comorbidity burden. Despite widespread use of computed tomography, preoperative diagnosis was achieved in only two-thirds of patients, and misdiagnosis persisted, consistent with the existing literature. Although conservative and endoscopic approaches showed limited effectiveness, the majority of patients required emergency surgery. Enterotomy with bezoar extraction was the most commonly performed and effective surgical method, whereas the need for bowel resection remained limited. The absence of mortality and acceptable complication rates support the safety of early and timely surgical intervention. Therefore, appropriate clinical suspicion, effective imaging, and prompt surgical decision-making are critical to reducing morbidity and preventing recurrence.

Clinical outcomes of a case series of heller myotomy and Dor fundoplycation for achalasia

Edip Akpınar, Veli Kılıç, Özgür Yıldırım Yıldırım, Erhan Gök

Department of General Surgery, University of Health Sciences Türkiye, Adana City Hospital, Adana

Objective: Achalasia is a rare primary esophageal motility disorder affecting 1.6 people per 100,000 annually, characterized by progressive dysphagia, regurgitation, and nocturnal aspiration. If left untreated, patients eventually become unable to maintain oral feeding, leading to significant nutritional deficiencies and weight loss. The physical discomfort and social eating restrictions caused by chronic symptoms significantly reduce the patients' health-related quality of life.

Material and Methods: This case series includes five patients admitted and treated at a tertiary teaching hospital between 2018 and 2025. All patients underwent diagnostic evaluation with preoperative contrast esophageal radiography, esophagogastroscopy, and esophageal manometry. Three patients had previously undergone unsuccessful endoscopic balloon dilation at other centers. All patients underwent laparoscopic Heller myotomy and partial anterior (Dor) fundoplication to prevent reflux. The patients' clinical outcomes were evaluated preoperatively and postoperatively using the Eckardt score (range 0-12).

Results: The study included five patients with an average age of 46 (29-56). All procedures were successfully completed laparoscopically. During myotomy, an undesirable disruption of mucosal integrity (mucosal opening) was detected in two patients, but these were immediately noticed and corrected with primary repair during surgery. In the postoperative period, all patients showed uneventful recovery, with no signs of leakage or infection. Patients were discharged on the 3rd or 4th day postoperatively without any delay caused by intraoperative repairs. The mean follow-up period was 77 months (33-95 months), and in the last clinical evaluation in January 2026, it was determined that all five patients had completely resolved their dysphagia and reflux symptoms and achieved clinical improvement (Eckardt score <1).

Conclusion: Laparoscopic myotomy and Dor fundoplication provide safe, permanent, and effective long-term relief for achalasia despite failed endoscopic treatments.

Keywords: Achalasia, heller myotomy, Dor fundoplication, Eckardt score

Clinicopathological features of patients diagnosed with gastrointestinal stromal tumor (GIST): A single-center experience

Nebile Çamaş, Kutay Sağlam

Bursa Uludağ University Faculty of Medicine, Bursa

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract and exhibit heterogeneous clinical and histopathological characteristics. This study aimed to evaluate the demographic, clinical, and pathological features of patients diagnosed with GIST between 2015 and 2025 at our center, and to analyze recurrence rates and synchronous/metachronous tumor associations.

Material and Methods: A total of 83 patients diagnosed histopathologically with GIST between 2015 and 2025 were retrospectively analyzed. Demographic data, tumor localization, histological and immunohistochemical features, surgical approaches, and adjuvant treatment information were obtained from medical records.

Results: The mean age was 60.7 years; 48 patients (57.8%) were male and 35 (42.2%) were female. The most common presenting symptoms were abdominal pain (n=26) and gastrointestinal bleeding (n=16). Tumors were most frequently located in the stomach (47%), followed by the small intestine (26.5%) and other sites (14.5%). Recurrence developed in 10 patients (12%), with 50% of recurrences involving the liver. Open resection was performed in 65 patients, while 18 underwent laparoscopic surgery. The recurrence rate was 5.6% in the laparoscopic group and 13.8% in the open surgery group. Absence of mitosis was observed in 42.9% of recurrent cases and in 28.6% of non-recurrent cases. Metachronous tumors were detected in 12 patients (14.5%). Synchronous malignancies were identified in 11 cases (13.3%). In these patients, the Ki-67 proliferation index was lower compared to the primary pathology, and 7 cases were reported as micro-GIST.

Conclusion: GISTs are most commonly located in the stomach, and our findings are consistent with the literature regarding demographic and clinical distribution. The considerable rate of liver recurrence and concomitant malignancies highlights the importance of long-term multidisciplinary follow-up in these patients.

Keywords: Gastrointestinal stromal tumor (GIST), recurrence, synchronous malignancy

Current approach to post-resuscitation care after cardiac arrest in the surgical critical care unit: Fever control instead of therapeutic hypothermia

Mehmet Eren Yüksel

Department of Surgical Critical Care Unit, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Targeted temperature management has long been considered one of the main components of post-resuscitation care in order to reduce hypoxic-ischemic brain injury after cardiac arrest. Previous international guidelines recommended therapeutic hypothermia (32-34 °C) as a standard approach in comatose patients who achieved return of spontaneous circulation (ROSC). However, large randomized controlled trials published in recent years and updated guidelines have questioned the clinical benefit of routine hypothermic cooling and have brought active prevention of fever to the forefront. The aim of this report is to evaluate, in light of the 2025 European Resuscitation Council (ERC) and European Society of Intensive Care Medicine (ESICM) guidelines, why fever control has become a higher priority than therapeutic hypothermia in post-resuscitation care after cardiac arrest.

Material and Methods: This study was conducted based on randomized controlled trials, systematic reviews, and meta-analyses published after 2021, with particular emphasis on the 2025 ERC-ESICM Post-Resuscitation Care Guidelines. Therapeutic hypothermia, controlled normothermia, and active fever prevention strategies were comparatively analyzed in terms of mortality, neurological outcomes, and treatment-related complications.

Results: Current evidence indicates that deep therapeutic hypothermia (32-34 °C) does not provide a significant advantage over normothermia with active fever control in terms of survival or favorable neurological outcome. In contrast, aggressive cooling strategies have been reported to increase the incidence of complications such as arrhythmias, electrolyte disturbances, infections, and coagulopathy. In accordance with these findings, the 2025 ERC guidelines no longer recommend therapeutic hypothermia as a routine and mandatory intervention in comatose patients after ROSC; instead, continuous temperature monitoring and active prevention of fever are defined as the primary goals. The target temperature for fever control is generally specified as ≤37.5-37.7 °C, and this strategy is recommended to be maintained for 36-72 hours. Selection of lower target temperatures is left to individual clinical assessment in specific patient subgroups.

Conclusion: The current approach to post-resuscitation care after cardiac arrest has shifted away from routine therapeutic hypothermia toward effective and continuous control of fever. This approach reflects an important change that enhances patient safety, reduces the risk of complications, and supports evidence-based individualized critical care management. In surgical critical care units, in cases of cardiac arrest occurring in the postoperative period or due to surgical conditions such as trauma, sepsis, and massive hemorrhage, post-resuscitation temperature management should be regarded as a critical component of care that directly affects clinical outcomes.

Keywords: Cardiac arrest, fever, post-resuscitation care, surgical critical care, therapeutic hypothermia

Laparoscopy in emergency general surgery: Balancing benefit and risk from hernia to trauma and emergency colorectal surgery (a synthesis of six systematic reviews)

Türker Kaymak, Mehmet Oğuzhan Polat, Veysel Barış Turhan, Murat Kendirci

Department of General Surgery, Hitit University Faculty of Medicine, Çorum

Objective: Although minimally invasive, laparoscopy in emergency general surgery remains debated due to sepsis, hostile anatomy, hemodynamic instability, and the need for conversion. We synthesized short-term outcomes of laparoscopy versus open surgery across major emergency indications using existing systematic reviews/meta-analyses.

Material and Methods: Systematic reviews/meta-analyses comparing laparoscopic and open approaches in adult emergency general surgery were collated across six domains: Emergency inguinal hernia repair, emergency femoral hernia management (minimally invasive strategies), laparoscopic peritoneal lavage (LPL) versus resection for complicated perforated diverticulitis, laparoscopic versus open surgery after stenting for obstructive colorectal cancer, laparoscopy versus laparotomy in abdominal trauma, and laparoscopy versus open surgery in emergency colorectal procedures. Primary outcomes were mortality, morbidity, and length of stay (LOS). Secondary outcomes included surgical site infection (SSI)/wound complications, pulmonary complications, ileus, reintervention, and conversion. Findings were narratively synthesized by direction of effect and reported p-values.

Results: In emergency inguinal hernia repair (13 studies; 38,659 patients), laparoscopy reduced LOS (MD -2.96 days; p=0.0074) and lowered wound infection (p<0.0001), with a 2.78% conversion rate. Evidence for emergency femoral hernia was limited and largely non-comparative; nevertheless, minimally invasive approaches—particularly TAPP—were highlighted for evaluating hernia content and potentially avoiding non-therapeutic laparotomy. For complicated perforated diverticulitis, LPL decreased mortality and permanent stoma rates (p<0.001) but increased sepsis (p=0.03), intra-abdominal abscess (p<0.001), and recurrence (p<0.001). After stenting for obstructive colorectal cancer (12 cohorts; 933 patients), laparoscopy reduced overall complications (p<0.0001), LOS (p=0.001), and SSI (p=0.04), at the expense of longer operative time (p=0.03), while 30-day mortality was similar (p=0.95). In abdominal trauma, missed injury and mortality were comparable (p=0.90 and p=0.09), whereas wound infection was lower with laparoscopy (p=0.002). In emergency colorectal surgery (29 studies; 63,727 patients), laparoscopy was associated with lower mortality and morbidity (both p<0.001), and reduced ileus (p=0.009) and pulmonary complications (p<0.001).

Conclusion: Across meta-analytic evidence, laparoscopy appears to be a safe alternative in selected emergency patients managed by experienced teams, with particularly favorable short-term outcomes in emergency colorectal and hernia surgery. In contrast, in complicated peritonitis (as exemplified by LPL), the increased risk of abscess/recurrence underscores the importance of careful selection, robust source control, and a low threshold for conversion.

Surgical and clinical outcomes of kidney transplantation according to renal artery number

Erbay Tümer[1], Yücel Yüksel[2], Kerem Özgü[2]

[1]*Clinic of Urology, NCR International Hospital, Gaziantep*

[2]*Clinic of General Surgery, University of Health Sciences Türkiye, Gaziantep City Hospital, Gaziantep*

Objective: Kidney transplantation is the most effective treatment for end-stage renal disease. The presence of multiple renal arteries in donor kidneys has traditionally been considered a controversial issue due to the increased complexity of vascular anastomosis. This study aimed to evaluate the surgical and early-to-midterm clinical outcomes of kidney transplants performed at our center according to the number of renal arteries.

Material and Methods: Patients who underwent kidney transplantation at our center between 2021 and 2025 were retrospectively analyzed. Recipients were divided into two groups based on graft renal artery number: Single-artery and multiple-artery (≥2 arteries) grafts. Demographic data, donor type, perioperative findings, vascular and urological complications, and follow-up serum creatinine levels were analyzed. Data were evaluated using descriptive statistical methods.

Results: A total of 200 kidney transplants were evaluated. Single renal artery was present in 142 patients (71.0%), while 58 patients (29.0%) had multiple renal arteries. Among the multiple-artery grafts, 49 had two arteries, 8 had three arteries, and 1 had four arteries. The incidence of vascular complications in multiple-artery grafts did not show a significant increase compared with single-artery grafts. During follow-up, serum creatinine levels remained within acceptable ranges in both groups.

Conclusion: This study demonstrates that the presence of multiple renal arteries in kidney transplantation does not constitute a disadvantage in terms of surgical or early-to-midterm clinical outcomes. With appropriate vascular reconstruction techniques in experienced centers, kidneys with multiple arteries—including selected cases with four arteries—can be safely transplanted, achieving functional outcomes comparable to those of single-artery grafts.

Keywords: Kidney transplants, multiple renal arteries

Exposure to electrocautery smoke in operating rooms and nurse awareness: An observational poster study

Yeliz Bağbozan

Pamukkale University Hospitals, Denizli

Objective: Surgical smoke generated during the use of electrocautery constitutes a significant occupational risk for healthcare professionals working in operating rooms. Inhalation of surgical smoke has been associated with respiratory tract irritation, headaches, and potential long-term health problems.

Material and Methods: This study was designed as an observational study based on clinical practices in operating rooms. In surgeries where electrocautery was used, the occurrence of surgical smoke, the use of smoke evacuation systems, and the types of masks preferred were evaluated. In addition, operating room nurses' awareness of the possible health effects of electrocautery smoke was assessed through clinical observations.

Results: Observations revealed that surgical smoke occurred in the majority of procedures involving electrocautery. It was noted that smoke evacuation systems were not actively used in every case and that standard surgical masks were predominantly preferred. Nurses' awareness regarding the long-term health effects of electrocautery smoke was found to be insufficient.

Conclusion: Electrocautery smoke represents an important source of occupational exposure for operating room nurses. Therefore, effective use of smoke evacuation systems and the planning of awareness-enhancing educational programs for nurses are necessary.

Keywords: Operating room nursing, surgical smoke, occupational safety, nurse health, electrocautery smoke

Figure 1. Exposure to electrocautery smoke in operating rooms and nurse awareness: An observational poster study.

• Observation of surgical smoke generated during electrocautery use • Operating room nurse exposed to electrocautery smoke • Dispersion of surgical smoke within the operating room environment • Use of a smoke evacuation system to reduce exposure to surgical smoke • Use of standard surgical masks during procedures involving electrocautery.

Information continuity in the operating room: The impact of communication channels on workflow

Müjde Vicir

İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir

Objective: Operating rooms are high-risk environments where multidisciplinary teams work simultaneously, and the continuity of information flow directly impacts patient safety and workflow. The objective of this study is to evaluate the impact of communication channels used in the operating room on information continuity and their relationship with the workflow.

Material and Methods: This study is a descriptive and observational evaluation conducted in the operating room of a large-scale hospital. Communication methods used among nurses, surgeons, and anesthesia teams during surgical processes were examined; specifically, information transfer processes during shift handovers, emergency cases, and peak working hours were observed. No patient data were used in the study, and it did not require ethics committee approval.

Results: The evaluation revealed that communication breakdowns increased in cases where information transfer was person-dependent and relied solely on verbal communication. The absence of a standardized information transfer process, particularly during shift handovers, led to workflow disruptions, prolonged surgical preparation times, and increased stress levels within the team. Conversely, it was observed that structured and documented communication channels supported information continuity.

Conclusion: Ensuring information continuity in the operating room is of critical importance for the sustainability of safe surgical practices. Standardizing communication channels and developing specific information transfer models for shift processes can positively influence workflow and enhance team performance. This study highlights areas for communication-based improvements in perioperative nursing.

Keywords: Perioperative nursing, communication, information continuity, shift, workflow

[P-258]

A retrospective evaluation of surgical site infection in patients undergoing colostomy closure

Bourak Chousein[1], Harun Karabacak[1], Serhat Tokgöz[2], Serkan Demir[2]

[1]*Clinic of General Surgery, Lokman Hekim Etlik Hospital, Ankara*

[2]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Colostomy closure is a commonly performed procedure in gastrointestinal surgery; however, surgical site infections remain one of the most frequent postoperative complications. These infections may lead to prolonged hospital stay, additional treatment requirements, and increased postoperative morbidity. The aim of this study was to retrospectively evaluate surgical site infections following colostomy closure and to identify associated risk factors.

Material and Methods: This retrospective study reviewed medical records of patients who underwent colostomy closure at the University of Health Sciences Türkiye, Ankara Etlik City Hospital, Department of General Surgery between 2023 and 2025. Patients aged ≥18 years, with at least 30 days of postoperative follow-up and documented surgical site infection status were included. Patients with incomplete records, additional surgeries, or immunosuppression were excluded. Demographic data, comorbidities, surgical details, and postoperative outcomes were collected. Patients with and without surgical site infections were compared. Continuous variables were analyzed using Independent t-test or Mann-Whitney U test, and categorical variables using chi-square or Fisher's exact test. Statistical significance was set at $p<0.05$.

Results: In this study of 80 patients, the overall incidence of surgical site infection (SSI) was 23.7%. Univariate analyses identified smoking history ($p=0.004$), emergency surgery ($p=0.002$), and longer operative time ($p=0.005$) as significant factors associated with increased SSI risk. Additionally, a strong association was observed between skin closure method and infection development ($p<0.001$). Multivariate analysis demonstrated that operative time (OR: 1.066; $p=0.012$) and skin closure method (OR: 19.911; $p=0.002$) were independent risk factors for the development of SSI.

Conclusion: Surgical site infection after colostomy closure remains a common complication. Primary skin closure and prolonged operative time are key independent risk factors. Awareness of these factors may guide surgical planning and perioperative management to reduce SSI incidence and improve postoperative outcomes.

Keywords: Colostomy closure, surgical site infection, risk factors, surgical complications

Surgical management and pathological reclassification of non-parasitic cystic lesions of the liver: A single-center experience (2019-2025)

Alpen Yahya Gümüşoğlu, Anıl Karagöz, Hamit Ahmet Kabuli, Zehra Sibel Kahraman, Yasir Musa Kesgin, Hakan Yırgın, Ahmet Sürek

Department of General Surgery, University of Health Sciences Türkiye, Bakırköy Dr. Sadi Konuk Training and Research Hospital, İstanbul

Objective: Non-parasitic cystic lesions of the liver are pathologies that require careful surveillance and appropriate management due to their potential risk of malignancy. In this context, the data of patients who were operated on with a preliminary diagnosis of biliary cystadenoma at our institution were retrospectively analyzed.

Material and Methods: The surgical approaches performed between 2019 and 2025 and postoperative complications were evaluated. In addition, the pathological specimens of cases diagnosed with biliary cystadenoma were re-examined to confirm and clarify the diagnoses of mucinous cystic neoplasm (MCN) and biliary intraductal papillary neoplasm (IPNB)

Results: A total of 12 patients were operated on between 2019 and 2025. Nine patients (75%) were female and three (25%) were male, with a mean age of 53.5 years (range, 36-78 years). Regarding lesion localization, four patients had right lobe involvement and eight had left lobe involvement. Ten patients were primary cases, whereas two underwent surgery for recurrence. In terms of surgical approach, robotic surgery was performed in one patient, laparoscopic surgery in six patients, and open surgery in five patients. Final pathological evaluation revealed mucinous cystic neoplasm (MCN) in eight patients, intraductal papillary neoplasm of the bile duct (IPNB) in two patients, and simple cyst in two patients. One patient developed a postoperative intra-abdominal collection, which was successfully managed with percutaneous intervention. The mean follow-up duration was 57 months.

Conclusion: Non-parasitic cystic lesions of the liver should be carefully evaluated due to their potential for malignancy. A multidisciplinary approach is essential in the diagnostic and therapeutic process. With appropriate patient selection, minimally invasive surgical techniques can be applied safely and effectively.

The need for formal recognition of endocrine surgery as a subspecialty of general surgery in Türkiye

Lara Kavaşoğlu, Mehmet Eren Yüksel

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: General surgery has evolved over time into a discipline composed of focused areas of expertise. While structured fellowship programs and "focused practice" designations have been developed in the United States (USA), only surgical oncology, intensive care, and gastrointestinal surgery are currently recognized as formal subspecialties in Türkiye. Endocrine surgery, despite its high technical complexity and steadily increasing case volume, is not included among the general surgery subspecialty programs in Türkiye.

Material and Methods: The subspecialty system in Türkiye was compared with the training model defined by the American Medical Association FREIDA database (2024) and the American Board of Surgery. The number of accredited programs, training structure, and officially recognized fellowship areas were reviewed, with particular focus on endocrine surgery.

Results: In the USA, general surgery training is conducted as a five-year residency in 368 accredited programs, followed by structured fellowship programs in multiple focused fields. These include complex general surgical oncology, hepatopancreatobiliary surgery, colorectal surgery, minimally invasive surgery, pediatric surgery, vascular surgery, transplant surgery, surgical critical care, breast surgery, burn surgery, and hand surgery. Endocrine surgery is practiced as an independent field in high-volume centers, encompassing thyroid, parathyroid, adrenal, and neuroendocrine diseases. Surgeons who have received subspecialty training in this field have been shown to have lower complication rates and better functional outcomes. Endocrine surgery is an advanced field requiring detailed anatomical knowledge, nerve preservation, hormonal physiology, and the integration of oncologic principles. A strong association between high case volume and improved surgical outcomes has been demonstrated, supporting the value of focused training. However, there is currently no standardized subspecialty training program in endocrine surgery in Türkiye.

Conclusion: Formal recognition of endocrine surgery as a subspecialty of general surgery in Türkiye would provide standardization in training and enhance patient safety.

Keywords: Endocrine surgery, focused practice, general surgery, subspecialty training

Integration of robotic colorectal surgery into clinical practice: First year experience and early clinical outcomes

Fatih Türkoğlu, Sinan Şener, Hüseyin Yılmaz

Department of General Surgery, Selçuk University Faculty of Medicine Hospital, Konya

Objective: Robotic surgery (da Vinci Surgical System) offers advanced visualization and instrumentation advantages in colorectal resections. However, data regarding the early phase of integration of a robotic platform into an established surgical practice remain limited in the literature. This study aimed to evaluate the safety and early clinical outcomes of a robotic colorectal surgery program initiated at our center between December 2024 and December 2025.

Material and Methods: A total of 48 patients who underwent robotic colorectal surgery between December 2024 and December 2025 were retrospectively analyzed. Demographic characteristics, ASA score, type of operation, operative time, estimated blood loss, conversion rate (to open surgery), postoperative complications, and length of hospital stay were recorded. Major complications were defined as Clavien-Dindo grade ≥III. Continuous variables were analyzed using appropriate parametric or non-parametric tests, and categorical variables were compared using the chi-square test. A p-value <0.05 was considered statistically significant. All procedures were performed by the same experienced surgical team following standardized surgical principles.

Results: Among the 48 patients included in the study, 56.3% were male, and the median age was 61.5 years (range, 38-81). ASA ≥3 was present in 20.8% of patients. The most frequently performed procedures were anterior resection (n=20, 41.7%) and right hemicolectomy (n=16, 33.3%). The mean operative time was 213 minutes, and the median estimated blood loss was 120 mL. Conversion to open surgery occurred in 5 patients (10.4%). The overall complication rate was 18.8%, and the major complication rate was 6.2%. The anastomotic leak rate was 4.2%, and no mortality was observed. The median length of hospital stay was 7 days (range, 4-14). All oncologic resections achieved negative surgical margins (R0). Comparison between the early (first 24 cases) and late (last 24 cases) periods demonstrated a statistically significant reduction in operative time, blood loss, overall complication rate, and length of hospital stay (p<0.05).

Conclusion: The integration of robotic colorectal surgery into a tertiary referral center appears to be safe, with low mortality, acceptable complication rates, and conversion rates consistent with the literature during the first year of implementation. The observed improvements in clinical parameters suggest a structured learning curve. Although the retrospective design and limited sample size restrict generalizability, these findings support that robotic colorectal surgery can be effectively and sustainably integrated into clinical practice in the presence of an experienced surgical team and appropriate institutional organization.

Table 1. Learning curve analysis according to clinical parameters

Parameter	All cases	First 24 cases	Last 24 cases	p
Operative time, min (mean)	213.2	232.6	193.8	**<0.001**[a]
Blood loss, mL (median)	120.5	155.5	100.5	**<0.001**[b]
Length of hospital stay, days (median)	7.0	9.5	5.0	**<0.001**[b]
Conversion, n (%)	10.4	12.5	8.3	1.000[c]
Complications, n (%)	18.8	33.3	4.2	**0.023**[c]

Patients after cardiopulmonary resuscitation should be evaluated for organ donation: CPR is not a contraindication to organ transplantation!

Mehmet Eren Yüksel

Surgical Critical Care Unit, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: A substantial proportion of patients who achieve return of spontaneous circulation after cardiac arrest die due to irreversible hypoxic brain injury or progressive multiple organ failure. It was a widespread belief that patients who had undergone cardiopulmonary resuscitation (CPR) would not be suitable for organ donation. However, the 2025 Post-Resuscitation Care Guidelines of the European Resuscitation Council and the European Society of Intensive Care Medicine have stated that this belief is incorrect and recommend that patients after cardiac arrest should be evaluated for their potential as organ donors.

Material and Methods: In this study, recommendations regarding organ donation after cardiac arrest were reviewed on the basis of the 2025 Post-Resuscitation Care Guidelines of the European Resuscitation Council and the European Society of Intensive Care Medicine.

Results: The guideline clearly states that all patients who achieve return of spontaneous circulation after cardiopulmonary resuscitation should be assessed for organ donation. Numerous observational studies have shown that there is no significant difference in graft function or recipient survival between organs obtained from resuscitated donors and those obtained from non-resuscitated donors. This finding applies to all major solid organs, including the heart, lungs, liver, kidneys, pancreas, and small intestine.

Conclusion: The main barrier to organ donation after cardiac arrest is not a lack of medical evidence, but the insufficiently systematic evaluation of potential donors. The guideline defines organ donation as an integral component of post-cardiac arrest care. The fact that cardiopulmonary resuscitation has been performed is not, by itself, a determinant of donor suitability. Surgeons and intensivists working in surgical critical care units play an important role in the early identification of potential donors and timely notification of transplantation teams. Organ donation after cardiac arrest is an evidence-based practice that remains underutilized. The 2025 European Resuscitation Council and European Society of Intensive Care Medicine Post-Resuscitation Care Guidelines recommend that every patient who dies after successful cardiopulmonary resuscitation should be evaluated for organ donation. Evaluation of patients after CPR in surgical critical care units will increase the number of potential donors.

Multimodal risk assessment of thyroid malignancy in nodules with indeterminate cytology: Six years of research analysis

Esma Çınar[1], Demet Şengül[1], İlker Şengül[2]

[1]*Department of Pathology, Giresun University Faculty of Medicine, Giresun*

[2]*Thyroidology Unit, Division of Endocrine Surgery, Department of General Surgery, Giresun University Faculty of Medicine, Giresun*

Objective: Thyroid nodules are a common clinical finding, with prevalence rates ranging from 19% to 68% in the general population, largely due to the widespread use of high-resolution ultrasonography (US). While the vast majority of these nodules are benign, a significant proportion necessitate further evaluation to rule out malignancy. To evaluate the clinical, ultrasonographic, and elastographic parameters for risk stratification of malignancy in thyroid nodules with indeterminate cytology according to The Bethesda System for Reporting Thyroid Cytology (TBSRTC).

Material and Methods: This retrospective, single-center study analyzed 838 thyroid nodules from 716 consecutive patients for six years. The diagnostic performance of nodule size, Doppler US features, American Thyroid Association (ATA) risk of malignancy (ROM) guidelines, and Tsukuba elasticity scores (TES) via strain elastography (SE) was assessed. A multinomial logistic regression analysis was employed to compare indeterminate cytology (categories III, IV, and V) with benign cytology (category II) to identify independent predictors of malignancy.

Results: Nodules with ambiguous cytology exhibited larger mean diameters compared to benign nodules (20.83±9.89 mm vs. 18.65±9.08 mm; $p<0.05$), and significant associations were found between categories III, IV, and V and increased peripheral/central vascularization, high-risk ATA ROM classifications, and high TES (4 and 5). Histopathological malignancy rates were higher in the ambiguous groups ($p<0.05$); however, patient age and nodule localization did not show significant predictive value.

Conclusion: The integrated assessment of nodule size, Doppler vascularity, ATA risk stratification, and SE significantly enhances the predictive accuracy for malignancy in nodules with indeterminate cytology. Eventually, these multiparametric indices may provide essential guidance for optimizing surgical indications and clinical management in cases of diagnostic uncertainty.

Keywords: Thyroid gland, cytology, risk

Results and patient satisfaction of inguinal hernia repair in a teaching hospital

Kazım İncesoy, Edip Akpınar

Department of General Surgery, University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Inguinal hernia is one of the most common diseases in general surgery practice, affecting 2-4% of the population and with a lifetime risk of approximately 30% in men. Due to its high prevalence and the applicability of different surgical techniques (open and laparoscopic), not only recurrence and chronic pain but also long-term quality of life and patient satisfaction are important in evaluating the success of these elective procedures.

Material and Methods: Adult mesh inguinal hernia repairs (Lichtenstein, TEP, TAPP) performed at our tertiary training hospital between January 2020 and December 2023 were retrospectively analyzed. Patients were divided into four groups according to surgical technique (open/laparoscopic) and side (unilateral/bilateral). Postoperative outcomes (recurrence, chronic pain, quality of life) were compared. Statistical analyses were performed using R software.

Results: A total of 153 patients (mean age 55±14) were divided into four groups: Laparoscopic bilateral (LB, n=58), Open bilateral (AB, n=42), open unilateral (AU, n=33), and laparoscopic unilateral (LU, n=20). Follow-up was achieved in 139 patients (91%), while 9% were not followed up. The overall recurrence rate in the entire cohort was 10% (n=14), and the rate of chronic pain was 6% (n=8). Recurrence rates were 0% in the AB group, 15% in the AU group, 12% in the LB group, and 15% in the LU group. There was no statistically significant difference in recurrence rates between the surgical techniques (p=0.117). Similarly, there was no significant difference in the incidence of chronic pain (p=0.38). There were also no significant differences between the groups in terms of patient satisfaction and quality of life (p=0.12).

Conclusion: Inguinal hernia repairs performed at a tertiary teaching hospital resulted in good postoperative quality of life and similar recurrence and morbidity rates among the techniques. High patient satisfaction was noteworthy in open bilateral repair. The relatively high recurrence rates observed in the laparoscopic group require evaluation in larger series.

Keywords: Inguinal hernia, teaching hospital, recurrence

Table 1. Clinical outcomes and patient satisfaction by surgical technique

Group	N.	Reached	Recurrence	Chronic pain	Satisfaction	Quality of life
Open bilateral	37	37 (100%)	0 (0%)	1 (3%)	35 (95%)	9.3

Early mortality rate in laparoscopic sleeve gastrectomies: A single center review, this time we'll point the finger at ourselves

Ahmet Mücteba Öztürk[1], Ahmet Erim Erdoğan[2], Mehmet Yıldırım[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Bozyaka Training and Research Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

Objective: The increasing rate of worldwide obesity is considered one of the most challenging contemporary threats to public health. Over 50% of bariatric surgeries performed are laparoscopic sleeve gastrectomy (LSG) at worldwide. The remaining 30% are gastric bypass and metabolic surgeries. Laparoscopic sleeve gastrectomy remaining most chosen technique in bariatric surgical treatment because of cost effectivity rate, technical simplicity and remaining digestive system. According to IFSO data, the mortality rate after LGS varies between 0.18% and 0.27% depending on age, gender, and comorbidities.

Material and Methods: In our study, we examined the total number of laparoscopic sleeve gastrectomies performed at the Clinic of General Surgery, İzmir Bozyaka Training and Research Hospital, University of Health Sciences Türkiye.

Results: Our study revealed that a total of 680 patients performed laparoscopic sleeve gastrectomy. %88 of the patients were female and %12 were male. The age distribution of the cases ranged from 18 to 71. The average hospital recovery period for patients after surgery was 4 days. The postoperative mortality rate of our patients was 0.7% (5 patients). The cause of death in these patients was gastrointestinal perforation in 3 patients and sudden cardiac death in 2 patients.

Conclusion: The number of sleeve gastrectomy operations is directly proportional to the obesity rate in the population. While the postoperative mortality rate is 0.7% in our clinic, this rate may vary in more experienced centers. Patients existing comorbidities and age distribution affect postoperative mortality and morbidity rates. There is a need for multicenter studies on this subject in our country.

A portal vein branch identified in the gallbladder bed during laparoscopic cholecystectomy: A rare and high-risk case report

Furkan Güngör, Abdusselam Ağcakoyun, Ömer Faruk Özkan

Clinic of General Surgery, University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Portal vein anatomy and its variations are of clinical importance in hepatobiliary surgery. Although these variations are most commonly considered during hepatic resections and major liver surgeries, they may rarely pose a risk of serious vascular injury during laparoscopic cholecystectomy as well. In particular, portal vein branches coursing within the gallbladder bed may lead to difficult-to-control and potentially life-threatening hemorrhage if unrecognized. In this report, we present a case of a portal vein branch that was identified intraoperatively during laparoscopic cholecystectomy and required a modification of the surgical approach.

Results: A 52-year-old male patient presented to our outpatient clinic with complaints of biliary colic. Preoperative ultrasonography and computed tomography revealed a 9-mm gallstone. No variations related to portal vein anatomy were reported on preoperative imaging. An elective laparoscopic cholecystectomy was planned for the patient. Following standard trocar placement, adhesions between the gallbladder and the omentum were separated using sharp and blunt dissection. The cystic duct and cystic artery were carefully dissected, clipped, and divided. During dissection of the gallbladder from the liver bed, a vascular structure consistent with a portal vein branch, approximately 1 cm in diameter and 2 cm in length, was identified within the gallbladder bed, following an atypical anatomical course. Given the location and diameter of the identified vascular structure, it was considered that standard electrocautery dissection could result in severe and difficult-to-control hemorrhage. At this stage, the surgical strategy was revised intraoperatively; dissection was continued carefully and in a controlled manner without the use of energy devices, with preservation of the vascular structure. The portal vein branch was successfully preserved without injury, and the gallbladder was completely separated from the liver bed (Figure 1). No intraoperative bleeding was observed, and no additional surgical intervention was required. The gallbladder was removed in an endobag and sent for pathological examination. No postoperative complications such as bleeding or bile leakage were observed. The patient was discharged on postoperative day 1. No complications were noted during a six-month follow-up period.

Conclusion: This case demonstrates that portal vein variations may pose a risk of serious vascular injury not only during major hepatic surgeries but also during commonly performed procedures such as laparoscopic cholecystectomy. When unexpected vascular structures are encountered in the gallbladder bed, intraoperative awareness and appropriate modification of the dissection strategy are crucial for preventing major hemorrhage and ensuring safe surgery.

Laparoscopic surgical approach in acute cholecystitis: A single-center retrospective study

Batuhan Karaköse, Rona Cansu Kavar Ağcabay, Nami Ünal Polat, Erdinç Tekel, Nuri Emrah Göret, Cem Tuğmen

Department of General Surgery, Bakırçay University Çiğli Training and Research Hospital, İzmir

Objective: Acute cholecystitis is an acute inflammatory disease of the gallbladder, most commonly caused by gallstones. It occupies an important place among the causes of acute abdomen, and if not treated surgically in time, morbidity may increase. Nowadays, laparoscopic cholecystectomy has become the standard treatment approach for patients diagnosed early due to its feasibility in the early period, shorter hospital stay, and lower complication rates. This study aimed to evaluate demographic data, comorbidities, intraoperative findings, and postoperative outcomes in patients who underwent laparoscopic cholecystectomy for acute cholecystitis.

Material and Methods: Between February 2024 and January 2026, a total of 47 patients who underwent laparoscopic cholecystectomy with a diagnosis of acute cholecystitis in the Department of General Surgery, Bakırçay University Çiğli Training and Research Hospital, were retrospectively analyzed. The following data were recorded: age, sex, body mass index (BMI), comorbidities, previous surgical history, Parkland score, time from symptom onset to surgery, Tokyo classification of acute cholecystitis, intensive care unit (ICU) stay, development of complications, and postoperative length of hospital stay.

Results: Of the patients, 26 (55.3%) were female and 21 (44.7%) were male. The mean age was 60.8±15.4 years, and the mean BMI was 28.7±4.8 kg/m². The most common comorbidities were hypertension (40.4%), diabetes mellitus (23.4%), and cardiac disease (19.1%). Previous abdominal surgery was present in 46.8% of patients. Based on the Tokyo Classification, 18 patients were Grade 1 and 29 were Grade 2. The Parkland score was 2 in 3 patients, 3 in 19 patients, 4 in 10 patients, and 5 in 15 patients. The mean time from the onset of symptoms to surgery was 3.3 days. Postoperative respiratory complications occurred in only one patient (2.1%), and no surgical complications were observed. The mean postoperative hospital stay was 3.0±1.5 days.

Conclusion: Laparoscopic cholecystectomy in acute cholecystitis is a safe surgical method when appropriate patient selection is made, offering a low complication rate and shorter hospital stay. Although advanced age, high BMI, and comorbidities may increase surgical difficulty, they do not significantly raise complication rates.

Keywords: Acute cholecystitis, laparoscopic cholecystectomy, Parkland classification

[P-282]

Postoperative recurrence in intra-abdominal and retroperitoneal sarcomatosis: A ten-year retrospective analysis of 82 cases

Mahmut Kaan Demircioğlu[1], Pırıltı Özcan[2], Özgül Düzgün[3]

[1]*Clinic of Surgical Oncology, Denizli State Hospital, Denizli*

[2]*Clinic of General Surgery, Yerköy Şehit Korgeneral Osman Erbaş State Hospital, Yozgat*

[3]*Clinic of Surgical Oncology, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul*

Objective: Intra-abdominal and retroperitoneal soft tissue sarcomas are rare tumors characterized by aggressive biological behavior and high rates of local recurrence, necessitating close postoperative surveillance. The development of sarcomatosis represents an advanced stage of disease; however, data addressing long-term recurrence patterns and the impact of prior surgical interventions in this patient population remain limited. The aim of this study was to comprehensively evaluate histopathological subtype distribution, postoperative recurrence timing, and the effect of previous surgical history in patients undergoing surgery for intra-abdominal and retroperitoneal sarcomatosis.

Material and Methods: A total of 82 patients who underwent surgery for intra-abdominal and retroperitoneal sarcomatosis over a 10-year period were retrospectively analyzed. Histopathological diagnoses, history of previous sarcoma-related surgery at other institutions, postoperative recurrence, and time to recurrence were evaluated. Patients presenting with sarcomatosis as recurrence or disease progression following prior surgery were analyzed as a distinct subgroup.

Results: The histopathological distribution of the 82 patients was heterogeneous and consistent with the existing literature. The most common diagnosis was liposarcoma, observed in 41 patients (50.0%), followed by leiomyosarcoma in 18 patients (22.0%) and undifferentiated pleomorphic sarcoma in 11 patients (13.4%). Less frequent subtypes included solitary fibrous tumor in 5 patients (6.1%), malignant peripheral nerve sheath tumor in 4 patients (4.9%), and other high-grade sarcoma subtypes in 3 patients (3.6%). Postoperative recurrences occurred predominantly during the early and intermediate follow-up periods. The median time to recurrence was 16 months (IQR: 9-32 months). Overall, 62% of recurrences developed within the first 24 months, and 85% occurred within the first 60 months. Patients with a history of prior surgery at other institutions had a shorter median time to recurrence (12 months) compared with those whose primary surgery was performed at our center (22 months), indicating a significant impact of previous surgical interventions on recurrence patterns.

Conclusion: This study represents one of the largest single-center series detailing postoperative recurrence timing and histopathological distribution in patients with intra-abdominal and retroperitoneal sarcomatosis. The demonstrated association between prior surgical history and earlier recurrence constitutes a key original contribution of this analysis. Our findings underscore the importance of initial sarcoma surgery being planned and performed in experienced, high-volume centers using a multidisciplinary approach, as well as the need for intensive, long-term follow-up strategies focused on the early postoperative period in this high-risk patient population.

Keywords: Intra-abdominal sarcoma, retroperitoneal sarcoma, postoperative recurrence

[P-283]

The experience of four young general surgeons (experience <5 years) in colorectal malignancy surgery at the newly opened University of Health Sciences Türkiye, Antalya City Hospital: Is comprehensive and high-quality colorectal surgery possible with standard core training?

Alper Seydican Türker, Necla Reyhanlı, Aydın Dinçer, Hasan Özkan, Mehmet Ölçüm, Erdal Karagülle

Department of General Surgery, University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Colorectal cancer surgery is most often performed in high-volume tertiary centers by subspecialist surgeons. In addition to technical success, adherence to oncological surgical principles is of paramount importance. The aim of this study was to evaluate the experience of four young general surgeons, all graduates of the same training center and trained under the same core curriculum, who are currently working at the newly established University of Health Sciences Türkiye, Antalya City Hospital, and to assess the impact of standardized training on clinical practice in terms of surgical approach diversity and pathological quality criteria.

Material and Methods: This retrospective descriptive study included patients who underwent surgery for colorectal malignancy between March 2024 and December 2025 at the newly established tertiary-care University of Health Sciences Türkiye, Antalya City Hospital, University of Health Sciences Türkiye. Demographic data, emergency versus elective surgical status, surgical approach, and pathological outcomes were analyzed. All procedures were performed by four general surgeons who shared the same education.

Results: A total of 101 patients were included in the study. The mean age was 66.3±15.25 years (range: 31-91 years). Of the patients, 60.4% were male and 39.6% were female. Fifty-nine surgeries (57.8%) were performed electively, 42 (41.2%) were performed under emergency conditions. Tumor localization was as follows: right colon in 24 patients (23.7%), left colon in 8 (8%), transverse colon in 2 (2%), sigmoid colon in 17 (16.8%), and rectum in 50 patients (49.5%). Regarding surgical approach, 54 patients (52.9%) underwent open surgery, 22 (21.6%) laparoscopic surgery, and 26 (25.5%) robotic surgery. The overall rate of minimally invasive surgery was 47.1%. No positive surgical margins were detected pathologically. In 14 patients (13.8%), the number of harvested lymph nodes was fewer than 12, whereas adequate lymph node dissection with complete mesocolic excision was achieved in 86.2% of patients. These findings were consistent with the existing literature. Postoperatively, 8 patients (7.9%) died in the intensive care unit due to non-surgical causes; all patients had undergone emergency surgery. Three patients (3%) died due to postoperative surgical complications. These mortality rates were consistent with those reported in the literature.

Conclusion: Young general surgeons trained through a standardized and robust core curriculum are capable of performing colorectal cancer surgery in city hospital settings not only with technical proficiency but also in accordance with oncological principles and pathological quality standards. However, as not all residency training centers provide education at the same standard, the continuation of post-graduate training and the active involvement of the Turkish Surgical Association and the Turkish Society of Colorectal Surgery remain crucial.

Keywords: Colorectal cancer, core curriculum training, oncological surgical quality

Evaluation of colonoscopic polypectomy outcomes: University of Health Sciences Türkiye, Bağcılar Training and Research Hospital experience

Turan Pehlivan

Department of General Surgery, University of Health Sciences Türkiye, Bağcılar Training and Research Hospital, İstanbul

Objective: Polyps are defined as abnormal mucosal growths protruding into the lumen of the colon and rectum. Colonoscopy is considered the gold standard for both diagnosis and treatment of colorectal polyps. In addition, colonoscopic polypectomy is a fundamental method for preventing the development of colorectal cancer. We aimed to evaluate the endoscopic and histopathological characteristics of patients who underwent colonoscopic polypectomy.

Material and Methods: Between 2018 and 2024, a total of 10,927 lower gastrointestinal endoscopic examinations were performed in the endoscopy unit of the general surgery department. Among these, 2,364 patients (21.6%) who underwent colonoscopic polypectomy and 3,291 polyps were retrospectively analyzed. Demographic characteristics, polyp localization, number, size, histopathological type, degree of dysplasia, and malignancy rates were recorded.

Results: The male-to-female ratio was 1,488/876 and the median age was 58 years (range: 16-92). Polyps were detected in 3.291 locations during 2.364 procedures (cecum 177, ascending colon 370, transverse colon 385, descending colon 482, sigmoid colon 1.052, rectum 735). The sigmoid colon was the most frequent location. Polyps were found in a single location in 774 cases and in multiple locations in 1,590 cases. The median polyp size was 5 mm (range: 1-45). Histopathological evaluation revealed benign lesions in 1.370 polyps (41.7%), premalignant lesions in 1.745 polyps (53%), and malignant lesions in 176 polyps (5.3%). Dysplasia was low-grade in 316 polyps (9.5%) and high-grade in 340 polyps (10.3%). Malignant lesions were detected in 111 of 2.183 polyps (5.1%) in 1.488 male patients and in 65 of 1.108 polyps (5.9%) in 876 female patients.

Conclusion: Colonoscopic polypectomy, when performed in experienced centers, is a safe and effective method with a low complication risk for both the diagnosis and treatment of colorectal cancer. Given the high frequency of premalignant lesions, particularly in the sigmoid colon and rectum, rectosigmoidoscopic examination may be appropriate in screening programs. Larger studies are needed to better define the prevalence and prognosis of premalignant lesions.

Keywords: Polypectomy, colonoscopy, colorectal cancer

Impact of emergency and elective surgery on short-term clinical outcomes in right colon cancer: A single-center experience (2023-2026)

Ahmet Sürek[1], Murat Çikot[1], Turgut Dönmez[1], Ferman Tevfik Özyalvaç[1], Nurettin Şahin[1], Mahmut Said Değerli[1], Özden Canöz[1], Burak Suskun[2], Mücahit Berk Eliş[1], Özcan Düz[1]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, Bakırköy Dr. Sadi Konuk Training and Research Hospital, İstanbul*

[2]*Clinic of General Surgery, Esenyurt Necmi Kadıoğlu State Hospital, İstanbul*

Objective: In this study, we aimed to evaluate the impact of emergency surgery on short-term clinical outcomes in patients undergoing surgical resection for right colon cancer and to compare these outcomes with those of elective surgery.

Material and Methods: In this retrospective single-center study, 102 patients who underwent surgery for right colon cancer between 2023- 2026, were included. Patients were divided into two groups according to emergency (n=32) and elective surgery (n=70). The primary endpoint was defined as major morbidity (Clavien-Dindo ≥3). Secondary endpoints included 30-day mortality, anastomotic leakage, intensive care unit (ICU) requirement, and length of hospital stay. Continuous variables were expressed as median and analyzed using the Mann-Whitney U test, while categorical variables were analyzed using Fisher's exact test or the chi-square test.

Results: The groups were similar in terms of age (p=0.759).The rate of ASA ≥III was significantly higher in the emergency group (65.4% vs. 41.4%, p=0.042). No significant difference was detected between the groups regarding the Charlson comorbidity index (p=0.691). In the emergency group, preoperative CRP levels were significantly higher (44.05 vs. 6.15 mg/L, p<0.001), while albumin levels were significantly lower (3.46 vs. 4.18 g/dL, p=0.001). Regarding the surgical approach, 84.4% of patients in the emergency group underwent open surgery, whereas minimally invasive techniques were preferred in 77.1% of the elective group. The conversion rate was 60% in the emergency group and 11.1% in the elective group. Operative time was significantly longer in the elective group (197.5 vs. 150 minutes, p<0.001). Pathological staging showed a significant difference in T stage distribution between the groups (p<0.001); the T4 rate was 50% in the emergency group compared with 12.9% in the elective group. Although the N2 rate was higher in the emergency group (34.4% vs. 17.1%, p=0.074). There was no significant difference in the total number of retrieved lymph nodes between the groups [22 (16.8-34.2) in the emergency group vs. 20 (17.0-25.0) in the elective group, p=0.178]. The rate of major morbidity was significantly higher in the emergency group (21.9% vs. 1.4% ,p=0.001). Thirty-day mortality was also higher in the emergency group (18.8% vs. 2.9%,p=0.011). Anastomotic leakage was observed only in the emergency group (12.5% vs. 0%, p=0.008). Length of stay was significantly longer in the emergency group (8 vs. 6 days, p=0.041).

Conclusion: Emergency surgery in right colon cancer is associated with advanced T stage, higher rates of open surgery and conversion, and significantly increased major morbidity and mortality. Although the oncological quality of surgery is comparable, emergency presentation significantly worsens short-term clinical outcomes due to loss of physiological reserve and greater disease burden.

clinical outcomes.

Reduction of biopsy requirement with magnetic resonance imaging in breast cancer: A five-year clinical experience in high-risk women

Murat Kalın, Haluk Kerim Karakullukcu, Mina Karakullukcu, Nurper Denizoğlu, Gülçin Ercan

Department of General Surgery, University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: In women with familial risk of breast cancer, mammography and ultrasound (US) can yield indeterminate findings that prompt biopsy. Breast magnetic resonance imaging (MRI) may better characterize lesions, reduce avoidable procedures, and reveal malignancies occult on conventional imaging. To compare biopsy recommendations generated by mammography/US with those after breast MRI and to summarize a five-year single-center experience.

Material and Methods: We retrospectively reviewed 99 women with a positive family history who underwent breast MRI between January 2020 and January 2025 at a tertiary center. Familial risk was defined as breast cancer in a first-degree relative (mother and/or sister) and/or a second-degree maternal relative (maternal aunt). Imaging assessments from mammography and/or US were compared with subsequent MRI interpretations. A biopsy recommendation was considered indicated when the index lesion was categorized as BI-RADS 4-5 on the reporting modality (mammography, US, or MRI). The primary outcome was the change in biopsy recommendation after MRI (withdrawal or new indication). Secondary outcomes were pathology results and short-term safety of deferring biopsy.

Results: Overall, biopsy was recommended in 26/99 patients (26.3%). Sixteen patients had BI-RADS 4 findings on mammography and/or US prompting biopsy. After MRI, 10/16 (62.5%) were downgraded to BI-RADS 2-3 and biopsy was withdrawn; no malignancy was observed during a minimum 12-month follow-up using clinical assessment plus interval imaging (US and/or mammography). The remaining 6/16 (37.5%) continued to meet BI-RADS 4-5 criteria and underwent biopsy; all pathology results were benign. Among patients without a biopsy indication on mammography/US, MRI alone prompted biopsy in 10/99 (10.1%). Seven underwent biopsy: 5 benign and 2 malignant. Biopsy was not performed in 3 patients and follow-up data were unavailable; these cases were treated as missing and excluded from outcome assessment.

Conclusion: In women with familial risk, adding breast MRI to mammography and US reduced biopsy recommendations by downgrading many BI-RADS 4 findings with reassuring follow-up, while also detecting malignancy in a subset not identified by conventional imaging. MRI appears to be a useful problem-solving adjunct within guideline-based screening pathways for this population.

[P-287]

Is non-surgical treatment of breast cancer possible

Ali Şahin

University of Health Sciences Türkiye, Sancaktepe Şehit Prof. Dr. İlhan Varank Training and Research Hospital, İstanbul

Objective: Breast cancer, once considered untreatable, has evolved into an era where the necessity of surgery is being questioned. Thanks to molecular advancements, cancer subtypes can be defined on a receptor basis, allowing for the development of disease-specific, targeted treatment strategies. With increased experience and advancements in imaging technologies, early diagnosis rates are rising. In light of these developments, the opportunity has arisen to answer the question: Is non-surgical breast cancer treatment possible?

Material and Methods: Studies published in the PubMed database between 2017-2025, which reported the accuracy of pathologic response via minimal invasive biopsy prior to surgery after neoadjuvant therapy, were screened. Keywords used included "Neoadjuvant therapy", "pathologic complete response", "vacuum-assisted biopsy", "core needle biopsy", and "surgery omission". Prospective, retrospective comparative, feasibility, and accuracy studies were included, while case reports and studies with insufficient methodology were excluded. Literature findings were synthesized to evaluate the efficacy of biopsy-based surgery omission strategies.

Results: Breast cancer is classified into four subtypes: Luminal A, Luminal B, HER2+, and Triple Negative, which show significant differences in treatment response and prognosis. Current neoadjuvant chemotherapy and radiotherapy applications have increased clinical complete remission rates, reaching up to 60% specifically in HER2+ and triple-negative patients. However, reliably ruling out residual tumor after neoadjuvant therapy remains challenging; while the sensitivity and specificity of imaging methods vary (Table 1), some studies have shown that results can be improved with artificial intelligence. Regarding axillary management, the AMAROS trial (2001-2010, n=4806) compared 1425 cN+ patients and found 5-year axillary recurrence rates of 0.43% in the axillary lymph node dissection (ALND) group and 1.19% in the radiotherapy (RT) group. Disease-free survival was 86.9% and 82.7%, respectively, while overall survival was 81.4% and 84.6%. In detecting breast pathologic complete response (pCR), the false-negative rate of invasive biopsies ranges from 0% to 49% depending on factors such as needle size and technique (VAB, CNB). A review of studies over the years indicates that pCR rates are progressing positively (Table 2).

Conclusion: Avoidance of surgery cannot yet enter routine practice; prospective studies should be awaited. The crucial point is to prove the accuracy of pathologic complete response via non-surgical methods. Current methods lack sufficient sensitivity and specificity to select patients with pathologic complete response. While moving away from breast cancer surgeries is an inevitable trend, higher quality clinical studies are required. Treatment algorithms will be reshaped in the future with the results of AI and multi-center studies.

Keywords: Non-operative management of breast cancer

Table 1. Sensitivity and specificity of imaging methods

	Sensitivity (%)	Specificity (%)
Mammography (3)	81	48
Diffusion-weighted MRI (4)	93	82
USG (5)	90	80
PET-CT (6)	84	71

Table 2. Pathologic complete response (pCR) rates by subtype

	Multi-center	TR (7)
Luminal A	10-15%	8.7%
Luminal B	15-30%	10.8%
Luminal B HER2 +	30-55%	42.4%
HER2+ HR-	50%+	54.5%
Triple negative	30-60%	46.7%

[P-288]

Bilateral breast cancer: A single-center experience

Kübra Ergin Karabalık, Firdevs Melike Onuktav, Gülay Özbölük, Ebru Şen

Clinic of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam ve Sakura City Hospital, İstanbul

Objective: Bilateral breast cancer is a rare disease entity that presents diagnostic and therapeutic challenges due to its clinical and pathological heterogeneity. Tumors may develop in both breasts either synchronously or at different time points, necessitating individualized surgical approaches and adjuvant treatment planning. The aim of this study was to evaluate the clinicopathological characteristics and treatment approaches of patients diagnosed with bilateral breast cancer.

Material and Methods: In this retrospective study, patients diagnosed with metachronous bilateral breast cancer at our center between 2021 and 2026 were analyzed. Demographic characteristics, tumor localization, histological and molecular subtypes, surgical procedures, and adjuvant treatments were evaluated using patient medical records and electronic databases.

Results: A total of 21 patients were included in the study. The median age of the patients was 47 years (range: 39-78). The mean follow-up period was 29.4 months (range: 2.1-61.2). Histopathological evaluation revealed mixed invasive lobular and invasive ductal carcinoma in 2 patients (9.5%), while invasive ductal carcinoma was present in 19 patients (90.5%). Bilateral luminal-type tumors were observed in 16 patients (76.2%), whereas 5 patients (23.8%) had luminal-type breast cancer in one breast and hormone receptor-positive, HER2-positive breast cancer in the contralateral breast. Breast-conserving surgery was performed in 10 patients (47.6%), while mastectomy was performed in 11 patients (52.4%). Pathological staging revealed advanced-stage disease in both tumors in 1 patient (4.8%), whereas all remaining patients were diagnosed at an early stage. In 3 patients (14.3%), the second tumor was identified as carcinoma *in situ*. During the follow-up period, no local recurrence or distant metastasis was observed.

Conclusion: In this single-center experience, the prognosis of patients with metachronous bilateral breast cancer was found to be comparable to that of patients with unilateral breast cancer. Although the literature reports a higher incidence of invasive lobular carcinoma in bilateral breast cancer, invasive lobular carcinoma was observed only in patients with mixed histopathological subtype in our series. Despite the relatively short follow-up period, favorable clinical outcomes were observed, likely attributable to the fact that the majority of patients were diagnosed at an early stage. Accordingly, breast-conserving surgery was feasible in nearly half of the patients. These findings suggest that appropriate patient selection and individualized treatment strategies may play a decisive role in the prognosis of metachronous bilateral breast cancer.

Keywords: Bilateral breast cancer, metachronous breast cancer, breast-conserving surgery

Imaging-guided localization of non-palpable early-stage breast cancer and its surgical and oncological outcomes: A single-center registry study

Osman Sezer, Haeun Lee, Mine Özşen, Volkan Polatkan, Şehsuvar Gökgöz, Kazım Şenol

Department of General Surgery, Bursa Uludağ University Faculty of Medicine, Bursa

Objective: With the widespread use of screening programs and neoadjuvant therapies, non-palpable breast cancers are encountered more frequently in clinical practice. In these patients, preoperative localization is of great importance in terms of achieving complete tumor excision, reducing the need for re-surgery, and preserving cosmetic results.

Material and Methods: This retrospective registry analysis included 67 patients with non-palpable breast cancer at Tis-T1N0M0 stage who underwent breast-conserving surgery with image-guided localization between 2015 and 2024. Complete data on surgical outcomes were available for 50 patients. Demographic characteristics, tumor characteristics, and oncological outcomes were evaluated using descriptive statistical methods.

Results: The mean age of the patients was 55.2±10.1 years. The mean diameter of the largest tumor was 13.9±4.5 mm, consistent with early-stage disease. Three patients (6%) required re-excision after the first surgery. A second re-excision was performed in two patients (4%). During follow-up, local recurrence was observed in one patient (2%), regional recurrence in one patient (2%), and systemic recurrence in two patients (4%). Disease-related mortality occurred in one patient (2%).

Conclusion: In non-palpable early-stage breast cancer, imaging-guided localization appears to be a safe and effective approach with low re-excision rates and favorable oncological outcomes. Larger multicenter studies are needed to evaluate the impact of different localization techniques on long-term outcomes.

Is the stage at diagnosis advanced in patients under 40 years of age with breast cancer?: A single-center experience

Zeynep Taşkın, Beyza Sümeyya Budak, Mehmet Alperen Uğur

Department of General Surgery and Organ Transplantation, University of Health Sciences Türkiye, İzmir City Hospital, İzmir

Objective: Breast cancer occurring at a young age represents a distinct clinical subgroup due to its more aggressive biological characteristics and exclusion from routine screening programs. This study aimed to evaluate the clinical stage distribution at diagnosis in patients under 40 years of age with breast cancer and to compare the proportion of advanced-stage disease (Stage III-IV) with population-based literature data.

Material and Methods: In this single-center retrospective study, 62 patients under the age of 40 diagnosed with invasive breast cancer and evaluated at the multidisciplinary breast tumor board in 2025 were analyzed. Clinical stages were reclassified according to the AJCC 8th edition, and Stage III-IV disease was defined as "advanced stage." The observed proportion of advanced-stage disease was compared with rates reported in national and international population-based studies using a one-sample proportion test.

Results: Among the 62 patients, 11 (17.7%; 95% CI: 10.2-29.0%) were diagnosed with advanced-stage disease. The rate of metastatic disease at presentation was 4.8%. The observed advanced-stage proportion did not differ significantly from the approximately 15-20% rates reported in the Turkish National Breast Cancer Registry Program and SEER data (p=0.64).

Conclusion: In this single-center young-age cohort, the proportion of advanced-stage disease was comparable to population-based data. Despite the well-documented increased biological aggressiveness of breast cancer in younger patients, the stage distribution did not demonstrate a marked deviation from that of the general population. Larger, multicenter studies are warranted.

Keywords: Breast cancer, early-onset, staging

Clinical characteristics and surgical outcomes of hypercalcemic patients aged 65 years and older with primary hyperparathyroidism

Ayşe Zülfinaz Aygün, Arzu Akan, Uğur Kesici, Naciye Kış, Orhan Yalçın

Clinic of General Surgery, University of Health Sciences Türkiye, İstanbul Prof. Dr. Cemil Taşcıoğlu City Hospital, İstanbul

Objective: Primary hyperparathyroidism represents the leading cause of hypercalcemia. Although hypercalcemia is frequently asymptomatic across age groups, elders tend to present with atypical and non-specific manifestations, which may contribute to delayed diagnosis. This study aimed to characterize the clinical presentation and therapeutic outcomes of patients aged ≥65 years with hypercalcemia and to evaluate the necessity and effectiveness of surgical management in this population.

Material and Methods: Patients diagnosed with hyperparathyroidism, either referred from internal medicine/endocrinology clinic or consult to general surgery clinic between September 2022-2025 were retrospectively evaluated. Demographics, laboratory data, imaging modalities, and treatments were systematically reviewed. All patients underwent neck ultrasonography and parathyroid scintigraphy; 4D computed tomography (4D-CT) was employed when initial imaging failed to localize a parathyroid lesion.

Results: Among 165 patients diagnosed with hyperparathyroidism and hypercalcemia, 22 (13.3%) were ≥65 years of age. The cohort consisted of 15 women (68.1%) and 7 men (31.8%), with a mean age of 70.5 years; while female patients demonstrated a slightly higher mean age (71.5 years). Hypercalcemia was incidentally detected in laboratory tests in 7 patients (31.8%). Musculoskeletal complaints were reported by 8 patients (36.3%), whereas hypertension and cognitive dysfunction each constituted the presenting symptom in 3 patients (13.6%). One patient (4.5%) was diagnosed with nephrolithiasis. All patients with confirmed biochemical hyperparathyroidism underwent minimally invasive parathyroidectomy. In 8 cases, the addition of 4D-CT facilitated precise localization and optimized the surgical approach. A double adenoma was identified in one patient via 4D-CT. A 53-year-old male patient with primary hyperparathyroidism in whom a parathyroid adenoma could not be identified by ultrasonography or scintigraphic imaging; however, the lesion was successfully diagnosed and localized using four-dimensional computed tomography (4D CT).

Conclusion: Primary hyperparathyroidism in elderly patients most commonly arises from parathyroid adenoma, lesser hyperplasia, or, least frequently, parathyroid carcinoma. Given the potential multisystem involvement of hypercalcemia in this age group, timely intervention is imperative. Surgical treatment should be prioritized in patients who do not respond adequately to medical therapy. Considering the higher prevalence of comorbid conditions in the elderly, accurate preoperative localization is crucial to minimize operative time and reduce perioperative morbidity. Focused minimally invasive parathyroidectomy represents an optimal first-line strategy, offering shorter operative duration and lower complication rates.

Evaluation of clinical, pathological, and genetic findings in medullary thyroid carcinoma: A single-center experience

Muhammed Metin Yüksel[1], Faruk Yazıcı[2], Muhammed Salih Süer[1], Serkan Demir[1], Şener Balas[1], Melih Akıncı[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Medullary thyroid carcinoma (MTC) holds a distinctive position among thyroid malignancies due to its aggressive biological behavior, potential for early lymph node metastasis, monitorability via biochemical markers, and strong association with familial/genetic syndromes. The extent of surgical treatment, neck dissection strategies, and the genetic evaluation process are fundamental factors directly impacting prognosis. This study aims to provide a detailed evaluation of the demographic, clinical, genetic, surgical, and pathological characteristics of MTC patients surgically treated at University of Health Sciences Türkiye, Ankara Etlik City Hospital, Department of General Surgery; to present short-term follow-up outcomes, and to emphasize the role of institutional experience in MTC management.

Material and Methods: In this retrospective observational study, seven patients operated on with a diagnosis of MTC were analyzed. Parameters including age, sex, ASA score, familial MTC/MEN history, presence of MEN syndrome, RET mutation status, preoperative calcitonin and CEA levels, surgical procedures performed, pathological findings, and follow-up data were recorded. Continuous variables were presented as mean ± standard deviation or median (minimum–maximum), and categorical variables were expressed as frequencies and percentages.

Results: All patients were female, with a mean age of 40.4±6.9 years. Most patients were ASA II (71.4%). A family history of MTC/MEN was present in 28.6%, and RET mutation was positive in 28.6%. One patient (14.3%) had MEN 2A syndrome (Table 1). Preoperative biochemical assessment revealed a median calcitonin level of 585 pg/mL (120-2000 pg/mL) and a median CEA level of 18 ng/mL (4-65 ng/mL). All patients underwent total thyroidectomy and central neck dissection; 42.9% required lateral neck dissection (Table 2). Mean tumor diameter was 2.1±0.7 cm. Multicentricity and extrathyroidal extension rates were both 28.6%. Lymph node metastasis was identified in 42.9% of cases. Over a median follow-up of 17 months (4-41 months), no recurrence or mortality was observed (Table 3).

Conclusion: Despite its low incidence, MTC is a malignancy that requires high clinical vigilance during surgical planning and follow-up. Given the high rates of lymph node metastasis and recurrence risk reported in the literature, the complete implementation of standard surgical approaches and multidisciplinary evaluation in our series resulted in zero short-term recurrence and mortality. Our findings support that early diagnosis, genetic screening, and appropriate neck dissection strategies are decisive factors for prognosis, underscoring the importance of institutional experience and structured surgical approaches in this rare tumor group (Table 4).

Our results of parathyroid surgery: A single-center experience (2020-2025)

Atalay Altınkaynak, İbrahim Ahmet Özdal, Furkan Yağmur, Deniz Can Irmak, Kerem Talha Düz, Fırat Çağlar Sezmiş, Nail Can Adıgüzel, Şevki Furkan Demirer, Koray Şen, Gizem Duran, Mehmet Karahan, Yasin Tosun, Yunus Emre Altuntaş, Hasan Fehmi Küçük

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Hyperparathyroidism is characterized by elevated parathyroid hormone (PTH) levels and impaired calcium metabolism. The most common etiological factor is parathyroid adenoma, while parathyroid hyperplasia and, rarely, parathyroid carcinoma may also be responsible. Surgical treatment provides definitive management in appropriate patients. Preoperative imaging plays a critical role in localizing pathological glands and improving surgical success.

Material and Methods: A total of 265 patients who underwent surgery for hyperparathyroidism, hypercalcemia, or parathyroid adenoma at University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital between January 2020 and June 2025 were retrospectively analyzed. Demographic characteristics, imaging modalities, surgical techniques, preoperative and postoperative PTH and calcium levels, and pathological findings were evaluated. Ultrasonography and scintigraphy were used for preoperative localization in all patients.

Results: Of the patients, 75 (28.3%) were male and 190 (71.7%) were female, with a mean age of 46 years. Chronic kidney disease was present in 71 patients, and 14 patients had a history of renal transplantation. The mean preoperative PTH level decreased from 623 pg/mL to 68.7 pg/mL postoperatively. Mean serum calcium levels decreased from 10.88 mg/dL preoperatively to 8.78 mg/dL postoperatively. The most common localization was the left inferior parathyroid gland, and the mean lesion size was 1.93 cm. Subtotal (3.5-gland) parathyroidectomy with autotransplantation was performed in 38 patients. Pathological examination revealed parathyroid adenoma in 190 patients, parathyroid hyperplasia in 58 patients, and normal parathyroid tissue/thymus in 17 patients. Parathyroid carcinoma was detected in three patients, and parathyromatosis in one patient.

Conclusion: Parathyroid surgery is a safe and effective treatment for hyperparathyroidism. The combined use of ultrasonography and scintigraphy provides accurate preoperative localization. In our series, parathyroid adenoma was the most common pathology, and significant reductions in PTH and calcium levels were observed after surgery. Our findings support the effectiveness of surgical management in hyperparathyroidism.

Clinical significance of prognostic nutritional and inflammatory indices in patients undergoing the Whipple procedure: Analysis of PNI, AGR, and CAR

Evren Peker, Hilmi Bozkurt, Hakan Canbaz

Department of General Surgery, Mersin University Faculty of Medicine, Mersin

Objective: The aim of this study was to evaluate the relationship between inflammation- and nutrition-based indices, including the prognostic nutritional index (PNI), albumin-globulin ratio (AGR), and C-reactive protein-albumin ratio (CAR), and the clinical and pathological characteristics of patients undergoing pancreaticoduodenectomy (Whipple procedure).

Material and Methods: This retrospective study included 89 patients who underwent the Whipple procedure at the Department of General Surgery, Mersin University Faculty of Medicine, within the last five years. Demographic data, pathological diagnoses, tumor stages, and preoperative laboratory parameters were recorded. PNI was calculated using the formula 10× albumin (g/dL) + 0.005× total lymphocyte count; AGR as albumin/(total protein-albumin); and CAR as CRP/albumin. Patients with available pathological stage information were considered to have adenocarcinoma. The associations between these indices and age groups, pathological diagnosis, and tumor stage were analyzed.

Results: The mean age of the patients was 62.9±11.9 years. Seventy patients (78.7%) were diagnosed with adenocarcinoma. Patients with adenocarcinoma had lower PNI values and higher CAR values compared to patients with other pathologies. In patients aged ≥70 years, PNI and AGR values were markedly lower, while CAR values were significantly higher.As pathological stage advanced, PNI values decreased and CAR values increased. Although AGR values were similar between adenocarcinoma and non-adenocarcinoma groups, a decreasing trend was observed in the elderly population. Low PNI and high CAR values were more pronounced in patients with advanced-stage disease, suggesting that increasing inflammatory burden adversely affects nutritional and immune status.

Conclusion: PNI, AGR, and CAR values were found to be associated with clinical and pathological characteristics in patients undergoing the Whipple procedure. Low PNI and high CAR, in particular, appear to be important indicators reflecting advanced disease burden and increased systemic inflammation. AGR may serve as a supportive parameter reflecting the patient's overall inflammatory and nutritional status rather than tumor biology. Incorporation of these indices into preoperative assessment may contribute to improved risk stratification and surgical management.

Keywords: Whipple procedure, PNI, CAR, AGR, pancreatic cancer, prognostic indices

Table 1. PNI, CAR, and AGR values according to pathological stage

Pathological stage	Number of patients (n)	PNI (mean ± SD)	CAR (mean ± SD)	AGR (mean ± SD)
Stage 1a	11	31.9±4.8	33.3±28.1	1.25±0.36
Stage 1b	13	33.0±5.1	24.7±23.0	1.29±0.47
Stage 2a	3	25.0±2.8	35.5±24.3	0.97±0.32
Stage 2b	26	33.4±5.5	23.3±19.7	1.36±0.38
Stage 3	13	35.8±7.5	24.2±22.0	1.22±0.42

Clinicopathological features and surgical outcomes of incidental and non-incidental gallbladder adenocarcinoma: A retrospective study

Mehmet Özer[1], Serdar Gökay Terzioğlu[1], Kübra Bilge Polat[1], Murat Özgür Kılıç[2]

[1]*University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara*

[2]*Eskişehir City Hospital, Eskişehir*

Objective: Gallbladder adenocarcinoma (GBC) is a rare malignancy with aggressive biological behavior and poor prognosis. Due to the absence of disease-specific clinical symptoms and the limited diagnostic sensitivity of radiological imaging, a substantial proportion of cases are diagnosed incidentally during histopathological examination of cholecystectomy specimens. Early diagnosis remains challenging, and surgical resection is the only potentially curative treatment option. This study aimed to evaluate the clinicopathological characteristics, diagnostic findings, and surgical management of patients with GBC, with particular emphasis on differences between incidental and non-incidental cases.

Material and Methods: This retrospective study included 48 patients diagnosed with GBC between 2015 and 2025 in Ankara Bilkent City Hospital. Patients were classified according to the mode of diagnosis as incidental GBC (n=28) and non-incidental GBC (n=20). Demographic data, clinical presentation, radiological findings, operative procedures, tumor localization, and pathological staging were recorded. Tumor staging was assessed according to the AJCC 8th edition. Comparative analyses were performed to identify differences in disease presentation and tumor stage between the two groups.

Results: The study cohort consisted of 32 women (66.7%) and 16 men (33.3%), with a mean age of 65.9 years. More than half of the patients were older than 65 years at diagnosis. Most patients presented with non-specific symptoms, and gallstones were present in 40 cases. Cholecystectomy alone was oncologically sufficient in 12 patients (25%), whereas additional hepatic resection was required in 25 patients (52.1%). Tumors were most frequently located in the fundus (27.1%), while multifocal or diffuse involvement was observed in 22.9% of patients. In the incidental GBC group, 81.4% of patients had early-stage tumors (T1-T2). In contrast, 85% of patients in the non-incidental GBC group, including inoperable cases, had advanced-stage disease (T3-T4).

Conclusion: GBC is frequently diagnosed incidentally due to the lack of specific clinical and radiological findings. Non-incidental cases are more commonly associated with advanced tumor stage and multifocal involvement. Careful preoperative evaluation is therefore essential for optimal surgical planning. Adequate surgical resection remains the only potentially curative treatment

[P-296]

Comparison of the peritoneal cancer index, the morphological stage of the tumor, and cytology results detected by staging laparoscopy in gastric cancer, with the results after neoadjuvant chemotherapy and postoperative pathology results: A single-center experience with 89 patients

Ömer Faruk Kandaz, Muhammet İkbal Akın, Canberk Toy, Mustafa Duman, Ahmet Orhan Sunar

Department of Gastrointestinal Surgery, University of Health Sciences Türkiye, Koşuyolu High Specilization Training and Research Hospital, İstanbul

Objective: Staging laparoscopy performed before neoadjuvant chemotherapy (CT) in gastric cancer;plays an important role in assessing peritoneal spread of the tumor, determining whether the tumor is T4, whether it has invaded the serosa, and enabling cytology work, thereby facilitating the detection of free tumor cells. This helps guide initial treatment and provides insight into the course of the disease. So, how much and how do these data change in patients after CT? Our study aimed to compare the PCI score determined before neoadjuvant CT, the morphological status of the tumor, and cytological data with the findings and pathologies after surgery following CT.

Material and Methods: Patients diagnosed with gastric adenocarcinoma at our center who require neoadjuvant CT are routinely evaluated with staging laparoscopy. In our study, patients scheduled for neoadjuvant CT and undergoing staging laparoscopy between January 1, 2022, and January 1, 2026, were retrospectively evaluated. During pre-CT laparoscopy, the PCI score was calculated, serosal invasion of the tumor was assessed, and peritoneal lavage cytology was obtained. Following neoadjuvant CT, patients were re-evaluated during surgery or repeat laparoscopy, and findings before and after CT were analyzed comparatively.

Results: In the pre-CT assessment, cytology positivity was detected in a certain proportion of patients, along with serosalinvasion and varying levels of PCI scores. In the evaluation performed after neoadjuvant CT, cytology negativity, regression of serosalinvasion, and changes in PCI scores were observed in a group of patients. However, it was noted that peritoneal disease persisted in another groupof patients. Overall, variable responses in peritoneal tumor burden were observed after CT. In conclusion, neoadjuvant CT may improve the response rate to subsequent treatment in patients with peritoneal metastasis.

Conclusion: Laparoscopic staging is becoming increasingly important in the management of patients diagnosed with gastric cancer. Peritoneal cytology after neoadjuvant CT may reveal changes in tumor serosal invasion and PCI scores. Our study specifically seeks to answer the question of what should be expected from neoadjuvant therapy at which point and in which patient group. The question of what these changes in PCI, cytology, and serosal invasion following neoadjuvant therapy correspond to in the final surgical pathology of patients remains relevant and requires further detailed evaluation.

Early feeding management after surgery and the role of the nurse: An integrative review

Emine Bayat, Ayça Elmaderesi Aydın, Onur Turhan

Hacettepe University Adult Hospital, Ankara

Objective: Surgical interventions lead to a distinct metabolic stress response characterized by hypermetabolism and increased protein breakdown in the organism. Malnutrition that may develop during this physiological process is associated with clinically important outcomes such as delayed wound healing, increased risk of infection, and prolonged length of hospital stay in surgical patients. Enhanced recovery after surgery (ERAS) protocols developed in recent years recommend the initiation of early feeding within the first 24 hours after surgery in order to reduce the aforementioned adverse effects.

Material and Methods: In this review, it is aimed to present current evidence regarding post-operative early feeding practices, ESPEN (European Society for Clinical Nutrition and Metabolism) guidelines, and nursing interventions. Accordingly, the study was planned and conducted using the integrative review method. The literature search was performed in PubMed, ScienceDirect, and Google Scholar databases using the keywords “early feeding”, “nursing care”, “malnutrition”, “ERAS”, and “surgical”. No restriction was made in terms of study type; a total of 26 studies published between 2015-2025, with full text access, in English and Turkish were included in the review. The examined publications consist of systematic reviews, multicenter randomized controlled trials, observational data analyses, and meta-analyses.

Results: In the vast majority of the studies examined, it has been reported that post-operative early oral or enteral feeding is safe and does not increase the risk of anastomotic leakage. Furthermore, it is stated that early feeding ensures the onset of bowel motility (gas and stool passage) in an earlier period. Studies show that early feeding practices significantly reduce the length of hospital stay and health care costs; moreover, they provide positive effects on immune functions. Nurses have basic responsibilities within the multidisciplinary health team such as assessing nutritional risk with screening tools like NRS-2002, monitoring gastrointestinal tolerance (nausea, vomiting), maintaining enteral feeding tube care, and implementing interventions to prevent aspiration. However, in some studies, it is emphasized that nurses still maintain traditional long-term fasting approaches and that the need for education regarding current evidence-based protocols continues.

Conclusion: Early feeding in the post-operative period is an effective care approach supported by strong scientific evidence that reduces morbidity and improves patient outcomes. Increasing nurses’ knowledge and awareness levels regarding early feeding will play an important role in enhancing the quality of care by contributing to the effective transfer of evidence-based protocols into clinical practice.

Keywords: Early feeding, ERAS, nursing care

[P-298]

The effect of early enteral nutrition on clinical outcomes in surgical intensive care patients: An integrative review

Necla Bozkurt

Hacettepe University, Adult Hospital, Ankara

Objective: In surgical intensive care units (SICUs), inadequate nutritional support is associated with increased morbidity, prolonged hospitalization, infectious complications, and impaired wound healing. Early enteral nutrition (EEN), initiated within the first 24-48 hours of intensive care admission, has been recommended to preserve gut integrity, modulate immune response, and improve clinical outcomes. Despite growing evidence supporting early enteral feeding in critically ill patients, the effects of EEN specifically in surgical intensive care populations remain inconsistent across studies. This integrative review aimed to evaluate the effects of EEN on clinical outcomes in surgical intensive care patients.

Material and Methods: An integrative review methodology was used. A comprehensive literature search was conducted in PubMed, ScienceDirect, CINAHL, and Google Scholar databases using the keywords "EEN," "SICU", "critically ill patients," and "clinical outcomes." Studies published between 2005 and 2025, available in full text, and written in English or Turkish were included without restriction on study design. A total of 10 studies meeting the inclusion criteria were analyzed, including systematic reviews, meta-analyses, and clinical studies focusing on surgical intensive care populations.

Results: The reviewed studies demonstrated that EEN in surgical intensive care patients was associated with reduced infectious complications, shorter intensive care unit and hospital length of stay, and improved nutritional adequacy. Several studies reported a decrease in postoperative pulmonary complications and mortality rates among patients receiving EEN compared to delayed feeding. Additionally, EEN was shown to be well tolerated, with no significant increase in gastrointestinal intolerance or aspiration risk when appropriate patient selection and monitoring were applied. Most studies emphasized the importance of standardized feeding protocols and multidisciplinary collaboration to optimize

Conclusion: This integrative review indicates that EEN positively affects clinical outcomes in surgical intensive care patients. Initiating enteral feeding within the early phase of intensive care may reduce complications and support recovery. Nurse-led nutritional assessment and protocol-driven enteral feeding practices play a critical role in the successful implementation of EEN. Further randomized controlled studies focusing specifically on surgical intensive care populations are needed to strengthen the existing evidence.

Keywords: Early enteral nutrition, surgical intensive care unit, critically ill patients, clinical outcomes, nursing care

"More than a superficial finding? The relationship between seat belt injury and severe intra-abdominal trauma"

Ünal Yağmur, Sena Özgül, Serkan Demir, Bahattin Bayar, Alper Yavuz, Muhammed Salih Süer

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Seat belt injury is an important clinical finding that may be associated with serious intra-abdominal injuries following blunt abdominal trauma. The aim of this study was to evaluate the clinical, radiological, and surgical characteristics of patients with seat belt injury and to assess the clinical course in this patient group.

Material and Methods: This study was conducted through a retrospective review of patients followed with a diagnosis of seat belt injury at the University of Health Sciences Türkiye, Ankara Etlik City Hospital General Surgery Clinic. Demographic data, clinical and laboratory findings at presentation, imaging results, need for surgical intervention, and clinical outcomes were evaluated based on patient medical records. The study was descriptive in nature, and no statistical comparisons were performed.

Results: A total of two patients with seat belt injury were included in the study. The median age was 71 years (IQR:68-74), and the sex distribution was equal; all patients were passengers in the vehicle. Although they were hemodynamically stable at presentation, admission lactate levels were markedly elevated (median 8.25 mmol/L; IQR:7.98-8.53), and free intraperitoneal fluid was detected in all cases. Imaging findings supported suspicion of intra-abdominal injury, with mesenteric injury and bowel wall thickening identified in half of the cases. Organ injury was present in all patients. Based on this clinical and radiological picture, all patients underwent surgical intervention, with the time to operation ranging from 4 to 6 hours; the amount of intra-abdominal bleeding was recorded as 500-600 cc. In the postoperative period, major complications developed in all cases, all required intensive care, and a fatal outcome was observed; the median length of hospital stay was 2.5 days (IQR: 2.25-2.75).

Conclusion: The literature reports that seat belt injury is a high-risk clinical marker, particularly for mesenteric and bowel injuries, and may be associated with increased morbidity and mortality due to delayed diagnosis even in hemodynamically stable patients. In our study, a severe clinical course was observed despite initial hemodynamic stability, accompanied by markedly elevated lactate levels, the presence of free intraperitoneal fluid on imaging, and extensive organ injuries. These findings support the notion that seat belt injury should not be regarded merely as a superficial sign of trauma, but rather as a potential harbinger of serious intra-abdominal injuries. In patients with seat belt injury, close clinical monitoring, low-threshold advanced imaging, and prompt surgical consultation are of vital importance. Our study represents a case series consistent with the literature, emphasizing seat belt injury as an indicator of severe trauma and generating hypotheses for future studies.

Unexpected histopathological findings in appendectomy specimens: Analysis of Ordu University Training and Research Hospital

Mümin Demir[1], Hamza Çınar[2]

[1]*Department of General Surgery, Ordu University Training and Research Hospital, Ordu*

[2]*Department of Gastroenterologic Surgery, Pamukkale University Faculty of Medicine, Denizli*

Objective: Acute appendicitis (AA) is the most frequently performed emergency abdominal surgical procedure worldwide. While the primary pathogenesis involves luminal obstruction due to fecaliths or lymphoid hyperplasia, rare infectious, inflammatory, or neoplastic conditions may also lead to AA. This study aims to analyze the pathological results and unexpected findings of patients operated on with a diagnosis of AA at Ordu University Training and Research Hospital.

Material and Methods: The data of 337 patients who underwent emergency surgery for AA at Ordu University Training and Research Hospital, Department of General Surgery, between January 2020 and January 2026 were retrospectively reviewed. Patient demographics (age, gender) and histopathological reports were analyzed. Findings such as mucinous neoplasms, adenocarcinoma, parasitic infections, and endometriosis were categorized as "unexpected findings."

Results: Of the 337 patients, 218 (64.7%) were male and 119 (35.3%) were female, with a mean age of 38.8 years. Unexpected pathological results were detected in 10 patients (3%). The mean age of patients with unexpected findings (48.5 years) was significantly higher than the overall appendectomy group (p=0.012). The distribution of unexpected findings was as follows: Low-grade appendiceal mucinous neoplasia in 5 patients (1.57%), endometriosis in 2 patients (0.52%), adenocarcinoma in 1 patient (0.26%), Enterobius vermicularis in 1 patient (0.13%), and granulomatous inflammation in 1 patient (0.13%).

Conclusion: Although the most common causes of AA are lymphoid hyperplasia and fecaliths, neoplastic and non-inflammatory etiologies should be considered, especially in older patients. Routine histopathological examination of all appendectomy specimens is essential, regardless of whether they appear macroscopically normal, to ensure patients receive correct follow-up treatments such as chemotherapy or oncological surgery.

Keywords: Acute appendicitis, appendectomy, appendiceal neoplasms, histopatolological examination, unexpected pathological findings

Beyond acute appendicitis: Unexpected histopathological findings in appendectomy specimens- a four-year single-center experience

Osman Gökhan Gökdere, Bahadır Öndeş

Malatya Turgut Özal University, Malatya

Objective: Acute appendicitis is one of the most common causes of emergency abdominal surgery, and appendectomy remains the standard treatment. However, the necessity of routine histopathological examination of appendectomy specimens is still controversial. Appendices that appear macroscopically normal or simply inflamed may harbor clinically significant and unexpected pathologies that cannot be predicted preoperatively. In particular, neoplastic and premalignant lesions can only be diagnosed through histopathological evaluation, and their early detection is crucial for appropriate postoperative management and prognosis. This study aimed to evaluate the incidence, spectrum, and clinical impact of unexpected histopathological findings other than acute appendicitis in appendectomy specimens.

Material and Methods: This retrospective, single-center cohort study included adult patients (≥18 years) who underwent appendectomy for presumed acute appendicitis between January 2021 and December 2024. Patients with known malignancy, those who underwent interval appendectomy, incidental appendectomy during unrelated surgical procedures, or cases with missing histopathological data were excluded. Demographic characteristics, surgical approach, and histopathological findings were retrospectively analyzed. All pathological findings other than acute appendicitis were classified as incidental pathology.

Results: A total of 2.010 appendectomy specimens were evaluated, and incidental pathological findings other than acute appendicitis were identified in 33 cases (1.64%). The most frequent lesions were neuroendocrine neoplasms (n=12, 0.6%) and mucinous neoplasms (n=9, 0.45%). Patients with incidental pathology were significantly older and more frequently female compared with the overall cohort (p<0.05). All patients with neoplastic or premalignant lesions required additional postoperative evaluation, including imaging, colonoscopy, or oncological consultation, leading to changes in follow-up strategies.

Conclusion: Although unexpected histopathological findings in appendectomy specimens are relatively uncommon, they may have significant clinical implications. Routine histopathological examination enables early detection of lesions that cannot be identified by macroscopic assessment alone and that may directly influence postoperative management and surveillance. Therefore, routine histopathological evaluation of all appendectomy specimens should be maintained to ensure patient safety and optimal clinical outcomes.

Keywords: Acute appendicitis, appendectomy, ıncidental pathology, mucinous neoplasm, neuroendocrine neoplasm

General surgery consultations in a newly established city hospital: A first-year descriptive study

Fazlı Aladağ, Ahmet Mert Özhasırcı, Erdal Karagülle, Kadir Can Şahin, Ahmet Cem Esmer

Department of Generak Surgery, University of Health Sciences Türkiye, Antalya City Hospital, Antalya

Objective: Defining the consultation workload and service profile of general surgery clinics during the early period of newly established city hospitals is important for effective healthcare planning. In this study, we aimed to evaluate the distribution and characteristics of consultations requested from the General Surgery Clinic of Antalya City Hospital during its first year of operation.

Material and Methods: This descriptive study retrospectively reviewed consultations requested from the general surgery clinic between April 2024 and April 2025, following the opening of Antalya City Hospital. The source of consultations (emergency department, inpatient wards, or intensive care unit) was recorded. Consultation numbers were evaluated on a monthly basis to identify changes in workload over time.

Results: During the study period, a total of 3.674 consultations were evaluated by the general surgery clinic. Of these, 2.441 consultations (66.4%) originated from the emergency department. Monthly analysis demonstrated that the proportion of emergency department-based consultations ranged between 61% and 70% throughout the study period. While this proportion remained relatively stable, a noticeable increase in the total number of consultations was observed toward the end of 2024 and into early 2025. The majority of surgical interventions performed were appendectomy and diagnostic laparotomy related to perforation or trauma.

Conclusion: In newly established city hospitals, a substantial proportion of general surgery consultations originate from the emergency department, and the overall service workload increases significantly over time. This evaluation indicates that the interaction between the emergency department and general surgery, as well as the growing consultation burden, should be taken into account at an early stage in workforce planning, bed capacity management, and operating room organization. In addition, the allocation of an on-call general surgeon within the emergency department may also be considered.

Keywords: General surgery, consultation, emergency department, workload, retrospective descriptive study

A rare indication for emergency breast surgery

Nurbolot Akmatov, Hande Köksal

Department of General Surgery, Selçuk University Faculty of Medicine, Konya

Objective: Emergency breast surgery is a very rare condition in the management of breast malignancies. In this report, we present a patient who required emergency surgery due to tumor progression and bleeding despite receiving neoadjuvant chemotherapy.

Material and Methods: A 61-year-old female patient with a diagnosis of breast carcinoma, who had been receiving active chemotherapy at in a different hospital for 5 months, presented to our clinic because of an increase in tumor size and bleeding within the last week despite chemotherapy. Physical examination at admission revealed a fragile, partially ulcerated, and bleeding lesion with infectious looking surface, measuring approximately 20 cm in diameter on the anterior surface of the left breast, demonstrating an expansile growth pattern and a polypoid appearance. In addition, multiple hard, conglomerated lymph nodes fixed to the surrounding tissues were palpated in the left axillary region. Laboratory evaluation at admission revealed normocytic anemia. Positron Emission Computed tomography performed at presentation showed no evidence of distant metastasis.

Results: The patient underwent surgery the following day. Wide resection of the left breast including surrounding tissues and left axillary dissection were performed. The skin defect resulting from the resection was reconstructed using a split-thickness skin graft harvested from the anterolateral aspect of the left thigh. The postoperative course was uneventful, and the patient was discharged on postoperative day 2. Histopathological examination revealed metaplastic carcinoma; 8 cm raised from the skin and 20x8x12 cm in dimensions. The tumor consisted of 40% invasive ductal carcinoma and 60% undifferentiated pleomorphic sarcoma. Receptor status was negative for estrogen and progesterone receptors. The HER2 receptor score was +2, and fluorescence *in situ* hybridization analysis was pending. Additionally, 14 metastatic lymph nodes were identified in the axillary dissection specimen, all demonstrating extracapsular extension.

Conclusion: In this patient, due to tumor progression despite chemotherapy and uncontrollable bleeding and infection, emergency surgery was planned, and curative surgery was considered because there was no extramammarian involvement. Emergency surgical intervention in breast cancer is a rare occurrence; however, it should be considered as a treatment option in cases where chemotherapy is ineffective.

Keywords: Breast cancer, emergency surgery, pleomorphic sarcoma

Figure 1. A fragile, 20 cm diameter lesion exhibiting an expansive growth pattern and growing in a polypoid shape, originating from the anterior surface of the left breast, with areas of ulceration and bleeding.

Figure 2. The skin defect created after the resection was closed with a split-thickness skin graft taken from the anterolateral surface of the left leg.

The relationship between medical genetic screening and surgery in patients with familial Mediterranean fever (FMF)

İbrahim Çakır[1], Turan Pehlivan[2], Alperen İbrahim Sayar[2], Candaş Erçetin[2], Osman Bilgin Gülçiçek[2], Hakan Yiğitbaş[2], Erkan Yavuz[2]

[1]*İskilip Atıf Hoca State Hospital, Çorum*

[2]*Clinic of General Surgery, University of Health Sciences Türkiye, İstanbul Bağcılar Training and Research Hospital, İstanbul*

Objective: Familial Mediterranean fever (FMF) is a chronic autoinflammatory disease characterized by recurrent fever and serous inflammation attacks. FMF, recurrent fever and serositis (for example, peritonitis, pleurisy, pericarditis, synovitis) or erysipelas-like erythema attacks are characterized. Mediterranean fever (MEFV) is associated with mutations in the gene. In this study, we investigated genetic mutations in FMF patients and the effects of these mutations on BT symptoms and surgical outcomes in patients presenting to the emergency department with abdominal pain. In this way, we aimed to show that early medical genetic screening/diagnosis in FMF patients can reduce emergency hospital admissions and surgery.

Material and Methods: This study included 171 patients with MEFV gene mutations among 239 patients who presented to the medical genetics outpatient clinic of University of Health Sciences Türkiye, Bağcılar Training and Research Hospital and underwent MEFV gene mutation testing between January 1, 2021, and December 31, 2024. The genetic mutations in patients with MEFV gene mutations and the relationship between these mutations and the presentation to the emergency room, CT findings, and surgical history of patients presenting with abdominal pain were investigated.

Results: Of 240 patients examined for MEFV gene mutations, 171 patients with MEFV gene mutations were examined. A statistically significant difference was found between the number of mutations and CT findings ($p>0.05$). A statistically significant relationship was found between CT findings and surgical status ($p<0.05$). A significant relationship was found between the number of surgical cases and the number of emergency visits ($p<0.05$). The rate of ACMG class: VUS in patients with CT findings was statistically significantly higher than the rate of ACMG class: VUS in patients without CT findings ($p<0.05$).

Conclusion: The presence of CT findings plays a significant role in patients undergoing surgery. There is a correlation between emergency hospital admissions and surgically treated patients. The VUS variant is closely related to CT findings. In conclusion, our study did not find a significant difference between genetic mutations and emergency hospital admissions due to abdominal pain. However, CT findings are indicative of emergency hospital admissions due to abdominal pain in FMF patients. A statistically significant difference was found between the number of mutations and CT findings ($p<0.05$); while CT findings were more prevalent in those with a single mutation, the lower rate in those with two mutations is noteworthy. One case with four mutations had CT findings.

Keywords: Familial Mediterranean fever, genetic mutation, emergency admission

Clinical characteristics and treatment approaches of patients presenting to the emergency department due to rectal foreign bodies: A single-centre experience

Tahir Mehmet Güler[1], Faruk Yazıcı[2], Salih Süer[1], Serkan Demir[1], Alper Yavuz[1], Şener Balas[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Ankara Yenimahalle Training and Research Hospital, Ankara*

Objective: Patients presenting to the emergency general surgery department due to rectal foreign bodies, although rare, represent a group with important clinical decision points during diagnosis and treatment. This study aimed to descriptively evaluate the demographic, clinical, diagnostic and treatment-related characteristics of cases presenting to the General Surgery Clinic of University of Health Sciences Türkiye, Ankara Etlik City Hospital due to rectal foreign bodies.

Material and Methods: In this single-centre retrospective study, the records of patients evaluated as emergency cases due to rectal foreign bodies at the General Surgery Clinic of University of Health Sciences Türkiye, Ankara Etlik City Hospital were reviewed. Demographic data (age, sex); presentation time and symptoms; type and size of the foreign body; prior attempts at removal at home/outside the hospital; use of computed tomography (CT) and presence of perforation/free air; treatment method (manual, endoscopic or surgical); need for anaesthesia/sedation; complications; and length of hospital stay were recorded and summarised using descriptive statistics.

Results: A total of 9 patients presenting with rectal foreign bodies were included. All were male, with a mean age of 56±21.5 years (26-92). Sixty-six point seven per cent presented within 24 hours and 33.3% after more than 24 hours. The most common symptoms were pain (44.4%) and difficulty defecating (33.3%); 22.2% presented with bleeding. Foreign bodies were ≥10 cm in 77.8%. Plastic (44.4%) and glass (44.4%) were the most frequent materials; one case (11.1%) involved an organic object. Twenty-two point two per cent had a history of attempted removal at home or at an external centre prior to presentation. CT was performed in 55.6% and no perforation or free air was detected. Manual removal was performed in 33.3%, while surgery was required in 66.7%. Anaesthesia or sedation was required in 66.7%. No complications occurred. Mean hospital stay was 2.7±1.2 days (median 3 days).

Conclusion: The literature emphasises that management varies by case; foreign body size, delay in presentation and tissue injury findings are key factors determining the need for surgery and morbidity. In our study, consistent with the large size of most foreign bodies, the surgical requirement was high; however, no perforation or complications were observed. This suggests morbidity can be kept low with appropriate patient assessment and timely implementation of a stepwise treatment approach, and short hospitalisation indicates safe and effective clinical management.

Necessity of imaging modalities in patients consulted for acute abdomen: A 10-year single-center experience

Mert Yiğit Akdoğan, İsmail Sezikli, Orhan Aslan, Bahadır Kartal, Adnan Özarslan, Aşkın Kadir Perçem, Mahmut Arif Yüksek, Ertuğrul Gazi Alkurt, Ramazan Topcu, Veysel Barış Turhan, Murat Kendirci

Department of General Surgery, Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: This study aimed to evaluate the frequency and necessity of imaging modalities and the distribution of surgical pathologies in patients consulted from the emergency department to the general surgery clinic with a preliminary diagnosis of acute abdomen, and to emphasize the role of clinical evaluation in acute abdomen management.

Material and Methods: In this retrospective study, patients evaluated in the emergency department and consulted to the general surgery clinic with suspected acute abdomen between January 1, 2025, and December 31, 2025, were analyzed. Demographic characteristics, imaging modalities, hospitalization status, and clinical diagnoses were obtained from the hospital database. Clinical and radiological data of 2524 patients were evaluated. The results were compared with our similar study conducted at our institution 10 years earlier.

Results: The mean age was 54.9 years; 1381 patients (54.7%) were male and 1143 (45.3%) were female. CT was performed in 2296 patients (90.9%), ultrasonography in 1208 patients (47.9%), and both modalities in 980 patients (38.8%). Additionally, 1316 patients (52.1%) were evaluated directly with CT without prior ultrasonography based on clinical assessment. Advanced imaging such as MRCP was performed in 23 patients (0.9%), and repeat CT imaging during the same admission occurred in 27 patients (1.1%). Following surgical evaluation, 1948 patients (77.2%) were hospitalized. The most common diagnoses were ileus (552, 21.9%), acute appendicitis (484, 19.2%), acute cholecystitis (376, 14.9%), acute pancreatitis (208, 8.2%), incarcerated hernia (164, 6.5%), gastrointestinal perforation (48, 1.9%), and trauma (114, 4.5%; including stab wounds, firearm injuries, traffic accidents, falls, and burns). Patients not requiring admission were primarily diagnosed with non-specific abdominal pain, urinary tract infections, biliary colic, and gynecological pathologies.

Conclusion: Nearly 9 out of 10 patients underwent CT imaging, indicating extensive reliance on imaging. In surgical conditions such as incarcerated hernia and acute appendicitis, careful history and physical examination remain fundamental. Despite structural improvements in emergency services, CT utilization remains remarkably high. Similar findings to our 2017 study suggest no substantial improvement in acute abdomen evaluation. Surgical decision-making must rely primarily on clinical assessment, imaging should be selectively used, and advanced imaging before surgical evaluation should be restricted. Management of emergency departments by general surgeons should also be reconsidered.

Keywords: Acute abdomen, computed tomography, emergency department

Our electric arc burn cases in the last two years

Barış Tüzün[1], Mehmet Özyıldız[1], Cansu Alyeşil Özturan[2], Gamzenur Güney[3], Sude Sezer[3], Murat Özdamar[3]

[1]*Department of General Surgery, Burn Center, University of Health Sciences Türkiye, Kocaeli City Hospital, İzmit*

[2]*Department of Emergency Medicine, University of Health Sciences Türkiye, Kocaeli City Hospital, İzmit*

[3]*Department of General Surgery, University of Health Sciences Türkiye, Kocaeli City Hospital, İzmit*

Objective: Electric arc burns are burns caused by the sudden release of energy from devices such as high-energy transformers due to faulty equipment or short circuits. Besides the blast effect of electrical energy, contact burns, flame burns due to clothing catching fire, and, worst of all, inhalation burns which involve respiratory damage, can also occur.

Material and Methods: Between January 1, 2024, and January 1, 2026, 18 cases treated at our Burn Center were evaluated in terms of age, gender, burn percentage, burn location, inhalation injury, presence of compartment syndrome, use of biodegradable temporary matrix (BTM), percentage of escharectomy and graft number, significant complications, mortality, intensive care unit stay, hospital stay, and abbreviated burn injury scale (ABSI) score.

Results: The mean age of the nineteen cases was 29.8 (16-53) and all were male. Burn percentages were 33.1% (7-75%), with head and neck burns in 11 (57.8%) cases, trunk burns in 15 (83.3%) cases, and extremity burns in 17 (94.4%) cases. Five (27.7%) cases had inhalation burns, and six (33.3%) cases had compartment syndrome. Seventeen (94.4%) cases underwent an average of 3.05 (1-8) escharectomy sessions, and 14 (77.7%) cases underwent an average of 1.8 (1-4) grafting sessions. Four (22.2%) cases required btm (body transplantation). The mean hospital stay was 30.1 (5-85) days. The need for intensive care was observed in 15 (83.3%) cases, and the average intensive care stay was calculated as 14.3 (1-67) days. Intubation was required in 7 (41.1%) cases, and these cases remained intubated for 19.2 (8-53) days. The average ABSI values were 7.1 (2-12). Mortality occurred in two (11.1%) cases.

Conclusion: Arc burns, while having effects similar to contact electrical burns, burn large surfaces due to blast effect. Inhalation burns and compartment syndrome are common, and the morbidity is quite high. Even in burn centers, these cases are complicated, with high ABSI scores and associated mortality. If possible, patients should be immediately referred after stabilization is achieved.

Table 1. Casting of electric arc burns

	Case n	Percentage %
Absi	18	7.11
Inhalation injury	5	27.7
Compartment	6	33,3
Btm	4	22,2
Intensive care	15	83.3
Intubation	6	33.3
Mortality	2	11.1

[P-353]

Early clinical experience with microwave energy ablation in simple anal fistula: A 20-patient case series

Hacı Vural Soyer, Sinan Aslan, Samed Sayar, Güvenç Diner

University of Health Sciences Türkiye, Mersin City Hospital, Mersin

Objective: Anal fistula treatment aims to eradicate sepsis while preserving continence. Conventional sphincter-sparing techniques often require seton placement and prolonged wound care. Microwave energy ablation (MEA) is a novel minimally invasive technique that induces controlled thermal destruction of the fistula tract. This study presents our initial clinical experience with MEA in simple anal fistulas.

Material and Methods: Twenty consecutive patients diagnosed with intersphincteric or low transsphincteric anal fistula underwent MEA. All procedures were performed under regional anesthesia in the lithotomy position. After identification of the external and internal openings, a microwave probe was introduced into the fistula tract, and circumferential thermal ablation was applied along the entire tract. The internal opening was subsequently sealed using focused microwave coagulation. No seton placement or sphincter division was performed in any patient. Patients were followed for three months, and postoperative pain (VAS), wound healing, discharge, recurrence, continence status, operative time, and hospital stay were recorded retrospectively.

Results: Twenty patients underwent MEA for a simple anal fistula. The mean operative time was approximately 5-10 minutes, and all patients were discharged after a one-day hospital stay. Postoperative pain was low and progressively decreased during follow-up (VAS 3-4 at week 1, 2-3 at month 1, and approximately 2 at month 3). Complete wound healing was achieved within 2-3 months in the majority of patients. Only one recurrence was observed during follow-up. This patient was found to have a previously unrecognized secondary fistula tract associated with abscess formation. No intraoperative or postoperative complications occurred, and no deterioration in continence was detected in any patient.

Conclusion: MEA appears to be a safe and feasible sphincter-preserving treatment for simple anal fistulas, providing minimal postoperative pain and a short operative time. Early recurrence was rare and was associated with an unrecognized secondary tract and abscess formation, highlighting the importance of careful preoperative tract evaluation.

Keywords: Anal fistula, microwave ablation, sphincter preserving treatment

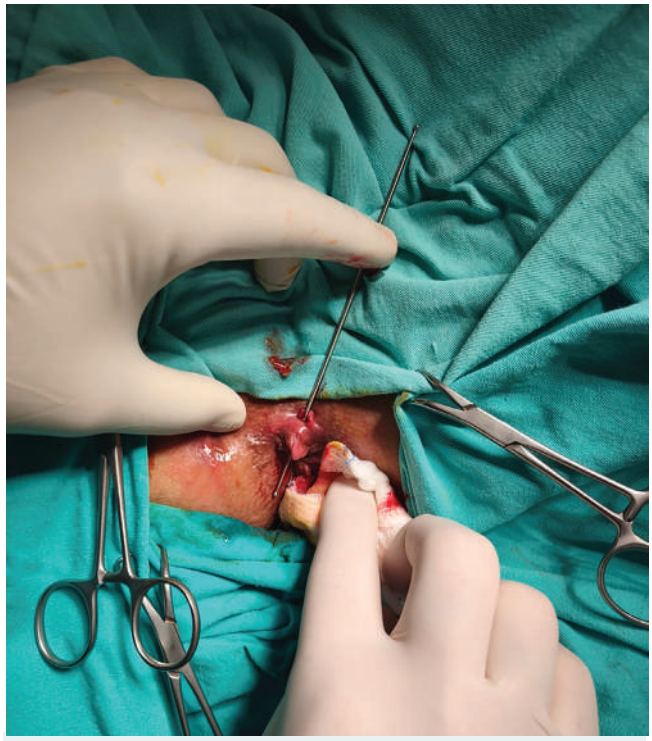

Figure 1. Recurrent case: Intraoperative identification of the primary fistula tract using a stylet probe.

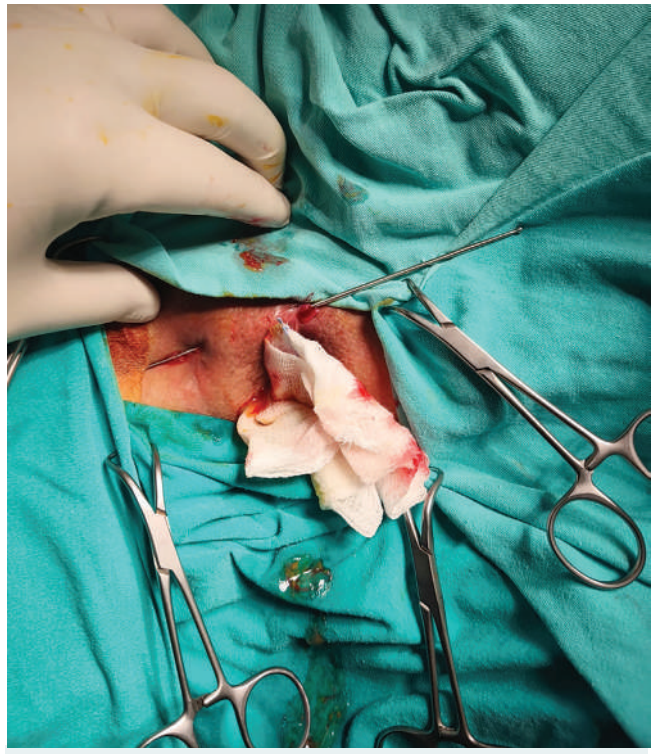

Figure 2. Recurrent case: Secondary fistula tract associated with abscess formation.

Factors affecting survival in metaplastic breast cancer: A single-center experience

İbrahim Ali Özemir, Şurahbil Yağbasa, Doğaç Demir, İrem Erol, Hakan Baysal, Arda Işık

Department of General Surgery, İstanbul Mendeniyet University Faculty of Medicine, İstanbul

Objective: Metaplastic breast cancer (MBC) is a rare subtype of breast cancer characterized by the presence of both epithelial and mesenchymal components. It is known to exhibit a more aggressive clinical course and worse prognosis compared to other breast cancer subtypes. This study aimed to evaluate the clinical, pathological, and prognostic characteristics of patients with MBC who underwent surgery at our institution.

Material and Methods: Between 2017 and 2023, 31 patients diagnosed with MBC were identified. Three patients lost to follow-up were excluded, leaving 28 patients for retrospective analysis. Demographic characteristics, preoperative imaging findings, pathological data, molecular subtypes, surgical procedures, adjuvant therapies, and oncological outcomes were evaluated.

Results: All 28 patients were female, with a mean age of 55.1±16.1 years. The mean follow-up duration was 51.2±31.7 months. The tumor was located in the left breast in 17 (60.7%) patients and in the right breast in 11 (39.3%) patients. The most common tumor location was the upper outer quadrant (14 patients, 50%). At the time of diagnosis, 5 (17.9%) patients presented with ulcerated tumors. Preoperative staging revealed multicentric disease in 5 (17.9%) patients, axillary lymph node metastasis in 10 (35.7%) patients, and distant metastasis in 8 (28.6%) patients. The mean tumor size was 64.4±73.3 mm. A significant association was found between tumor size and disease-related mortality (114.2 mm vs. 64.4 mm, p=0.002). In patients with tumor diameter ≥4 cm, rates of disease progression (recurrence and metastasis) (60% vs. 23.1%) and mortality (60% vs. 7.7%) were significantly higher than in those with tumors <4 cm (p=0.048 and p=0.003, respectively). Regarding molecular subtypes, 3 (10.7%) patients were classified as Luminal, 7 (25%) patients as HER2-positive, and 18 (64.3%) patients as Triple-negative. Ki-67 proliferation index was >20% in all patients, with a mean value of 68.3±24.3%. E-cadherin expression was positive in 8 (28.6%) patients. Axillary metastatic lymph nodes were detected in 13 (46.4%) patients. No significant association was found between molecular subtypes, E-cadherin status, axillary lymph node metastasis, or Ki-67 index and disease progression or mortality. The presence of an ulcerated tumor was identified as an independent and strong poor prognostic factor for both local recurrence (80%) and mortality (100%) (p=0.002). During follow-up, disease progression occurred in 42.9%, locoregional recurrence in 35.7%, distant metastasis in 10.7%, and disease-related mortality in 35.7% of patients.

Conclusion: MBC exhibits an aggressive clinical behavior. Large tumor size and the presence of tumor ulceration are particularly associated with poor prognosis. Early diagnosis is of critical importance in improving survival outcomes in MBC patients.

Clinicopathological impact of MiNEN in gastric neuroendocrine neoplasms: A single-center experience

Tarık Yıldız, Kutay Sağlam

Department of General Surgery, Bursa Uludağ University Faculty of Medicine, Bursa

Objective: Gastric neuroendocrine neoplasms (NENs) represent a heterogeneous group ranging from well-differentiated neuroendocrine tumors to high-grade neuroendocrine carcinomas (NECs). Tumors containing both neuroendocrine and non-neuroendocrine components are classified by the World Health Organization as mixed neuroendocrine-non-neuroendocrine neoplasms (MiNEN). MiNENs are considered to demonstrate more aggressive biological behavior compared with conventional NENs. However, comparative clinicopathological data in gastric cases remain limited. This study aimed to compare the clinicopathological characteristics of gastric NEN and MiNEN cases in our institutional series.

Material and Methods: Patients diagnosed with gastric neuroendocrine neoplasms between 2015 and 2025 were retrospectively reviewed. Pathology reports were converted into a structured dataset. Cases were classified as MiNEN when both neuroendocrine and non-neuroendocrine components were identified, and as non-MiNEN gastric NEN when only a neuroendocrine component was present. Groups were compared in terms of age, maximum tumor diameter, Ki-67 proliferation index, p53 percentage, total and metastatic lymph node counts, and recorded tumor grade. Continuous variables were expressed as median (IQR) and analyzed using non-parametric tests. Categorical variables were evaluated using chi-square or Fisher's exact tests. A p-value <0.05 was considered statistically significant.

Results: A total of 19 gastric cases were analyzed; 15 (78.9%) were non-MiNEN NEN and 4 (21.1%) were MiNEN. There was no statistically significant difference in age between groups [MiNEN: 72.5 (65.5-76.5) years vs. NEN: 63.0 (59.0-72.5) years; p=0.365]. Maximum tumor diameter was similar [MiNEN: 4.05 (2.98-6.25) cm vs. NEN: 3.05 (2.00-5.63) cm; p=0.337]. Although the Ki-67 proliferation index was higher in the MiNEN group, the difference did not reach statistical significance [60.0 (50.0-62.5) vs. 12.0 (5.0-55.0); p=0.191]. Likewise, p53 percentage was higher in MiNEN cases but without significance [40.0 (22.5-52.5) vs. 0.0 (0.0-6.2); p=0.204]. The total number of retrieved lymph nodes was comparable between groups [26.0 (18.5-36.0) vs. 24.0 (11.5-30.5); p=0.652]. However, metastatic lymph nodes were significantly higher in the MiNEN group [6.5 (4.5-10.0) vs. 0.0 (0.0-2.5); p=0.009]. Tumor grade distribution differed significantly (p=0.034); all MiNEN cases were recorded as NEC, whereas the non-MiNEN group showed a heterogeneous distribution of G1, G2, G3, and NEC cases.

Conclusion: In this single-center gastric series, MiNEN cases were associated with a significantly higher metastatic lymph node burden compared to non-MiNEN gastric NENs. Although no significant differences were observed in age, tumor size, Ki-67, or p53, the increased nodal metastasis suggests more aggressive biological behavior in MiNEN. Careful pathological evaluation for a MiNEN component is essential for accurate classification and appropriate surgical management.

Table 1. Clinicopathological distribution according to tumor grade and MiNEN status in gastric NEN

Variable	Grade 1 (n=3)	Grade 2 (n=7)	Grade 3 (n=2)	NEK (n=3)	MiNEN (n=4)	p
Age (years)	76.0 (74.0-76.0)	63.0 (52.0-66.5)	68.5 (65.8-71.2)	63.0 (59.0-64.0)	72.5 (65.5-76.5)	0.365
Sex (M/F)	0/3	6/1	0/2	2/1	4/0	0.245
Max tumor size (cm)	4.8 (2.7-7.0)	3.5 (2.0-4.0)	4.0 (3.0-5.0)	2.6 (2.4-5.9)	4.0 (3.0-6.2)	0.337
Ki-67 (%)	12.0 (6.0-36.0)	6.0 (4.0-8.5)	35.0 (35.0-35.0)	80.0 (75.0-80.0)	60.0 (50.0-62.5)	0.191
p53 (%)	0.0 (0.0-40.0)	0.0 (0.0-0.0)	2.5 (1.2-3.8)	5.0 (2.5-7.5)	40.0 (22.5-52.5)	0.204
Total LN (n)	1.0 (0,5-17.0)	19.0 (12.0-26.5)	23.0 (18.0-28.0)	25.0 (24.5-32.0)	26.0 (18.5-36.0)	0.652
Metastatic LN (n)	0.0 (0.0-0.0)	0.0 (0.0-3.5)	1.5 (0.8-2.2)	1.0 (0.5-2.0)	6.5 (4.5-10.0)	0.009

Continuous variables are presented as median (interquartile range, IQR). Categorical variables are expressed as counts. Between-group comparisons were performed using appropriate non-parametric tests for continuous variables and chi-square or Fisher's exact test for categorical variables. A p-value <0.05 was considered statistically significant. LN: Lymph node, NEC: Neuroendocrine carcinoma, MiNEN: Mixed neuroendocrine–non-neuroendocrine neoplasm.

Surgical management of Mirizzi syndrome type Va: A single-center experience

Necati Osman Okumuş, Orhan Üreyen, Hüseyin Esin, Enver İlhan, Kemal Erdinç Kamer

Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir

Objective: Although Mirizzi syndrome is rare, the presence of a cholecystoenteric fistula in Type Va cases, along with challenging hepatocystic anatomy and an increased risk of bile duct injury, makes surgical management particularly complex. This study aimed to evaluate the diagnostic process, surgical approach, and short-term outcomes of Mirizzi Type Va cases based on our high-volume single-center experience.

Material and Methods: A total of 2,300 cholecystectomy cases performed at our center were retrospectively reviewed. Patients diagnosed with Type Va Mirizzi syndrome according to the Csendes classification were included in the study. Demographic characteristics, preoperative imaging modalities, timing of diagnosis (preoperative/intraoperative), fistula type, surgical approach, operative techniques applied, and postoperative outcomes were analyzed. Morbidity, mortality, and length of hospital stay were evaluated.

Results: Cholecystoenteric fistula consistent with Mirizzi Type Va was identified in 9 patients (0.39%). The median age was 61 years (min 39-max 75), and 55.6% of the patients were female. The cholecystoenteric fistula involved the duodenum in 6 cases and the colon in 3 cases. Diagnosis was established preoperatively in 22.2% of patients and intraoperatively in 77.8%. Surgery was initiated laparoscopically in 8 patients, with conversion required in 4 cases; primary open surgery was performed in 1 patient. Fistula repair varied according to surgeon preference, with double-layer primary repair ± omentopexy being the most commonly applied technique for duodenal fistulas (44.4%). Stapled wedge resection was performed in 2 cases (22.2%). In patients with colonic fistula, treatment consisted of right hemicolectomy (11.1%), primary repair (11.1%), and clip closure (11.1%). Postoperative morbidity developed in one patient (11.1%), presenting as biliary drainage from the surgical drain on postoperative day 1, which resolved spontaneously. One mortality related to cardiac morbidity was observed. The median length of hospital stay was 7 days.

Conclusion: Mirizzi Type Va syndrome is a condition that is most often recognized intraoperatively and requires a high level of surgical expertise for proper management. Since achieving the "critical view of safety" is frequently not feasible in these cases, early awareness and timely implementation of alternative surgical strategies are crucial to prevent bile duct injuries. Although a laparoscopic approach may be feasible in selected patients, the surgical strategy should be determined flexibly according to intraoperative findings.

[P-357]

Clinical and oncological outcomes of the standardized approach in gastrointestinal stromal tumor surgery at Cerrahpaşa Faculty of Medicine after 11 years

Makbule Unutkan[1], Anıl Orhan[2], Fadime Kutluk[1], Gökçe Aşkan[3], Şebnem Batur[3], Murat Süphan Ertürk[1], Süleyman Demiryas[1]

[1]Department of General Surgery, İstanbul University-Cerrahpaşa, CerrahpaşaFaculty of Medicine, İstanbul

[2]Department of General Surgery, University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, İstanbul

[3]Department of Medical Pathology, İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal system, exhibiting a heterogeneous spectrum of clinical behavior. Currently, surgical resection forms the basis of curative treatment, and a negative surgical margin (R0) is considered the most important prognostic factor for long-term survival. Surgical technique, patient selection, and a multidisciplinary approach directly influence oncological outcomes. In this study, the clinical and oncological outcomes of GIST cases operated on by a single surgical team over an 11-year period were analyzed to evaluate the effectiveness of a standardized surgical approach.

Material and Methods: A retrospective analysis was performed on 20 patients who underwent surgery for GIST between 2015 and 2026. All patients were operated on by the same experienced team. Demographic characteristics, tumor diameter, mitotic index, AFIP risk stratification, surgical approach, use of adjuvant therapy, length of hospital stay, and follow-up outcomes were examined.

Results: The mean age of the 20 patients was 63 years, with equal gender distribution (10/10). Tumors were located in the stomach (75%), small intestine/duodenum (20%), and rectum (5%). The mean tumor diameter was 8.4 cm (0.3-12 cm). The mean mitotic index was 7.4/5 mm^2, and the median was 2/5 mm^2 (0-98); 15% of patients had ≥6/5 mm^2 mitotic activity. One patient had a markedly high index of 98/5 mm^2. According to the AFIP classification, 35% were very low risk, 20% low risk, 40% intermediate risk, and 5% high risk. Open surgery was performed in 70% and minimally invasive surgery in 30% of patients. R0 resection was achieved in all cases, with no intraoperative tumor rupture. The median hospital stay was 4 days (3-9), shorter after minimally invasive procedures. Two high-risk patients (10%) received adjuvant imatinib. One (8 cm, 6/5 mm^2, multifocal duodenal tumor, NF-1 and T-ALL history) had no recurrence. The other (AFIP 6A; 8 cm ileal tumor, 98/5 mm^2, lymph node metastasis) developed distant metastases 28 months postoperatively (5%). No recurrence occurred in the low or intermediate risk groups, and no GIST-related mortality was observed.

Conclusion: A standardized surgical approach performed by a single surgical team can achieve a high R0 resection rate and low morbidity in GIST cases. The absence of recurrence in low and moderate-risk groups supports surgical efficacy, while the development of metastasis in high-risk cases highlights the prognostic value of the risk stratification. Minimally invasive surgery can be safely applied in selected cases.

Artificial intelligence in emergency surgery: Current applications, ethical debates, and future perspectives

Yunushan Furkan Aydoğdu, Murtaza Kaan Özdemir, Enes Faruk Belen, Enes Turgut

University of Health Sciences Türkiye, Ankara Training and Research Hospital, Ankara

Objective: Artificial intelligence (AI) has initiated a significant transformation in emergency surgical practice, driven by increasing patient volume, complex decision-making processes, and limited healthcare resources. AI-assisted systems have the potential to improve clinical decision-making by supporting diagnosis, treatment planning, education, and healthcare management. This article reviews the current applications of AI in emergency surgery, its ethical implications, role in surgical education, and future perspectives based on recent literature.

Material and Methods: AI is increasingly used in emergency surgery for diagnostic support, prediction of mortality and complications, and optimization of resource allocation. Particularly in trauma and intensive care surgery, real-time analysis of bedside clinical data enables accurate prediction of patient outcomes. AI-based tools such as POTTER and the Trauma Outcome Predictor have demonstrated high accuracy in predicting postoperative mortality and complications.

Results: AI shows potential in guiding complex decisions in emergency surgery, including situations involving treatment futility. However, its integration into clinical decision-making raises ethical concerns regarding

autonomy, accountability, and fairness in healthcare delivery. The extent to which AI should influence or replace human judgment remains controversial. Consequently, the implementation of human-supervised AI systems and the establishment of clear ethical frameworks are essential to maintain balanced and just clinical practice. AI-supported surgical simulation platforms offer personalized feedback and objective assessment of technical skills. Integration of AI algorithms into virtual reality, augmented reality, and mixed reality environments has been shown to shorten learning curves and improve preclinical competency evaluation. Additionally, these technologies facilitate individualized assessment in remote surgical education. In common emergency surgical conditions such as acute appendicitis, AI algorithms demonstrate promising diagnostic performance. Machine learning models including random forest, support vector machines, and decision trees can analyze clinical and imaging data to distinguish complicated from uncomplicated cases with high accuracy. This capability may support surgical decision-making in diagnostically ambiguous patients and reduce unnecessary surgical interventions.

Conclusion: The full potential of AI in emergency surgery has yet to be realized. Enhanced clinical integration, standardized ethical guidelines, and widespread adoption in surgical education are necessary to maximize its impact on patient safety and surgical outcomes. Future research supported by real-world data and strengthened multidisciplinary collaboration will be critical to ensuring a sustainable and effective transformation.

An innovative approach to pressure ulcer management in intensive care patients: Ultrasonic debridement

Nebi Acar

Kütahya Health Science University Faculty of Medicine, Kütahya

Objective: Pressure ulcers are a serious health problem with incidence rates ranging from 1.4% to 36.4%, particularly in intensive care unit patients, due to immobilization, sedation, tissue perfusion disorders, and malnutrition. Stage III and IV ulcers represent deep tissue loss extending to the fascia, muscle, and bone. Surgical debridement may not always be feasible in these patients due to coagulopathy or hemodynamic instability. Ultrasonic debridement offers a minimally invasive alternative for preserving healthy tissue, minimizing bleeding, and managing pain in this patient group.

Material and Methods: Patients with stage 3 and 4 pressure ulcers admitted to level 2 and 3 intensive care units between January 2025 and July 2025 were prospectively evaluated. Patients were divided into two groups: 1) patients who underwent ultrasonic debridement (Figures 1 and 2); 2) patients who underwent surgical debridement. These patients were evaluated in terms of age, gender, debridement effectiveness, and post-debridement bleeding.

Results: A total of 60 patients were included in the study. The median age was 68.8 (range 40-94 years). There were 17 female and 13 male patients who underwent ultrasonic debridement, while 13 female and 17 male patients underwent surgical debridement. In terms of debridement effectiveness between the two groups, debridement was not effective in 5 patients who underwent ultrasonic debridement. Debridement effectiveness was high in all patients who underwent surgical debridement. No significant difference in debridement efficacy was observed between the two groups. Bleeding was observed in 1 patient undergoing ultrasonic debridement. Bleeding was observed in 19 patients undergoing surgical debridement. In terms of bleeding ($p<0.001$), ultrasonic debridement was found to be safer.

Conclusion: Ultrasonic debridement is an alternative debridement method for the treatment of pressure ulcers in intensive care patients due to the mobility of the device, its applicability at the patient's bedside, its improvement of patient comfort in pain management, and its effective removal of necrotic tissue. In addition, it has a low risk of bleeding due to its preservation of living tissue. Despite its high cost, it is an effective debridement method.

Keywords: Pressure ulcer, surgical debridement, ultrasonic debridement, intensive care

Revision bariatric surgeries after sleeve gastrectomy: Indications and early clinical and metabolic outcomes

Yavuz Poyrazoğlu, Elif Didem Terzi, Nesibe Altay, Neslihan Alıcı, İrem Basmacı

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Sleeve gastrectomy is one of the most commonly performed bariatric surgical procedures for the treatment of morbid obesity. Despite its effectiveness in achieving significant weight loss and metabolic improvement, some patients may experience insufficient weight loss, weight regain, or inadequate metabolic response, necessitating additional surgical interventions. Consequently, revision surgery has become an important option in obesity management. The indications for revision surgery, selection of the appropriate surgical technique, and the clinical and metabolic outcomes of these procedures play a critical role in patient management. However, data regarding early outcomes of revision surgeries following sleeve gastrectomy remain limited. This study aims to evaluate the indications and early clinical and metabolic outcomes of patients undergoing revision surgery after sleeve gastrectomy.

Material and Methods: This retrospective study included patients who underwent revision surgery following sleeve gastrectomy. Data regarding patient age, primary surgical procedure, type of revision surgery, pre- and post-revision body weight and body mass index (BMI) values, and metabolic parameters (HbA1c and lipid profile) were recorded. Continuous variables were presented as mean ± standard deviation. Clinical and metabolic parameters before and after revision surgery were compared.

Results: A total of 8 patients were included in the study. The mean age of the patients was 38.4±5.4 years. All patients had previously undergone sleeve gastrectomy as the primary procedure. The main indications for revision surgery were insufficient weight loss and inadequate metabolic response. Revision procedures included gastric bypass and re-sleeve surgery. The mean pre-revision body weight was 113.1±16.9 kg and the mean BMI was 41.2±5.8 kg/m^2. Post-revision follow-up revealed a mean body weight of 99.4±15.2 kg and a mean BMI of 36.3±5.3 kg/m^2. The average decrease in BMI after revision surgery was 4.9 kg/m^2. Evaluation of metabolic parameters showed an improvement trend in HbA1c levels after revision surgery. In the lipid profile analysis, decreases in triglyceride and LDL levels were observed.

Conclusion: Revision bariatric surgeries performed due to insufficient weight loss or inadequate metabolic response after sleeve gastrectomy may provide significant early weight loss and improvement in metabolic parameters. With appropriate patient selection, revision surgery represents an effective option in the treatment of obesity. However, larger patient series and long-term follow-up results are required to confirm these findings.

Keywords: Sleeve gastrectomy, revision bariatric surgery, insufficient weight loss, metabolic response, bariatric surgery

Change in ferritin levels at the 6th month after sleeve gastrectomy: A single-center analysis

Arif Uysal, Bülent Öztürk, Hakan Buluş, Burak Telli, Yusuf Turan, Enes Ethem Onat

Department of General Surgery, University of Health Sciences Türkiye, Ankara Atatürk Sanatory Training and Research Hospital, Ankara

Objective: Laparoscopic sleeve gastrectomy is one of the most frequently performed bariatric surgical methods in the treatment of morbid obesity. Although it is a restrictive method, it can lead to a number of nutritional deficiencies in the early postoperative period. Serum ferritin levels are an important parameter reflecting the body's iron stores. Decreases in serum ferritin levels usually occur before the development of anemia. In this study, we aimed to evaluate the changes in serum ferritin levels before and at 6 months postoperatively in patients who underwent laparoscopic sleeve gastrectomy.

Material and Methods: Forty-eight patients (26 men, 22 women) who underwent Laparoscopic Sleeve Gastrectomy at our center between January 2025 and 2026 and had their serum ferritin levels measured preoperatively and at 6 months postoperatively were included in the study. All patients received a standard postoperative nutritional protocol and routine multivitamin (Argivit®) supplementation. Paired t-test and Wilcoxon test were used for statistical analysis. A p-value <0.05 was considered statistically significant.

Results: The mean preoperative serum ferritin levels were 90.2±88.8 ng/mL, and the mean postoperative 6-month level was 87.1±91.6 ng/mL. The median values were 64.5 and 60.5 ng/mL, respectively. The mean difference was not statistically significant (paired t-test p=0.73; Wilcoxon p=0.33). In patient-specific evaluation, serum ferritin levels fell below 30 ng/mL in 31% of cases and below 15 ng/mL in 17%. In some patients, a decrease in serum ferritin levels was detected even though serum hemoglobin levels did not reach the anemia threshold.

Conclusion: Even in the early period following laparoscopic sleeve gastrectomy, a decrease in serum iron stores can be observed. Although the average change was not statistically significant, approximately one-third of patients experienced insufficient serum iron stores. These findings indicate the existence of a clinically significant subgroup, even without statistical significance. The fact that serum ferritin levels precede the decrease in hemoglobin levels suggests that monitoring serum hemoglobin alone may be insufficient. Therefore, serum ferritin levels should be included as a routine monitoring parameter in patients who have undergone laparoscopic sleeve gastrectomy, and replacement planning should be done early when deemed necessary.

Keywords: Ferritin, nutritional deficiency, sleeve gastrectomy

[P-363]

Complication rate and management after sleeve gastrectomy surgery: A single center study

Ahmet Erim Erdoğan[1], Ahmet Mücteba Öztürk[2], Mehmet Yıldırım[1]

[1]*University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*University of Health Sciences Türkiye, İzmir Bozyaka Training and Research Hospital, İzmir*

Objective: Obesity is a modern public health problem affecting all segments of society. The obesity rate among the adult population in our country is 34%. In addition to medical treatments against obesity, surgical treatments are also used today. More than 50% of bariatric surgeries are laparoscopic sleeve gastrectomy (LSG). Surgical treatment maintains its popularity due to its low risk of complications and rapid results. LSG remains the most frequently performed independent bariatric operation because it both preserves the integrity of the digestive tract and is technically easier to perform compared to other operations. According to IFSO data, the postoperative complication rate after LSG is 2.12%.

Material and Methods: In our study, we examined laparoscopic sleeve gastrectomies performed at the General Surgery Clinic of İzmir Bozyaka Training and Research Hospital.

Results: Our study revealed that a total of 680 patients underwent LSG. 88% of the patients were female and 12% were male. The age range of the patients was 18-71 years. The average hospital stay after surgery was 4 days. The postoperative complication rate was 0.7% (5 patients). In our patients, intra-abdominal abscess formation due to leakage from the stapler line was observed after surgery. In these patients, external drainage catheter placement was performed by interventional radiology in the postoperative period. at the same time, stent placement was performed via gastroscopy to preserve the anastomosis line. During follow-up, intra abdominal abscess formation regressed in our patients, and they recovered their health.

Conclusion: Sleeve gastrectomy surgery is a solution that individuals around the world are turning to in the fight against obesity. Like any surgical procedure, sleeve gastrectomy carries various risks of complications. These complications can lead to life-threatening outcomes. Patients should be properly and comprehensively informed before the operation. While the postoperative complication rate is 0.7% in our clinic, this rate may vary in experienced centers. There is a need for multi center studies on this subject in our country.

Which technique should be preferred in concomitant elective laparoscopic cholecystectomy and inguinal hernia repair? A case series of 18 patients with a review of the literature

Muhammed Furkan Arslan[1], Murat Demir[1], Oğuzhan Tekin[1], Rıza Deryol[2], Hüseyin Kılavuz[3]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul*

[2]*Department of Surgical Oncology, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul*

[3]*Department of General Surgery, University of Health Sciences Türkiye, Hamidiye Faculty of Medicine, Başakşehir Çam and Sakura City Hospital, İstanbul*

Objective: Simultaneous elective laparoscopic cholecystectomy (LC) and inguinal hernia repair are considered advantageous approaches regarding patient comfort, anesthesia exposure, and cost-effectiveness. However, there is no clear consensus in the literature regarding the ideal technique selection and the risk of infection, particularly due to mesh use. This study aims to evaluate clinical outcomes of simultaneous LC and inguinal hernia repair to aid technique selection.

Material and Methods: Eigh-teen patients who underwent simultaneous LC and inguinal hernia repair under elective conditions at a single center between January 2021 and December 2025 were analyzed retrospectively. Demographics, comorbidities, hernia type, surgical technique, operative time, postoperative length of stay, and follow-up results were analyzed. The choice of surgical technique was determined based on patient characteristics and surgeon experience.

Results: Median age was 53 (26-75); 4 (22.2%) patients were female and 14 (77.8%) male. Bilateral inguinal hernias were present in two patients (11.1%); one underwent TAPP and the other TEP. In unilateral hernia cases (n=16), the most preferred technique was TAPP (56.3%), followed by TEP (25.0%) and open anterior repair (18.7%). The median operative time was 115 minutes, and the median postoperative stay was 1 day. No mesh infection or major complications were observed during follow-up. Seroma developed in two patients (11.1%) (one bilateral TEP, one unilateral TAPP). Scrotal pain was observed in three patients (16.7%) within the first 30 days, all in the TAPP group. No hernia recurrence was detected. One patient (5.6%) had an unexpected visit due to a hematoma at the LC trocar site; readmission was not required. This study demonstrates that simultaneous LC and inguinal hernia repair under elective conditions is a safe and feasible approach. Consistent with the literature, no increase in mesh infection risk was observed. While international guidelines report no significant superiority between TAPP and TEP regarding long-term results, they suggest selecting the technique based on surgeon experience and patient characteristics. In the presence of simultaneous LC, the TAPP technique may offer practical ease due to port compatibility and intra-abdominal evaluation. Short hospital stays and the absence of serious complications support the benefits of the minimally invasive approach. However, the small sample size and retrospective design are the study's main limitations.

Conclusion: Simultaneous elective LC and inguinal hernia repair is a safe approach. Regarding ideal technique selection, an individualized approach based on patient characteristics and surgeon experience should take precedence over the absolute superiority of a single method. Larger, prospective, and comparative studies are needed.

Re-operation due to postoperative deep neck hematoma after thyroidectomy: A single-center experience

Işık Çetinoğlu, Batuhan Hüsnü Ustabaş, Ozan Çalışkan, Mehmet Taner Ünlü, Ahmet Faruk Yener, Nurcihan Aygün, Mehmet Uludağ

Department of General Surgery, University of Health Sciences Türkiye, Şişli Hamidiye Etfal Training and Research Hospital, İstanbul

Objective: Postoperative deep neck hematoma after thyroidectomy is a rare but potentially life-threatening complication due to airway compression, laryngeal spasm, and edema, which may lead to acute airway obstruction. Early diagnosis and urgent surgical intervention are therefore critical. This issue has also been widely discussed in the context of the safety of thyroidectomy as a day-case procedure. We aimed to evaluate the clinical features, timing, and management outcomes of patients who required re-operation for postoperative neck hematoma and to present our single-center experience.

Material and Methods: Patients who underwent total thyroidectomy or lobectomy between 2020 and 2025 at the General Surgery Department of University of Health Sciences Türkiye, Şişli Hamidiye Etfal Training and Research Hospital were retrospectively reviewed. Those who developed postoperative neck hematoma requiring re-operation were included. Intraoperative nerve monitoring was used in all thyroidectomy procedures. Data regarding timing of hematoma, bleeding source, emergency management, and clinical outcomes were analyzed.

Results: A total of 1.115 patients underwent surgery (total thyroidectomy n=554; lobectomy n=561). Postoperative neck hematoma occurred in 7 patients (0.6%). Patients were aged 33-71 years; 6 were female and 1 male. Preoperative diagnoses were nodular goiter (n=3), Graves' disease (n=3), and primary hyperparathyroidism (n=1). Three patients underwent total thyroidectomy, three lobectomy, and one lobectomy with bilateral exploration. The time from initial surgery to re-operation ranged from 25 to 445 minutes. All patients were taken urgently to the operating room. The most common bleeding source was the left superior thyroid artery (n=4); one case originated from the Berry ligament and one from the left middle thyroid vein. All bleeding points were controlled with 3/0 silk sutures. Drains were present in five patients after the initial surgery and were reinserted after re-exploration. Three patients required intensive care monitoring. Hospital stay ranged from 1 to 4 days. Postoperative vocal cord examination revealed bilaterally mobile cords in all patients, and no mortality occurred.

Conclusion: Although postoperative deep neck hematoma after thyroidectomy is rare, it is a critical condition requiring urgent surgical intervention when it occurs. Hematomas generally develop in the early postoperative period; therefore, close monitoring of patients within the first 8 hours (480 minutes) is essential for early diagnosis. We believe that re-exploration of the thyroid bed with intraoperative nerve monitoring may be protective against vocal cord paralysis .O ur findings suggest that early recognition and prompt surgical intervention are crucial for airway safety and for reducing patient morbidity and mortality.

Regional distribution of public interest in robotic surgery in Türkiye: A comparative google trends analysis with other surgical techniques

Nagihan Gürel, Ümmehan Siper, Ümit Sekmen, Hakan Çakır

Acıbadem Fulya Hospital, İstanbul

Objective: Robotic surgery has gained increasing visibility among minimally invasive surgical techniques, accompanied by growing public awareness. However, how public interest in robotic surgery is regionally distributed compared with other surgical techniques remains unclear. Online health-related search behavior may serve as an indirect indicator of public interest. Google Trends provides a suitable platform for comparative and region-based analyses. This study aimed to evaluate the regional distribution of public interest in robotic surgery in Türkiye, in comparison with laparoscopic and open surgery.

Material and Methods: Google Trends data were retrieved for Türkiye for the period 2007-2026 using the search terms "robotic surgery," "laparoscopic surgery," and "open surgery". Province-level data were analyzed to identify regions with the highest relative interest for each surgical technique. All values were interpreted as normalized relative interest scores ranging from 0 to 100, and regional patterns of robotic surgery interest were compared with those of other surgical techniques.

Results: High relative interest in robotic surgery was observed in non-metropolitan provinces such as Artvin (100), Karabük (92), and Düzce (92). Among metropolitan cities, İzmir (85), İstanbul (78), and Ankara (78) also demonstrated high relative interest in robotic surgery. Interest in laparoscopic surgery was most prominent in provinces such as Isparta (100), Yozgat (75), and Bolu (75), whereas interest in open surgery was concentrated in a limited number of provinces, particularly Kars (100) and Denizli (53) (Table 1). When these distributions are considered, interest in laparoscopic surgery appears to be more geographically balanced across the country, while interest in robotic surgery (blue shades) shows marked clustering in specific provinces (Figure 1). The province-level distribution of interest in robotic surgery was more heterogeneous compared with other surgical techniques.

Conclusion: Google Trends data indicate that public interest in robotic surgery in Türkiye varies markedly across regions. The presence of high interest in robotic surgery in non-metropolitan provinces, compared with other surgical techniques, suggests that public expectations and awareness may develop independently of local service availability. These findings highlight the importance of region-specific patient education and health communication strategies regarding surgical technologies.

Table 1. Province-level distribution of public interest in robotic surgery compared with other surgical techniques (Google Trends, 2007-2026)

Surgical technique	Province	Relative interest score (0-100)
Robotic surgery	Artvin	100
Robotic surgery	Karabük	92
Robotic surgery	Düzce	92
Robotic surgery	Edirne	85
Robotic surgery	İzmir	85
Laparoscopic surgery	Isparta	100
Laparoscopic surgery	Yozgat	75
Laparoscopic surgery	Bolu	75
Laparoscopic surgery	Bursa	62
Laparoscopic surgery	Ankara	62
Open surgery	Kars	100
Open surgery	Denizli	53
Open surgery	Giresun	38
Open surgery	Zonguldak	30
Open surgery	Isparta	30

This table presents the province-level distribution of public interest in robotic, laparoscopic, and open surgery in Türkiye based on Google Trends data from 2007 to 2026. Values represent normalized relative interest scores ranging from 0 to 100 for each surgical technique. The table highlights regional differences in public interest in robotic surgery compared with other surgical approaches.

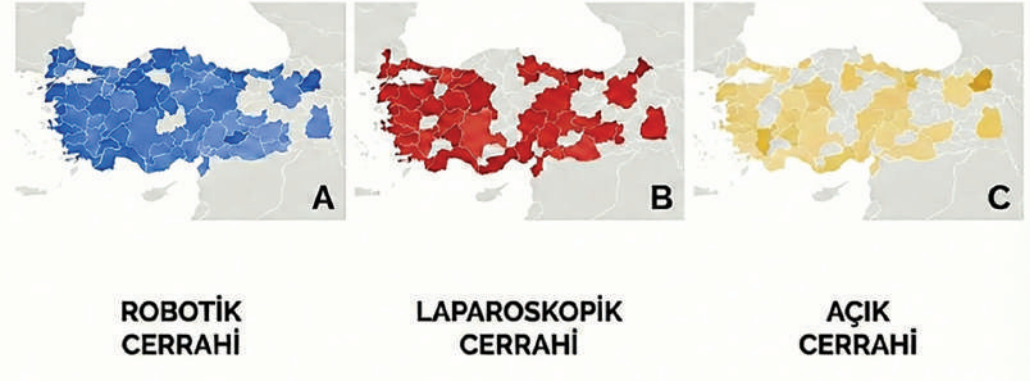

Figure 1. Province-level distribution of public interest in robotic, laparoscopic, and open surgery in Türkiye.

Province-level distribution of public interest in robotic (A), laparoscopic (B), and open surgery (C) in Türkiye based on Google Trends data from 2007 to 2026. Values represent normalized relative interest scores ranging from 0 to 100 for each search term. The maps illustrate distinct regional patterns and heterogeneity in public interest across different surgical techniques.

How should resection be performed in synchronous colon tumors

Zekerya Pelen, Kutay İşçen, Muhammed Özdemir, Doğan Gönüllü

Department of General Surgery, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul

Objective: There is no consensus on the surgical management of synchronous colon carcinomas. As the extent of resection increases, rates of morbidity and mortality also rise. This study is aiming to define appropriate resection limits in emergency and elective settings.

Material and Methods: Patients who underwent emergency or elective surgery for synchronous colorectal carcinoma at the Department of General Surgery, University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital between 2023 and 2026 were retrospectively analyzed.

Results: A total of nine patients were included, eight operated electively and one emergently. The male-to-female ratio was 4:5, and the mean age was 69.8 years (range 57-77). Mean preoperative carcinoembryonic antigen level was 25.1 ng/mL (0.5-54.1), and mean CA 19-9 level was 36.9 U/mL (1.2-74.9). Six patients underwent open surgery and three laparoscopic surgery. Subtotal colectomy was performed in seven patients, and extended left hemicolectomy with endoscopic submucosal dissection (ESD) in two patients. The emergency case underwent a Hartmann procedure due to perforation of the tumor, and following detection of an additional transverse colon tumor during pre colostomy reversal colonoscopy, completion to subtotal colectomy was performed. One patient had three synchronous malignant tumors in the colon, and another had two synchronous colonic malignancies along with another primary malignancy in the lower pole of the right kidney, for which subtotal colectomy and partial nephrectomy were performed in the same session. Four patients had multiple polypoid lesions in addition to malignant foci detected on colonoscopy. No distant metastases were identified. There was no early postoperative (<30 days) mortality. Loss of MLH1, MLH2, MSH6, or PMS2 expression was not observed in any patient except two.

Conclusion: In patients diagnosed with synchronous colon tumors, subtotal colectomy or extended hemicolectomy encompassing tumor-bearing segments alongside appropriate lymph node dissection are both surgical procedures that can be safely chosen. Colon-preserving resection may be achieved in selected patients with polypoid malignant tumors excised within safe margins using endoscopic techniques such as ESD.

Nipple-sparing mastectomy and implant reconstruction in breast cancer: Our one-year experience in a single center

Cenk Yazkan, Narmin Hajizada, Muhammet Said Aydın, Önder Özcan

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Breast cancer is the most common malignancy in women, and surgical treatment continues to play a fundamental role in the local control of the disease. Surgical approaches aim not only for good oncological outcomes but also to improve quality of life and cosmetic results. In this respect, breast tissue reconstruction (MBC) and implant-based reconstruction have become increasingly preferred approaches in the appropriate patient group. MBC offers aesthetic advantages by allowing the preservation of the breast skin and, in appropriate cases, the nipple-areola complex, and also improves psychosocial well-being when combined with implant-based reconstruction. However, the feasibility of this surgical approach requires careful evaluation of many factors such as tumor size, tumor-to-breast ratio, multifocality, axillary status, and histopathological features. This study aims to present the results of patients diagnosed with breast cancer and treated with MBC and implant reconstruction in our clinic.

Material and Methods: This retrospective, single-center study included 17 patients diagnosed with breast cancer and undergoing MBCM and implant-based reconstruction between January 2025 and January 2026. Demographic characteristics, tumor characteristics, molecular subtypes, neoadjuvant therapy (NAT) status, surgical indications, axillary surgical approach, pathological staging, length of hospital stay, and early (≤30 days) surgical complications were analyzed. Statistical evaluation was performed using descriptive methods.

Results: The mean age of the patients was 44.8 years. The most frequent histological type was ductal carcinoma (70.6%), and the most common molecular subtype was luminal A (41.2%). The most frequent surgical indication was the presence of a widespread *in situ* component (41.2%). NAT was performed in 35.3% of the patients. In all cases, reconstruction was performed with a subpectoral implant after MBKM. The overall early complication rate was 29.4%, and the major complication rate was 11.8%.

Conclusion: Nipple-sparing mastectomy and implant-based reconstruction, when performed with appropriate patient selection and a multidisciplinary approach, is a safe and effective method in breast cancer surgery that offers acceptable early surgical outcomes.

Use of intraoperative C-arm fluoroscopy in the excision of clip-/guidewire-marked breast lesions in patients who have received neoadjuvant chemotherapy

Suat Aktaş, Hasan Kumru, Fikret Ezberci, Aylin Acar, Tolga Canbak

Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul

Objective: In patients who have received neoadjuvant chemotherapy, difficulties may occasionally be encountered in the accurate intraoperative localization of breast lesions marked with clips or guidewires. Surgical planning is generally based on the report and imaging provided by the radiologist who placed the guidewire. In this study, we aimed to demonstrate that fluoroscopic imaging with a C-arm-performed both before the start of surgery to visualize the surgical field and after specimen excision to image the specimen-can facilitate the surgical process and reduce operative time.

Material and Methods: After excision of the clip-/guidewire-marked lesion, the specimen is sent for perioperative mammographic evaluation, and the completeness of lesion removal is assessed in collaboration with a radiologist. Over the past year, perioperative C-arm fluoroscopy has been used in our clinic in selected patients who received neoadjuvant chemotherapy and had breast lesions marked with clips/guidewires to optimize surgical planning and provide intraoperative confirmation. Cases with anticipated difficulty in intraoperative localization based on preoperative imaging and surgeon judgment were considered selected cases. Following induction of anesthesia and sterile field preparation, the C-arm fluoroscopy unit is positioned over the surgical area. Using a fine-tipped forceps, the position of the marker clip relative to the guidewire is assessed in a single fluoroscopic view to guide incision site selection and excision planning. After lesion excision, the specimen is re-evaluated intraoperatively using C-arm fluoroscopy. Once removal of the marker clip is confirmed, the specimen is sent for mammographic examination for detailed assessment and documentation, and the procedure is concluded after radiologic confirmation.

Results: In our limited initial experience, intraoperative evaluation of the excised lesion using C-arm fluoroscopy in the operating room was observed to provide an approximate 15-20 minute time reduction compared with waiting for the results of perioperative mammography/specimen mammography. This approach was considered to accelerate the surgeon's intraoperative decision-making process, positively contribute to morale and motivation, and allow earlier initiation of procedure completion while awaiting mammography/specimen mammography confirmation.

Conclusion: In patients who have received neoadjuvant chemotherapy, intraoperative localization of clip- and guidewire-marked breast lesions can be challenging. Our early experience suggests that perioperative C-arm fluoroscopy, used both before surgery and after lesion excision, is effective for target verification, facilitates surgical decision-making, and shortens operative time. Although intraoperative specimen radiography provides valuable support, its diagnostic performance may vary due to technical and operator-related factors. When combined with perioperative mammography, C-arm fluoroscopy can be considered a complementary technique that enhances surgical accuracy and safety in selected cases.

Simultaneous implant reconstruction in breast cancer: Risk factors and complication analysis in a single-center series

Orhan Üreyen[1], Necati Osman Okumuş[1], Cem Karaali[1], Efe Şimşekcan[2], Ata Mert Ateşçi[1], Enver İlhan[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of Plastic and Reconstructive Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

Objective: With the increasing adoption of skin-sparing mastectomy (SSM) and nipple-sparing mastectomy (NSM) in breast cancer surgery, immediate implant-based reconstruction has become a standard approach. However, the growing use of neoadjuvant therapies and the potential need for postoperative radiotherapy have made patient selection increasingly critical in terms of complication risk and surgical outcomes. This study aimed to evaluate early and late complications as well as potential risk factors in patients who underwent immediate permanent implant reconstruction in our single-center experience.

Material and Methods: A retrospective analysis was performed on 20 female patients who underwent mastectomy for breast cancer or prophylactic indications with simultaneous permanent implant reconstruction at our center over the past two years. Clinical stage (TNM), molecular subtype, history of neoadjuvant and adjuvant therapies, type of mastectomy (NSM/SSM), implant placement plane (prepectoral/subpectoral), and postoperative complications were recorded. Data were analyzed using descriptive statistical methods.

Results: The mean patient age was 44.1 years (range: 29-53), and the mean body mass index (BMI) was 26.2 kg/m^2 (range: 22-30). Active smoking was present in 30% of patients. Oncologic profile: At diagnosis, 70% of patients had invasive ductal carcinoma, 15% invasive lobular carcinoma, and 5% papillary carcinoma. Molecular subtype distribution was as follows: luminal A 40%, luminal B 35%, and triple-negative 10%. Two patients (10%) underwent prophylactic surgery. Neoadjuvant chemotherapy was administered in 45% of patients, and 45% received postoperative radiotherapy. The most common clinical stage was T2 (55%) with N0 disease observed in 60% of cases. Surgical data: NSM was performed in 85% of cases, while SSM was performed in 15%. Subpectoral implant placement was preferred in 19 patients, and prepectoral placement in one patient. The mean implant volume was 323 cc. Complications: Early complications included one case of skin necrosis, one case of nipple necrosis, and one case of wound complication. The overall implant loss rate was 10% (n=2). Both patients with implant loss had T2 disease, lymph node positivity, and had received neoadjuvant therapy; one patient had a BMI of 30, while the other was an active smoker. As a late complication, scar revision was required in six patients.

Conclusion: Immediate permanent implant reconstruction provides acceptable complication rates when appropriate patient selection is applied. However, the coexistence of neoadjuvant therapy, lymph node positivity, elevated BMI, and active smoking appears to constitute a notable risk profile for implant loss. Therefore, careful evaluation is recommended when considering single-stage implant reconstruction in this patient population.

Prognostic value of HALP score in patients with gallbladder carcinoma

Değercan Yeşilyurt[1], Samet Gökçedağ[1], Doğukan Birinci[1], Esma Bilgiç[2], Fuat Aksoy[1]

[1]*Department of General Surgery, Bursa Uludağ University Faculty of Medicine, Bursa*

[2]*Bursa Uludağ University Faculty of Medicine, Bursa*

Objective: Gallbladder carcinoma is an aggressive malignancy with poor prognosis. Recently, inflammation-based biomarkers have gained attention as potential prognostic indicators in various cancers. The hemoglobin, albumin, lymphocyte, and platelet (HALP) score reflects both nutritional and inflammatory status and has been associated with survival outcomes in several malignancies. However, its prognostic role in gallbladder carcinoma remains unclear. This study aimed to investigate the association between HALP score and overall survival in patients with gallbladder carcinoma.

Material and Methods: This retrospective study included patients diagnosed with gallbladder carcinoma at Bursa Uludağ University in 2010-2025. HALP score was calculated using the formula: HALP = hemoglobin × albumin × lymphocyte/platelet. Clinical and laboratory data were obtained from medical records. Overall survival was evaluated, and patients were categorized into groups according to their HALP scores. Survival outcomes were compared between groups.

Results: The mean age of the 85 patients was 70 years. There were 28 male and 57 female patients. The median HALP score of the patients was 44. In preliminary analyses, patients with lower HALP scores tended to have shorter overall survival, with a mean survival of 6 months. In contrast, patients with higher HALP scores had a longer mean survival of 12 months. The difference between the groups was statistically significant. These findings suggest that the HALP score may be associated with prognosis in patients with gallbladder carcinoma.

Conclusion: The HALP score may serve as a simple and easily accessible biomarker reflecting systemic inflammation and nutritional status in patients with gallbladder carcinoma. Further studies with larger patient cohorts are required to confirm its prognostic value.

Keywords: Gallbladder carcinoma, HALP score, survival

Metaplastic breast cancer: Case series

Mustafa Talha Bayram[1], Melek Gökova[1], Murat Kemal Atahan[2], Emine Özlem Gür[1], Ayşe Yazıcı[3], Yeliz Yılmaz Bozok[1]

[1]*Department of General Surgery, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

[2]*Clinic of General Surgery, İzmir Acıbadem Kent Hospital, İzmir*

[3]*Department of Pathology, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir*

Objective: Metaplastic breast carcinoma (MBC) is a rare subtype accounting for less than 1% of all invasive breast cancers. Clinically, it is typically observed in women over 50 years of age and is characterized by rapid growth, larger tumor size, lower rates of axillary lymph node involvement, and poorer prognosis compared with other breast cancer subtypes. Axillary lymph node metastasis has been reported in 25-30% of cases. Even in node-negative patients, recurrence rates range from 35-62% within 2-5 years. The risk of distant metastasis is higher than that of invasive ductal carcinoma. Due to its rarity, aggressive biological behavior, and limited response to standard treatment approaches, diagnosis and management remain challenging. In this study, we present a single-center series of 54 patients with MBC.

Material and Methods: A retrospective analysis was performed on 54 patients diagnosed with MBC and treated at our institution. Surgical management consisted of modified radical mastectomy or breast-conserving surgery. Axillary lymph node dissection or sentinel lymph node biopsy was performed when indicated. Demographic characteristics, surgical procedures, tumor size, axillary lymph node status, tumor stage, and adjuvant treatments were obtained from the institutional database. Statistical analyses were conducted using SPSS version 21. Continuous variables were expressed as mean ± standard deviation or median (interquartile range), as appropriate.

Results: A total of 54 female patients who underwent surgery between 2010 and 2025 were included in the study. The mean tumor diameter was 41.9 mm, and 83.3% of the patients had tumors larger than 20 mm. Histopathological evaluation demonstrated that the most common subtype was metaplastic carcinoma with mesenchymal differentiation (31.4%), followed by the squamous cell subtype (27.7%). Axillary lymph node metastasis was detected in 20.4% of the patients. Surgically, modified radical mastectomy was performed in 57.4% of cases, while 42.6% underwent breast-conserving surgery. Nearly all patients received postoperative adjuvant therapy. The lung was the most common site of distant metastasis.

Conclusion: Despite a relatively low rate of axillary lymph node involvement, MBC demonstrates aggressive clinical behavior characterized by large tumor size, high proliferation index, and hormone receptor negativity. Our single-center experience contributes to the existing literature regarding the clinicopathological features of MBC. A multidisciplinary approach and larger prospective studies are needed to optimize management strategies.

Keywords: Metaplastic, breast cancer, case series

Return to work after obesity surgery

İbrahim Özalp[1], İlke Karabağ[2], Başak Güven[3], Alper Güven[4]

[1]*Clinic of General Surgery, Private Akdamar Hospital, Van*

[2]*Department of Occupational and Environmental Diseases, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[3]*Department of Public Health, Division of Occupational and Environmental Diseases, Hacettepe University Faculty of Medicine, Ankara*

[4]*Department of Gastroenterology Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Obesity is a public health problem with increasing global prevalence and numerous comorbidities. Obesity surgery is considered an effective treatment option for achieving permanent weight loss and metabolic improvement. Reduced mortality and morbidity in the postoperative period, as well as increased functional capacity and reintegration into social life, are among the key indicators determining the success of the treatment. In this context, the return-to-work process after obesity surgery is important in terms of individual, social, and economic outcomes. The timing of return-to-work after obesity surgery varies depending on the surgical technique, perioperative complications, rate of weight loss, comorbidities, and the physical and psychosocial requirements of the individual's job. However, the literature shows limited data on the timing of return-to-work, suitability criteria, and long-term workforce participation after obesity surgery. This study was conducted to evaluate the postoperative return-to-work processes and the factors affecting this process in individuals who underwent bariatric surgery.

Material and Methods: Our study was conducted on patients who underwent bariatric surgery within the last year and are actively employed. Individuals who agreed to participate in the study were given questionnaires prepared via Google Forms.

Results: Patients invited to the study, 16 were actively employed. Eight (50.0%) patients reported taking at least threedays of sick leave due to health problems, and nine(56.2%) reported visiting a healthcare facility at least twice a year. The average postoperative hospital stay was 8.3±2.1 days. After returning to work following surgery, nine (56.2%) patients reported visiting ahealthcare facility at least once due to health problems, six (37.5%) reported taking sick leave due to health problems. Three pre-operative (18.7%) and one post-operative (6.2%) patients reported having to change jobs due to health problems. Post-operative work efficiency increased in six patients (37.5%), remained unchanged in eight patients (50.0%), and decreased in two patients (12.5%). During the return-to-work process, four of the six patients reported receiving support from their family, and two from their colleagues. One of three patients reported feeling like a burden to their colleagues before surgery, one after surgery, and one both before and after surgery. Eight patients (50.0%) reported experiencing psychological problems before surgery. Postoperatively, psychological problems decreased in four of these patients and increased in one. Access to appropriate postoperative dietary recommendations was available at work for eight patients (50.0%) and at home for fifteen patients (93.7%).

Conclusion: The findings indicate that developing supportive policies in workplaces and integrating them into the organizational culture to mitigate the challenges of the return-to-work process can improve employee job adjustment and productivity.

Postoperative intensive care patients the role of human factors and equipment use in fall prevention

Mehmet Ali Eryılmaz, Ahmet Sert, Meral Taşkın, Yasemin Sert

University of Health Sciences Türkiye, Konya City Hospital, Konya

Objective: This study aimed to evaluate the role of human factors and equipment use in preventing falls among patients monitored in the postoperative intensive care unit (ICU). Postoperative ICU patients are at high-risk of falls due to factors such as altered consciousness, limited mobility, and the use of analgesic and sedative medications. In this context, the study aimed to systematically assess fall risk and to determine the contribution of nursing care practices to patient safety.

Material and Methods: This retrospective and descriptive study was conducted in the adult general ICU 3 of a training and research hospital. Between 01/06/2025 and 31/12/2025, the records of 835 ICU patients were reviewed. According to the inclusion and exclusion criteria, 381 patients were excluded, and the study sample consisted of 454 postoperative patients. Data were collected using the patient identification form and the İTAKİ fall risk assessment scale. As part of standard care practices, bedside rails, wheelchairs, patient lifting slings, transfer boards, walkers, and non-slip, appropriately sized slippers were used in the unit.

Results: The mean fall risk score of the patients included in the study was 19.66. Female patients had higher fall risk scores compared with male patients (21.09 vs. 17.81). Higher fall risk scores were observed in patients with a length of stay longer than three days, a body mass index ≥25, three or more drains or catheters, and the presence of chronic disease.

Conclusion: Postoperative intensive care patients were found to be at high-risk for falls. Nursing care practices focusing on human factors, along with the standard and appropriate use of fall-prevention equipment, play a significant role in enhancing patient safety and reducing fall risk.

Keywords: Fall risk assessment, patient safety, postoperative intensive care

Table 1. Distribution of equipment used to prevent falls in postoperative intensive care patients according to their areas of use

Equipment type	Equipment used
Bed safety	Bed rails
Transfer equipment	Patient lifting lifts, transfer boards
Mobilization equipment	Wheelchair, walker
Personal protective equipment	Non-slip, patient-sized slippers/shoes

Fall prevention equipment by application area.

Table 2. Distribution of fall risk scores according to patients' demographic and clinical characteristics

Variable	Category	Average fall risk score
Gender	Woman	21.09
Gender	Men	17.81
Hospitalization duration	>3 day	23.19
BMI	≥25	20.02
Chronic disease	Yes	20.11

Fall risk scores based on patients' demographic and clinical characteristics (low risk: <10 points, high-risk: ≥10 points).

Comparison of early phase inflammatory markers in open and laparoscopic right hemicolectomy

Doğaç Demir, Mert Baymak, Muhammet Ali Aydemir, Tuğrul Özdemir, İrem Erol, Sobhi Skaik, Orhan Alimoğlu

Department of General Surgery, İstanbul Medeniyet University Faculty of Medicine, Göztepe Prof. Dr. Süleyman Yalçın City Hospital, İstanbul

Objective: With the widespread adoption of laparoscopic techniques today, laparoscopic surgery is increasingly preferred over open surgery due to the benefits of minimally invasive surgery. One of the proposed benefits is that it causes less trauma due to more minimal skin, subcutaneous tissue, and fascia incisions. In this study, the aim was to compare postoperative inflammatory markers in right hemicolectomy cases to assess the body's inflammatory response to trauma following these procedures.

Material and Methods: The study included 229 patients who underwent right hemicolectomy due to colon cancer between 2015 and 2025. Emergency cases and patients who underwent surgery for benign reasons other than colon cancer were excluded from the study. Preoperative and postoperative leukocyte, neutrophil, lymphocyte, and CRP values were recorded on days 1, 3, and 5 for the included patients. Before comparison, propensity score matching was performed at a 1:3 ratio, and 41 patients from the laparoscopy group were matched with 123 patients from the open surgery group. Age, gender, history of neoadjuvant therapy, and tumor histopathology were used for propensity score matching.

Results: Preoperative leukocyte, lymphocyte, neutrophil, and CRP values showed no difference between the two groups, indicating that the groups were evenly distributed. ($p>0.05$) On the first day after surgery, the CRP value was measured as an average of 105.11 in the open group and 79.91 in the laparoscopic group ($p=0.009$), showing that the CRP value was significantly lower in the laparoscopic group. Although statistically insignificant, the mean values of leukocytes, lymphocytes, and neutrophils on the first postoperative day tended to be lower in the laparoscopic group. There was no statistically significant difference in leukocyte, lymphocyte, and neutrophil values between the open and laparoscopic methods on the third postoperative day. On the 5th postoperative day, the mean CRP, leukocyte, and neutrophil values were minimally lower in the laparoscopic group, although this was not statistically significant.

Conclusion: In the comparison of early-phase acute-phase reactants in open and laparoscopic right hemicolectomy, it was determined that the CRP value on day 1 was significantly lower in the laparoscopic method. Although there was no difference between the groups on days 3 and 5, there was a tendency for lower values in the laparoscopic group.

Artificial intelligence-based prediction of length of hospital stay after colorectal surgery

Simge Nur Huseynov, Erdinç Çetinkaya, Sermet Terzi

Hacettepe University Faculty of Medicine Hospital, Ankara

Objective: Length of hospital stay is among the most frequent concerns expressed by surgical patients. Colorectal procedures may necessitate prolonged hospitalization due to postoperative care requirements and potential complications. Artificial intelligence systems have recently become widely accessible and may serve as practical decision-support tools for clinicians in predicting hospital stay. This study aimed to assess the reliability of AI-assisted estimation of postoperative length of stay in patients undergoing colorectal surgery.

Material and Methods: This retrospective observational study included randomly selected patients operated between 2018 and 2026 at Hacettepe University Faculty of Medicine Hospital. Demographic features, perioperative characteristics, surgical details, and oncologic treatment data were extracted from medical records and standardized for analysis. A total of 90 patients representing nine different colorectal procedures were evaluated. These operations included right hemicolectomy, total abdominal colectomy, rectopexy, left hemicolectomy, abdominoperineal resection, sigmoid resection, colocolonic anastomosis, low anterior resection, and segmental colon resection. Exclusion criteria comprised age <18 years, missing data, mortality within 30 days, ICU stay >48 hours, concurrent major surgery, non-surgical complications likely to prolong hospitalization, and cases without AI-generated predictions.

Results: Forty-nine patients were male and 41 were female; median age was 64 years and median hospital stay was 8 days. Twenty-seven procedures were emergency and 63 elective. Eigh-teen patients received chemotherapy, nine radiotherapy, and four both. Stoma formation was performed in 11 patients and was significantly associated with emergency surgery (p=0.001). Allowing a ±1 day margin, accuracy rates were 77% for ChatGPT, 74% for Gemini, and 72% for Grok. Advanced age, comorbidity burden, emergency surgery, and stoma creation were associated with longer hospitalization. Because the dataset consisted of paired non-parametric measures, the Wilcoxon signed-rank test was applied; p<0.05 was considered significant. No difference was observed for GPT (p=0.642) or Gemini (p=0.851), whereas Grok demonstrated significant deviation (p=0.00021).

Conclusion: AI-based approaches may meaningfully support clinical decision-making when estimating hospital stay after colorectal surgery. Nevertheless, model performances are not interchangeable, making appropriate selection essential for routine practice.

Keywords: Artificial intelligence, colorectal surgery, clinical decision support systems

A single surgeon's 6-year experience in 181 cases of thyroid surgery: A retrospective analysis from a tertiary center

Nazım Güreş[1], Muratcan Fırat[2], Server Sezgin Uludağ[2]

[1]*Balıkesir Atatürk City Hospital, Balıkesir*

[2]*İstanbul University Cerrahpaşa Faculty of Medicine, İstanbul*

Objective: Thyroid disorders are a common clinical challenge, with surgical intervention serving as a cornerstone of management for conditions ranging from symptomatic benign goiters to various types of thyroid carcinoma. The impact of surgeon volume on patient outcomes is a well-established principle in surgical oncology and endocrine surgery. High-volume surgeons, often defined as those performing more than 25 thyroidectomies annually, have consistently demonstrated lower rates of surgical complications such as permanent hypocalcemia and recurrent laryngeal nerve (RLN) injury. This is attributed to a refined surgical technique, meticulous attention to preserving the parathyroid glands and RLN, and a streamlined approach to complex cases. As such, single-surgeon series from high-volume tertiary centers serve as critical benchmarks for evaluating surgical safety and efficacy against international standards. This study retrospectively analyzes a single endocrine surgeon's 6-year experience, encompassing 181 consecutive thyroid surgeries. We present a comprehensive overview of patient demographics, the distribution of thyroid pathologies, and the indications for surgery.

Material and Methods: This retrospective cohort study included 181 consecutive patients who underwent thyroidectomy or lobectomy by a single endocrine surgeon at a tertiary referral center between March 2019 and August 2025. All procedures were performed under general anesthesia within a dedicated endocrine surgery unit.

Results: The cohort was predominantly female (85.1%) with a mean age of 53.9 years. The most common preoperative diagnoses were non-toxic multinodular goiter (37.0%) and papillary thyroid carcinoma (PTC) (23.2%). A significant proportion of non-toxic goiters (34.3%) were operated on due to two prior biopsies showing atypia of undetermined significance. The overall malignancy rate was 24.9%, consistent with published literature. The most frequent procedure was total thyroidectomy (61.9%), with bilateral central neck dissection performed in 14 PTC patients due to suspicious lymph nodes and in one patient with medullary thyroid carcinoma. The mean operation time was 85 minutes, and the average hospital stay was 1.2 days. Postoperative complications included transient hypocalcemia in 12.7% of patients and permanent hypocalcemia in 1.7%. A hematoma requiring reoperation occurred in a single hemodialysis patient. Transient voice quality reduction was observed in 2.8% of patients, with no permanent RLN palsy, superior laryngeal nerve injury, or swallowing difficulty.

Conclusion: The low incidence of complications highlights the safety and efficacy of thyroid surgery when performed by a specialized, high-volume surgeon in a dedicated center. These results align with international benchmarks and underscore the importance of surgical expertise in optimizing patient outcomes.

Keywords: Single surgeon, superior laryngeal nerve injury, thyroid surgery

Table 1. Complications and incidence rates

Complication	Incidence (n, %)	Details
Transient hypocalcemia (≤1 month)	23 (12.7)	Resolved with supplementation
Permanent hypocalcemia (>6 months)	3 (1.7)	Lifelong supplementation required
Hematoma requiring reoperation	1 (0.6)	Single hemodialysis patient
Transient voice reduction (≤6 weeks)	5 (2.8)	Resolved spontaneously or with voice therapy
Permanent RLN palsy	0 (0)	-
Superior laryngeal nerve injury	0 (0)	-
Swallowing difficulty	0 (0)	-
Tracheomalacia	0 (0)	- (All BAS-symptomatic patients informed preoperatively)
Infection	1 (0.6)	Superficial, managed medically
Total complications	33 (18.2)	-

RLN: Recurrent laryngeal nerve.

Table 2. Performed surgical procedures

Procedure	Number of patients (n, %)
Total thyroidectomy	112 (61.9%)
Hemithyroidectomy	45 (24.9%)
Total thyroidectomy + bilateral central neck dissection	15 (8.3%)
Completion thyroidectomy	5 (2.8%)
Other (e.g., subtotal)	4 (2.2%)
Total	181 (100%)

[P-387]

Clinicopathological characteristics and follow-up outcomes of patients undergoing hepatectomy for colorectal liver metastases: A single-center experience

Bilgi Karakaş, Baki Türkoğlu

University of Health Sciences Türkiye, Gülhane Training and Research Hospital, İstanbul

Objective: Colorectal liver metastases (CRLM) are among the most important factors determining the prognosis of colorectal cancer. In selected patients, hepatic resection constitutes the cornerstone of curative treatment. Previous studies have reported 3-year survival rates of 30-60% and 5-year survival rates of 16-51% following liver resection in patients with CRLM. This study aimed to descriptively evaluate the clinicopathological characteristics, treatment approaches, and follow-up outcomes of patients who underwent liver resection for CRLM at our center.

Material and Methods: This retrospective, single-center study included patients who underwent liver resection for CRLM. Demographic data, primary tumor characteristics, patterns of metastatic disease, surgical and oncological treatments, and follow-up data were reviewed. The data were analyzed using descriptive statistics and presented as median (range) or number (percentage).

Results: A total of 49 patients were included in the study. The median age at the time of liver resection was 59 years (25-85), and 65.3% of the patients were male. The primary tumor was located in the rectum in 55.1% of patients, in the left colon in 24.5%, and in the right colon in 14.3%. Liver metastases were synchronous in 44.9% and metachronous in 55.1% of cases. The median number of liver metastases was 1 (range, 1-11), and the median diameter of the largest metastasis was 4.0 cm (1.0-12.3). Bilobar involvement was present in 34.7% of patients. Resection of two or fewer segments was performed in 51.02% of patients, while resection of three or more segments was performed in 48.98%. At 24 months of follow-up, 73.47% of patients were alive, whereas 26.53% had died. No evidence of disease was observed in 24.5% of patients, while persistent or recurrent disease was present in 67.3%.

Conclusion: This single-center descriptive study demonstrates that, in patients undergoing surgical treatment for colorectal liver metastases, hepatic resection can provide acceptable long-term survival and disease control with careful patient selection. Despite heterogeneous metastatic patterns and varying tumor burdens, the achievement of disease-free follow-up in a substantial proportion of patients underscores the importance of a multidisciplinary approach and individualized treatment strategies. The findings highlight the central role of surgery in the management of colorectal liver metastases and reflect a valuable institutional experience that may serve as a basis for further survival analyses as well as prognostic and predictive modeling studies.

Keywords: Colorectal cancer, colorectal liver metastases, hepatectomy

Table 1. Liver metastases characteristics

Synchronous metastases	**22 (44.9%)**
Metachronous metastases	27 (55.1%)
Number of metastases, median (range)	1 (1-11)
Largest metastasis diameter, cm, median (range)	4.0 (1.0-12.3)
Bilobar involvement	17 (34.7%)

Timing, number, and distribution of liver metastases.

Table 2. Follow-up outcomes and disease status

Alive	28 (57.1%)
Deceased	18 (36.7%)
Disease-free follow-up	12 (24.5%)
Persistent/recurrent disease	33 (67.3%)

Patients' vital and oncological status.

Table 3. Demographics and primary tumor characteristics

Number of patients	**49**
Age, median (range)	59 (25-85)
Male	32 (65.3%)
Rectum	27 (55.1%)
Left colon	12 (24.5%)
Right colon	7 (14.3%)

Demographic characteristics of the patients and the location of the primary tumor.

Recurrence and omental metastasis 10 years after distal pancreatectomy in a young patient due to solid pseudopapillary tumor: Discussion of the decision for total pancreatectomy

Muzaffer Çınar, Adnan Kuvvetli

University of Health Sciences Türkiye, Adana City Training and Research Hospital, Adana

Objective: Solid pseudopapillary tumor is a rare pancreatic neoplasm with low malignant potential, typically observed in young patients. Although the prognosis after surgical resection is favorable, local recurrence and metastases are rarely reported during long-term follow-up. This case is presented to highlight the challenges in the surgical decision-making process due to recurrence and omental metastasis following a long-term follow-up period.

Material and Methods: This is the study of a patient undergoing treatment in our clinic.

Results: A 25-year-old male patient underwent a distal pancreatectomy 10 years ago due to an intra-abdominal mass, with the pathology reported as a solid pseudopapillary neoplasm. Following a 10-year period without follow-up, he was referred to our clinic after a pancreatic mass was detected during a routine check-up. The patient was asymptomatic at the time of admission, and his physical examination was unremarkable. Sectional imaging revealed an approximately 6.5×5.5 cm lesion at the head and body of the pancreas, along with multiple omental lesions, the largest measuring 2 cm. PET-CT demonstrated FDG uptake in the pancreas and omentum. After evaluation by the tumor board, an excisional biopsy was planned. During laparotomy, a mass in the pancreas and multiple malignant masses in the omentum were identified, and an omentectomy was performed. The pathological examination was reported as "Solid Pseudopapillary Tumor Metastasis" (Ki-67: 1%). Due to the low malignant character but the presence of progression, options for total pancreatectomy or continued observation are currently being evaluated by a multidisciplinary team.

Conclusion: In patients diagnosed with solid pseudopapillary tumors, recurrence and distant organ metastasis should be kept in mind even more than 10 years after surgery. Treatment decisions must be individualized, taking into account the patient's age and quality of life. Despite a low proliferation index in young patients, radical surgical decisions such as total pancreatectomy should be carefully evaluated. This case emphasizes the significance of long-term follow-up and an individualized treatment approach

Keywords: Omental metastasis, solid pseudopapillary tumor, total pancreatectomy

[P-389]

Laparoscopic appendectomy: A reliable multi-action approach and clinical outcomes

Mustafa Aykut Dadaşoğlu

Milas State Hospital, Muğla

Objective: Acute appendicitis is one of the most common abdominal pathologies requiring emergency surgery. Laparoscopic appendectomy offers advantages such as low morbidity, short hospital stay, and rapid recovery due to its minimally invasive nature. However, the sustainability of surgical success is possible not only through technical proficiency but also through a multi-faceted approach that involves the integrated management of preoperative, intraoperative, and postoperative processes.

Material and Methods: In this study, patients who underwent laparoscopic appendectomy with a diagnosis of acute appendicitis were retrospectively evaluated. The surgical process was examined under three main headings: preoperative optimization, step-by-step intraoperative surgical technique, and evidence-based postoperative follow-up. In the preoperative period, patients were optimized according to clinical, laboratory, and imaging findings. During the intraoperative phase, reliable multiple actions were performed step-by-step using the standard three-port technique. In the postoperative period, patients were followed up according to evidence-based monitoring protocols. Clinical outcomes were evaluated based on length of hospital stay, readmission rates, and postoperative complications. Complications were categorized according to the Clavien-Dindo classification.

Results: A total of 51 patients were included in the study. The median age of the patients was 36±8.97. Thirty-nine patients were male (76.5%), and 12 were female (23.5%). The median length of hospital stay was 1±0.40 days. The median time to readmission was 2±0.39 days. Postoperative complications were evaluated according to the Clavien-Dindo classification. Accordingly, no complications were detected in 49 patients (96.1%) (Clavien-Dindo 0). One patient (2.0%) developed a Clavien-Dindo class I complication, and one patient (2.0%) developed a Clavien-Dindo class II complication. No further complications were observed. No patient required conversion to open surgery, and no mortality was detected.

Conclusion: Laparoscopic appendectomy is a reliable and effective surgical method when performed using a multi-action approach that includes preoperative optimization, standardized intraoperative surgical steps, and evidence-based postoperative follow-up processes. This comprehensive approach provides positive clinical outcomes with low complication rates, short hospital stays, and limited readmission rates. The fact that postoperative complications are largely low-grade (Clavien-Dindo class I-II) indicates that the method is a predictable and manageable surgical option in terms of patient safety. Consequently, the structured multi-action approach integrated into laparoscopic appendectomy improves surgical quality and establishes an effective standard in modern acute appendicitis management.

Keywords: Laparoscopic appendectomy, surgical safety, reliable multi-action

Excisional biopsy with radiolabeled occult lesion localization (ROLL) in non-palpable inguinal and axillary lymph nodes: A single-center experience

Simge Tuna, Cumhur Özcan, Sami Benli, Seren Selçuk, Tahsin Çolak

Mersin University Faculty of Medicine, Mersin

Objective: Radioguided Occult Lesion Localisation (ROLL) technique was developed to locate the target lesion intraoperatively in non-palpable lymph nodes; however, data in extra-mammary locations is lacking. The aim of this study is to evaluate the diagnostic efficacy and safety of excisional biopsy performed with ROLL in non-palpable lymph nodes and to demonstrate the clinical contribution of the ROLL technique in this patient group.

Material and Methods: Patients who underwent ROLL-guided excisional biopsy for non-palpable enlarged lymph nodes at Mersin University Faculty of Medicine between 2021 and 2025 were retrospectively reviewed. Patients who has palpable lymph nodes and diagnosed with breast cancer excluded from study. Patients were evaluated in terms of diagnostic adequacy, correlation of ultrasound with histopathology, complications, and differences between localizations.

Results: The study included 86 patients. The mean age was 52.9±16.5 years, and 55.8% of patients (n=48) were female. Thirty-two patients (37.2%) underwent surgery in the inguinal region, and 54 patients (62.8%) underwent surgery in the axillary region. The preliminary diagnosis were lymphoma/lymphoproliferative disease (n=46, 53.5%), suspected malignancy/metastasis (n=20, 23.3%), solid tumor (n=8, 9.3%), cutaneous lymphoma (n=7, 8.1%), inflammatory/infectious disease (n=3, 3.5%), and rheumatological disease (n=2, 2.3%). The mean ultrasound size of lymph nodes was 20.7±8.5 mm. Malignant histology was detected in a total of 21 patients (24.4%). When comparing lymph nodes removed from the axillary and inguinal regions, the mean USG size (23 vs. 15 mm) and the size of the excised lymph node (3.1±1.5 vs. 2.2±0.8 cm) were found to be statistically significant ($p<0.05$). Age was identified as the only significant predictor of malignancy (57.8±15.9 years vs. 51.3±16.5 years; $p=0.049$). Of the patients who underwent preoperative FNAB (n=31), 15.1% (n=13) were benign, 18.6% (n=16) were atypical/excision recommended, and 2.3% (n=2) were malignant. Of the 18 patients with atypical or malignancy reported on FNAB, true malignant histology was detected in 66.7% (n=12) (PPV: 66.7%). None of the 13 patients with benign FNAB results had malignant histology. Malignant histology was detected in 16.4% of the 55 patients who did not undergo FNAB. The mean length of hospital stay was 1.63±0.93 days. Complications were observed in 14 patients (16.3%), including seroma (n=7), hematoma (n=5), and abscess (n=2).

Conclusion: The ROLL-guided excisional biopsy performed at our clinic is an effective and safe method for non-palpable lymph nodes. In situations where imaging alone is insufficient, considering the diagnostic limitations and risk of false negatives associated with FNAB, the ROLL technique should be integrated into the diagnostic algorithm for this patient group.

Clinical outcomes of arterial reconstruction techniques in kidney transplant recipients with multiple renal arteries

Yasin Tosun, Deniz Can Irmak, Aytaç Emre Kocaoğlu, Hasan Fehmi Küçük

University of Health Sciences Türkiye, Kartal Dr. Lütfi Kırdar City Hospital, İstanbul

Objective: Over recent decades, refinements in operative techniques together with the use of contemporary immunosuppressive protocols have led to marked improvements in both graft function and patient survival. Despite these advances, the ongoing scarcity of suitable donor organs remains a significant limitation, compelling transplant surgeons to utilize grafts with complex anatomical features. In this context, vascular anatomical variations—most notably multiple renal arteries (MRA)—represent a frequent and clinically relevant challenge. In the present study, we retrospectively analyzed the effectiveness and clinical outcomes of the vascular reconstruction techniques employed in kidney transplant recipients with MRA.

Material and Methods: A total of 67 kidney transplant recipients were analyzed by dividing them into three groups according to the arterial anastomosis technique used: Epigastric artery anastomosis (group 1, n=21), double artery side-by-side anastomosis (group 2, n=36), and two separate iliac artery anastomoses (group 3, n=10). Postoperative urea, creatinine, complications, and Doppler ultrasound images were compared between the groups.

Results: The rates of seroma or hematoma development detected by ultrasonography in the postoperative period were found to be comparable between the groups (p=0.99). While no significant difference was found in early postoperative serum creatinine levels (p=0.73), the mean follow-up periods were also similar between the groups (p=0.82). Overall, no statistically significant difference was observed between the three arterial anastomosis techniques in terms of short-term postoperative clinical and laboratory results.

Conclusion: Multiple renal arteries can be safely managed using a variety of vascular reconstruction techniques without compromising graft function or increasing perioperative complication rates. In our cohort, no significant differences in clinical outcomes were observed among the different anastomotic strategies, suggesting that the choice of technique may be guided primarily by anatomical considerations and surgical expertise.

Keywords: Renal transplant, multiple artery, epigastric anastomosis

Evaluation of 4th-year medical students' perspectives on the general surgery specialty in the context of clerkship experience

Osman Atalay, Ömer Kişi, Alper Varman

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: In recent years, it has been observed that medical students are increasingly distancing themselves from surgical specialties and leaning towards "lifestyle" specialties due to demanding working conditions and malpractice concerns. This study aims to evaluate the perceptions of 4th-year medical students regarding the general surgery specialty and to investigate the impact of early clinical exposure (clerkship experience) on their career choices.

Material and Methods: This observational, cross-sectional study included 133 4th-year medical students. The participants were divided into two groups: those who "have completed/are taking the general surgery clerkship" (n=65) and those who "have not yet taken it" (n=68). Data were collected using a 6-item questionnaire with a 5-point Likert scale, which evaluated demographic characteristics and professional perceptions (prestige, work-life balance, malpractice, professional satisfaction, and intention to choose surgery in the Medical Specialty Examination - TUS). Mann-Whitney U and chi-square tests were used for statistical analysis, with $p<0.05$ considered significant.

Results: The mean age of the participants was 23.3±0.8 years, and 53.4% were female. There was no significant difference between the groups in terms of age and gender ($p>0.05$). Initial interest in surgery and the perceived prestige of the profession were similarly high in both groups ($p>0.05$). Although agreement with the idea that "general surgeons can allocate enough time to their families" was low overall, this negative perception was significantly more pronounced in the group that had not yet taken the clerkship ($p<0.001$). Medicolegal anxiety regarding malpractice and complications was found to be significantly higher in the group with clerkship experience compared to the non-clerkship group ($p<0.001$). Conversely, the belief that general surgery provides adequate professional satisfaction ($p=0.048$) and the intention to choose general surgery in TUS ($p<0.001$) were significantly higher in the group that had received the clerkship training.

Conclusion: The general surgery clerkship increases students' medicolegal concerns, such as malpractice, as they face the realities of the field. However, operating room practice and clinical experience help mitigate unfounded prejudices regarding work-life balance, positively influencing the sense of professional satisfaction and the motivation to pursue a surgical career. To reduce vacancies in surgical residency programs, it is critical to increase active clinical involvement and foster positive role-model relationships during clerkship education.

Keywords: General surgery, clerkship, career choice

Surgical treatment and oncological outcomes in gastrointestinal stromal tumors: A single-center experience

Aslıhan Sarı, Müge Yurdacan Şahin, Mahmut Said Değerli, Nurettin Şahin, Ahmet Sürek, Murat Çikot

University of Health Sciences Türkiye, Bakırköy Dr. Sadi Konuk Training Research Hospital, İstanbul

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract. Surgical management is guided by tumor location, size, and risk classification, and laparoscopic approaches have become increasingly adopted. This study evaluated the clinicopathological features, surgical strategies, and oncological outcomes of patients undergoing surgery for GIST.

Material and Methods: Eighty-eight patients who underwent surgery for GIST between 2015 and 2025 were retrospectively analyzed. Demographic characteristics, tumor features, surgical approach, pathological risk classification (modified NIH), oncological treatment, recurrence, metastasis, and survival were assessed.

Results: Of the patients, 42 (47.7%) were female and 46 (52.3%) were male, with a mean age of 58.7±12.5 years (median, 61). The most common presenting symptoms were abdominal pain (60.2%) and upper gastrointestinal bleeding (31.8%). Emergency surgery was required in 22.7% (n=20), mainly due to bleeding. Tumor localization and risk distribution are summarized in Tables 1 and 2. Tumors were gastric in 72.7% and small intestinal in 26.1%. Within the stomach, the corpus (38.6%) and fundus (22.7%) were most frequently involved. Two incidental GISTs were detected during sleeve gastrectomy. High-risk disease was more common in non-gastric tumors (50.0%) than gastric tumors (21.9%). The median tumor diameter was 65 mm (5-450). Histologically, 55.7% were spindle cell type. Tumor necrosis, ulceration, and serosal invasion were observed in 48.9%, 34.1%, and 28.4%, respectively. Laparoscopic surgery was performed in 47.7% (n=42). The most common procedure was wedge resection (53.4%), followed by segmental resection and gastrectomy. Operative time and hospital stay were shorter in the laparoscopic group. R0 resection was achieved in 94.3%. Positive margins (4.5%) occurred in high-risk patients with tumor perforation. Adjuvant imatinib was administered to 28.4%, predominantly in high-risk cases; one patient received neoadjuvant therapy. Median follow-up was 4 years. Recurrence occurred in 4.5% and metastasis in 10.2%, most commonly to the liver. No recurrence or metastasis was observed in low-risk patients, whereas metastasis occurred in 30.8% of high-risk patients. Second primary malignancy was detected in 8.0%. Overall mortality was 3.4%.

Conclusion: Median follow-up was 4 years (1-10). Recurrence occurred in 4.5% and metastasis in 10.2%, most commonly to the liver. No recurrence or metastasis was observed in low-risk patients, whereas metastasis occurred in 30.8% of high-risk patients. Second primary malignancy was detected in 8.0%. Overall mortality was 3.4%. Laparoscopic surgery is safe and provides satisfactory oncological outcomes. The higher risk profile in non-gastric GISTs suggests the need for localization-specific follow-up, and risk stratification accurately predicts prognosis.

Keywords: Gastrointestinal stromal tumor, oncological outcomes

Table 1. Distribution of tumor localization

Localization	n (%)
Stomach	64 (72.7)
Corpus	34 (38.6)
Fundus	20 (22.7)
Antrum	6 (6.8)
Cardia	4 (4.5)
Small bowel	23 (26.1)

Is minimally invasive truly superior? Pre-evaluating laparoscopic and open incisional hernia repair based on single-center experience

Özlem Özaydın, Server Sezgin Uludağ, Sefa Ergün

İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul

Objective: Incisional hernia is a significant complication of abdominal surgery with considerable morbidity potential. Although laparoscopic repair is increasingly preferred due to its minimally invasive advantages, open surgery continues to play a role in complex defects. This study aims to compare the clinical performance of both approaches in light of the experience of İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, Department of General Surgery.

Material and Methods: Patients operated on for incisional hernia in our clinic were treated either with an open or laparoscopic approach. The choice of surgical technique was determined by defect characteristics, patient comorbidities, number of previous operations, and abdominal wall integrity. The perioperative process and early clinical outcomes were evaluated based on institutional experience.

Results: The laparoscopic approach was observed to be associated with lower wound-site complications and faster functional recovery in appropriately selected patients. The reduced tissue trauma of minimally invasive surgery provided an advantage in early postoperative comfort. However, in large and complex defects, open surgery offered a more controlled field for anatomical reconstruction and component separation techniques. Particularly in cases with advanced abdominal wall weakness, the technical reliability of the open approach was prominent.

Conclusion: Our single-center experience demonstrates that there is no single "best" method for incisional hernia repair. While the minimally invasive approach offers early postoperative advantages, the key determinant of surgical success is appropriate patient selection and an experienced surgical team. Laparoscopic and open techniques are not competing approaches but complementary methods when applied with proper indication.

Keywords: Incisional hernia, laparoscopic repair, open surgery, abdominal wall, minimally invasive surgery

Patient profile, burn etiologies, and admission patterns in University of Health Sciences Türkiye, Antalya City Hospital burn center: A retrospective descriptive study

Nimet Çat[1], Emin Türk[1], Erdal Karagülle[2], Fazlı Aladağ[2], Zeliha Akış Yıldız[1], Ayşe Karabağlı[1]

[1]*University of Health Sciences Türkiye, Antalya City Hospital, Burn Center, Antalya*

[2]*University of Health Sciences Türkiye, Antalya City Hospital, Antalya*

Objective: This study aimed to evaluate the early-period patient profile, burn etiologies, age distribution, and admission patterns of the ACH Burn Center, which became operational in 2024. By analyzing data from the initial phase, we sought to describe the clinical workload of the center and to generate practical information that may guide future planning regarding patient referral pathways, bed capacity, and intensive care unit requirements.

Material and Methods: This retrospective descriptive study included all patients treated at the University of Health Sciences Türkiye, Antalya City Hospital, Burn Center between March 1, 2024, and February 3, 2026. Patients were evaluated according to age groups (0-18, 18-55, and over 55 years), burn etiology (flame, electrical, and scald burns), mode of admission, and treatment location. Admission routes were categorized as outpatient clinic visits or emergency medical services referrals. Treatment settings were classified as outpatient clinics, inpatient wards, or intensive care units.

Results: During the study period, a total of 4.237 patients were managed at the burn center. Of these, 3.741 patients (77.2%) were followed in the adult outpatient clinic and 205 patients (4.2%) in the pediatric outpatient clinic. Inpatient treatment was required for 305 adult patients (6.3%) and 205 pediatric patients (4.2%). Intensive care follow-up was necessary for 93 adults (1.9%) and 5 pediatric patients (0.1%). Flame burns were the most common etiology, accounting for 48.4% of all admissions. Among patients with flame burns, 48.4% were aged 18-55 years, 34.6% were aged 0-18 years, and 17% were older than 55 years. A substantial proportion of flame burn patients were admitted via emergency medical services. Electrical burns constituted a smaller proportion of overall cases but were predominantly observed in adults. Patients aged 18-55 years accounted for 82.4% of electrical burn cases. The rate of admission through emergency medical services for electrical burns was 58.8%, which was higher than that observed for other burn etiologies. Scald burns were more frequent in the pediatric population, with 62.8% of cases occurring in patients aged 0-18 years. Most scald burn patients were managed on an outpatient basis, and the emergency medical services admission rate for this group was 29%.

Conclusion: The early-period experience of this newly established burn center demonstrates that while outpatient visits constitute the majority of admissions, patients requiring inpatient and intensive care treatment represent a considerable clinical workload. The observed distribution of burn etiologies and age groups is consistent with the existing literature. These findings provide real-world data that may support future institutional planning and optimization of burn care services.

The effect of intraperitoneal bupivacaine on postoperative analgesia in laparoscopic donor nephrectomy

Abdullah Furkan Toplaoğlu, Kerem Özgü, Ercan Korkut, Yücel Yüksel

Department of General Surgery, University of Health Sciences Türkiye, Gaziantep City Hospital, Gaziantep

Objective: Kidney transplantation is the gold standard treatment for end-stage renal disease. Laparoscopic donor nephrectomy (LDN) has become the preferred approach in living donors due to reduced morbidity and faster recovery compared to open surgery. However, postoperative visceral and port-site pain may delay recovery and impair patient comfort. Inadequate postoperative pain control may contribute to chronic pain development. Intraperitoneal local anesthetic instillation has been shown to improve pain control in laparoscopic surgery. This study evaluated the effect of intraperitoneal bupivacaine on postoperative pain following LDN.

Material and Methods: In this study, 120 adult living kidney donors who underwent LDN between January 1, 2021 and May 1, 2025 at University of Health Sciences Türkiye, Gaziantep City Hospital Organ Transplant Center were analyzed. Patients were divided into two groups: those who received 20 mL of 0.25% intraperitoneal bupivacaine at the end of surgery (group A, n=75) and those who did not (group B, n=45). Postoperative Visual Analog Scale (VAS) scores at 6, 12, and 24 hours and additional analgesic requirements were evaluated. A p-value <0.05 was considered statistically significant.

Results: Among 120 patients, 75 received intraperitoneal bupivacaine and 45 did not. VAS scores at 6 and 12 hours were significantly lower in group A compared to group B ($p<0.05$). No significant difference was observed at 24 hours ($p>0.05$). Additional analgesic requirements were lower in the bupivacaine group. No significant difference in complication rates was detected.

Conclusion: Intraperitoneal bupivacaine administration during LDN reduces early postoperative pain and analgesic requirements. Consistent with previous literature, this technique can be safely incorporated into multimodal analgesia protocols in living donors.

Keywords: Kidney transplantation, postoperative pain, donor nephrectomy

[P-416]

The role of artificial intelligence in robotic surgery: A bibliometric analysis

Hande Tüzün, Kübra Erdal, Fatma Cebeci

Department of Surgical Nursing, Akdeniz University Faculty of Nursing, Antalya

Objective: The field of surgery is undergoing a profound technological transformation driven by minimally invasive approaches and rapid technological advancements. While robotic surgery enhances surgical precision, artificial intelligence (AI)-based methods increasingly support clinical decision-making processes. The widespread adoption of machine learning and computer vision technologies necessitates a systematic evaluation of thematic trends within the literature. In this context, bibliometric analysis provides a robust analytical framework for mapping the intellectual landscape of the field. This study aimed to analyze the scientific literature on robotic and AI technologies in surgery using bibliometric methods to identify publication trends, thematic evolution, and emerging research priorities.

Material and Methods: A bibliometric analysis was conducted using the Web of Science Core Collection database on January 22, 2026. The literature search employed combinations of the following keywords: "surgery OR surgical procedure OR operative procedure," "AI OR machine learning OR deep learning," and "robotic surgery OR robot-assisted surgery." The retrieved data were analyzed in RStudio using relevant bibliometric packages to examine publication trends, citation patterns, and keyword distributions.

Results: Analysis of 66 studies published across 43 journals between 2018 and 2026 revealed a marked acceleration in publication and citation output, particularly after 2022, with research productivity peaking during 2024-2025. The United States demonstrated clear leadership in global scientific production (n=671). Keyword network analyses indicated that AI and robotic surgery have rapidly moved from peripheral topics to the intellectual core of surgical research. Collectively, these findings suggest that the field is approaching a technology-driven paradigm shift, with surgical care increasingly evolving toward data-intensive and intelligent systems.

Conclusion: This bibliometric study delineates the intellectual structure of the global literature on robotic and AI-driven surgical technologies, identifies critical research gaps, and highlights evolving thematic trajectories and scientific production dynamics. Future research should prioritize addressing these gaps and generating robust evidence to support clinical integration. The growing incorporation of AI and robotic technologies is redefining perioperative care, clinical decision-making processes, and patient safety responsibilities, underscoring the strategic need to strengthen the roles and competencies of nurses within technology-mediated care environments.

Clinical implications of the immune microenvironment in breast cancer: An analysis of tumor-infiltrating lymphocytes

Cenk Yazkan, Narmin Hajizada

Muğla Sıtkı Koçman University Faculty of Medicine, Muğla

Objective: Breast cancer is a heterogeneous disease shaped not only by the biological characteristics of tumor cells but also by the dynamic structure of the tumor microenvironment (TMIC). Tumor-infiltrating lymphocytes (TILs), a key component of the TMIC, represent immune cells located in the tumor stroma and peritumoral connective tissue and are considered a histopathological indicator of the antitumor immune response. Recent studies have shown that high TIL levels are associated with better survival and treatment response, particularly in biologically aggressive subtypes, especially triple-negative breast cancer. It has been reported that TILs increase pathological complete response rates after neoadjuvant chemotherapy in this patient group, thus possessing not only prognostic but also predictive biomarker potential. This study aimed to evaluate the presence and level of TILs and their relationship with clinical and histopathological features in patients diagnosed with breast cancer, and to reveal the possible prognostic and predictive clinical implications of TILs.

Material and Methods: This retrospective and observational study included a total of 37 patients who underwent surgery between January 2024 and December 2025 and whose pathology reports indicated the percentage of TILs (transient ischemic epithelial cells). The relationship between the patients' demographic, clinical, and pathological data and their TILs levels was evaluated.

Results: The mean age of the patients was 60.1±9.2 years. 45.9% (n=17) of the cases were in the high TILs (≥20%) group. Lymphovascular invasion (58.8% vs. 15.4%; p=0.019) and perineural invasion (64.7% vs. 23.1%; p=0.024) were significantly higher in the high TILs group compared to the low TILs group. A positive correlation was found between high TILs and a high Ki-67 index (r=0.482; p=0.003). No significant association was observed between TILs levels and age, tumor size, stage, hormone receptor status, and HER2 status.

Conclusion: In breast cancer, high TILs levels are associated with aggressive tumor features such as lymphovascular invasion, perineural invasion, and a high proliferative index. These findings suggest that TILs may have prognostic significance as an indicator of the local immune microenvironment. Further prospective studies are needed to elucidate their role, particularly in luminal subtypes.

The place of urachal cyst and related anomalies in the scientific literature: A bibliometric analysis based on PubMed

Emir Yetkin[1], Şükran Çavdar[4], Faruk Yazıcı[2], Muhammed Salih Süer[3], Serkan Demir[3], Alper Yavuz[3]

[1]*Polatlı Duatepe State Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[3]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[4]*Payas State Hospital, Hatay*

Objective: Urachal canal anomalies,and particularly urachal cysts,are largely represented in the literature by case reports and limited series due to their rarity and heterogeneous clinical manifestations. The aim of this study is to reveal the historical development, thematic structure, prolific authors, institutions, and countries of the scientific literature published on urachal canal cysts and related anomalies based on the PubMed database,and to analyze research trends in the field using bibliometric methods.

Material and Methods: Studies published in the PubMed database between 1956 and 2026 were searched using the keywords"urachal cyst,"urachus cyst","urachal anomaly,","urachal anomalies", and "urachal remnant". The data obtained were analyzed using Bibliometrix (R)-based software. Publication production trends,author and institutional contributions, distribution by country, keyword frequencies, Lotka and Bradford laws, thematic maps, and time-dependent topic trends were evaluated.

Results: A total of 924 publications published in PubMed between 1956 and 2026 were analyzed. The publications appeared in 364 journals; a total of 4.216 authors contributed. The annual growth rate was 2%,with a particularly noticeable increase in production after the 2000s. Bradford's Law showed that the literature was concentrated in a limited number of core journals. The most productive sources included the Journal of Pediatric Surgery, Cureus, Hinyokika Kiyo: Acta Urologica Japonica, Urology, and The Journal of Urology. Production dynamics supported a clustering tendency in Journals Focused on Pediatric Surgery and Urology. The US led production by country, followed by Japan, China, South Korea, and ürkiye. Analysis of corresponding authors revealed that most publications involved contributions from a single country, with limited international collaboration. Consistent with Lotka's Law, most authors contributed with a single publication, while a limited core group showed continuity. At the institutional level, universities/hospitals based in Japan and North America were particularly prominent. Keyword and theme analyses showed that the literature was concentrated on-the clinical-demographic axis; "humans", "male", "female" "adult", and "infant, newborn" were the most frequent terms. In thematic mapping, imaging, prenatal diagnosis, and surgical approaches were among the main themes, while topics such as cystectomy, immunohistochemistry, and urachus/pathology/surgery represented a more niche cluster. Trend analyses revealed that descriptive/pathology-heavy themes dominated in the early period, while imaging,minimally invasive surgery, and outcome-focused themes have increased in recent years.

Conclusion: This PubMed-based bibliometric analysis revealed that the literature on urachal canal cysts/urakus anomalies showed a steady but increasingly rapid production trend in recent years between 1956 and 2026; publications were concentrated around a small number of core journals (particularly in pediatric surgery and urology). Production is predominantly sourced from the US and Japan, with limited international collaboration and author contributions clustered around a small core group. The thematic pattern shows that, alongside basic clinical-demographic and imaging-focused themes, more specialized sub-themes such-as pathology/surgery (cystectomy, immunohistochemistry) are becoming increasingly prominent. By presenting a structural map of the literature on a scattered and rare clinical topic, this study provides a measurable reference framework for future multicenter, standardized, and outcome-focused research.

The etiology of surgical referrals from a second-level district hospital: Why can't we treat patients locally?

Şükran Çavdar[1], Faruk Yazıcı[3], Muhammed Salih Süer[2], Serkan Demir[2], Şener Balas[2]

[1]*Payas State Hospital, Hatay*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[3]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: We aimed to examine the etiological causes and organizational dynamics-of surgical referrals from secondary-level district hospitals to higher-level centers,assess the burden on the system in terms of local treatment options,determine the extent to which these referrals could be prevented,and reveal the potential cost implications for the healthcare system.

Material and Methods: In this retrospective observational study,patients referred from Payas State Hospital to other tertiary healthcare institutions for general surgical reasons were evaluated. Records of referrals made between January 2025 and January 2026 were reviewed, and a total of 75 patients were included in the study. Demographic data and clinical characteristics (age, gender, ASA score, triage code, hemodynamic status, andpresence/number of comorbidities), timing-of referral (during/after hours, weekday/weekend), referral etiology (primary and detailed reasons), referral logistics (transportation vehicle, distance,and-duration), and on-site treatment options were obtained from patient files and referral records. All variables were analyzed using descriptive statistics; continuous variables were presented as mean ± standard deviation or median (interquartile range), while categorical variables were presented as-counts and percentages.

Results: Seventy-five patients referred to a tertiary center for surgical reasons were included. The mean age was 44.1±18.0 years (median 40; range 27.5-58.5), and 54.7% were female. ASA distribution was ASAI 24.0%, ASAII 53.3% and ASA III 22.7%, with no ASA IV cases. Triage categories were yellow 68.0% and green 32.0%, with no red triage; 4.0% of cases were unstable. Comorbidity was present in 46.7%,with a mean of 0.83±1.10 (median 0; range 0-1). The most common diagnoses were urgent surgical need (30.7%), acute abdomen (29.3%), and follow-up for cholecystitis/pancreatitis/ileus (21.3%). Referrals occurred outside working hours in 77.3% and on weekends in 26.7%. Main referral reasons were lackof relevant specialists (60.0%) and equipment/devices (38.7%), while blood product shortage was rare (1.3%). The leading specific causes were absenceof a general surgeon (50.7%), CT malfunction/unavailability (18.7%), and lack of ultrasound (14.7%), followed by lack of anesthesia/staff (5.3%), endoscopy (4.0%), MRI and blood stock (each 2.7%), and patient request (1.3%). Transfers were mainly by regular transport (80.0%) or 112 ambulance (20.0%). Mean transfer distance and time were 14.1±18.7 km and 14.1±19.4 min (both median 8; IQR: 8-8), with no need for accompanying healthcare personnel. In-all cases, on-site treatment was-not feasible, primarily due to lack of specialist physicians (58.7%) and equipment/devices (40.0%), and rarely blood center limitations (1.3%).

Conclusion: This-study demonstrates that most surgical-referrals from secondary district hospitals to tertiary-centers stem from systemic and organizational constraints rather than clinical necessity. The predominance of stable, low-to-moderate risk patients suggests that referrals are driven more by deficiencies in human resources and basic infrastructure than by disease severity. The clustering of referrals during non-working hours and the prominence of factors such as lack of service continuity and basic imaging capacity contribute to unnecessary congestion and resource imbalance at tertiary centers. From-a-policy perspective,addressing referrals solely as an "advanced center requirement" is insufficient; targeted strengthening-of-human resources and basic infrastructure at the secondary level could substantially reduce referral burden. Viewed through a sociological lens,referral decisions reflect institutional capacity, shift conditions,and risk perception rather than isolated clinical judgment. Consequently, effective strategies should focus on-system-level planning and institutional design, enabling referral reduction while preserving patient safety and healthcare system efficiency.

A rare complication: Management of wire fracture during preoperative radiological wire localization in breast surgery

Mücahit Kaya, Mehmet Zeki Buldanlı

Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

Objective: Wire-guided excision is a widely-used and effective method for the surgical management of non-palpable breast lesions or suspicious microcalcifications. The overall complication rate has been reported to range between 2-10% in the literature. Wire-related complications are quite rare. The rate of wire fracture is reported to be less than 0.1%. In this study, we present a rare case of wire fracture occurring during radiological localization and discuss the management strategies of this complication with literature.

Material and Methods: A 59-year-old female patient underwent screening mammography, which revealed scattered punctate microcalcifications in the upper-outer quadrant of the left breast, classified as BI-RADS 4C. No palpable lesion was detected on physical examination. An excisional biopsy using wire-guided localization was planned. During the radiological localization procedure, the radiology department reported that the wire had fractured within the breast tissue. Careful and wider surgical excision was performed with the wire guidance. Complete removal of the wire and suspicious microcalcifications, and all fractured wire segments was confirmed by specimen mammography and anteroposterior chest x-ray intraoperatively. The patient was followed for 24 hours postoperatively and was discharged without any complications. Histopathological examination revealed findings consistent with fibrocystic changes (fibrosis, adenosis, ductal ectasia) and chronic mastitis. As the patient remained asymptomatic, annual clinical and imaging follow-up was recommended.

Results: Wire-guided excision of breast lesions is a safe and widely-used technique. The overall complication rate has been reported to range between 2-10% in the literature. The most common complications include hematoma (2-5%), infection (1-3%), and seroma. Positive surgical margin rates vary between 15-40% depending on the lesion type. Wire-related complications are less common. The incidence of wire migration has been reported to range between 0.1-0.7%, while wire fracture is reported to occur in less than 0.1% of cases. Possible causes of wire fracture include excessive manipulation, traction or tension during surgery, and structural weakness of the wire. Retained wire fragments may lead to serious complications such as migration, chronic inflammation, pain, and progression into the thoracic cavity. Therefore, intraoperative assessment of wire integrity, routine specimen mammography, and additional imaging in suspicious cases are recommended.

Conclusion: Wire-guided excision is a safe method for non-palpable breast lesions. Wire fracture is a rare but clinically significant complication. Awareness of this condition by both surgeons and radiologists, along with a multidisciplinary approach and the use of intraoperative imaging, plays a crucial role in preventing retained foreign bodies within the tissue.

Keywords: Intraoperative complication management- breast surgery, preoperative complication, wire-guided excisional biopsy

The role of open surgery in recurrent inguinal hernia after laparoscopic primary repair: Is national data needed?

Burak Yavuz[1], Cennet Gülnihal Şeker[1], Yiğit İskurt[1], Ediz Uymaz[2], İbrahim Halil Özata[1], Ahmet Rencüzoğulları[1], Emre Balık[1]

[1]*Department of General Surgery Koç University Faculty of Medicine, İstanbul*

[2]*ENKA Schools, İstanbul*

Objective: Recurrences following laparoscopic inguinal hernia repair (TEP/TAPP) remain a significant clinical challenge in surgical practice. Although anterior open repair is frequently preferred in this patient group, the existing literature largely consists of small case series, with insufficient national-level data regarding technical preferences, complication profiles, and long-term outcomes. This study aims to share our single-center experience and lay the groundwork for a multicenter national study.

Material and Methods: Patients who had previously undergone laparoscopic inguinal hernia repair and subsequently required open surgery for recurrence at Koç University Hospital between 2020 and 2025 were retrospectively reviewed. Demographic data, type of primary repair, side of recurrence, open repair technique employed, complications, and recurrence status during follow-up were recorded.

Results: Seven patients were included (mean age: 64.1±6.9; all male). Six patients had undergone TEP and one had undergone TAPP as the primary procedure. The distribution of recurrences was four right-sided, two left-sided, and one bilateral. Lichtenstein repair was performed in six patients and Shouldice technique in one. In one patient, the procedure was initiated laparoscopically and converted to open surgery. Mean operation duration was 114.3±37.1 minutes. Postoperatively, one patient developed hematoma and one developed orchitis. Median follow-up was 24 months (IQR: 5-42), with no re-recurrence detected in any patient.

Conclusion: Anterior open repair is a viable option for recurrent inguinal hernia following laparoscopic primary repair, with acceptable re-recurrence rates in the short-to-medium term; however, complication rates should not be overlooked. The existing literature on surgical management of recurrent inguinal hernia predominantly addresses recurrences after open primary repair. A multicenter, national-scale retrospective study is needed to reliably characterize complication predictors, technical preferences, and long-term re-recurrence rates. The data presented herein serve as a preliminary study toward this goal, with the aim of establishing a collaborative protocol.

An innovative approach in the management of hepatic hydatid cysts: Laparoscopic PAIR

İsmail Hasırcı, Abdullah Sami Maden, Ali Can Yalçın, Adil Kartal, Mehmet Ali Eryılmaz

Department of General Surgery, University of Health Sciences Türkiye, Konya City Hospital, Konya

Objective: The liver is the most commonly affected organ in hydatid disease. Although not every hepatic hydatid cyst requires intervention, surgery has traditionally been regarded as the standard treatment. In recent decades, minimally invasive techniques with outcomes comparable to open surgery have increasingly been adopted.We present a modified minimally invasive approach termed laparoscopic PAIR for selected hepatic hydatid cysts. In conventional practice, percutaneous puncture-aspirate-inject-reaspirate (PAIR) is performed under ultrasonographic guidance by interventional radiologists, provided that an adequate thickness of hepatic parenchyma overlies the cyst. Cysts lacking this safety margin are typically referred for surgery. In such cases, we perform PAIR under laparoscopic guidance in the operating room under general anesthesia. The procedural steps mirror classical PAIR, but visualization is achieved laparoscopically rather than with ultrasonography.

Material and Methods: With the patient in the supine position, pneumoperitoneum was established via an infraumbilical trocar. After diagnostic laparoscopy, additional trocars (one 10-mm and two accessory ports; total three trocars) were placed according to cyst location. Following careful isolation of the operative field, puncture, aspiration, injection of scolicidal agent, and re-aspiration were performed in accordance with the standard PAIR technique. Puncture was intentionally made at the dome of the cyst. Only Gharbi type I and II cysts were included. All patients received albendazole at 15 mg/kg/day for at least 20 days preoperatively.

Results: Over a 13-month period, laparoscopic PAIR was performed in 7 patients with a total of 11 cysts. Three patients were female and four were male; mean age was 48.3±15.9 years. Seven cysts were located in the right lobe and four in the left lobe. Mean cyst diameter was 91.2±24.3 mm. Mean operative time was 118.6±15.5 minutes, and mean hospital stay was 3.3±2.3 days.Routine drainage was not performed; drains were placed selectively when minimal leakage was suspected. Drain output was typically serous, and no viable or non-viable scolices were detected. Four patients underwent simultaneous treatment of two cysts. No anaphylaxis, infection, bile leakage, or recurrence occurred. One case required conversion to laparoscopic unroofing.

Conclusion: Laparoscopic PAIR appears to be a feasible and safe alternative for selected hepatic hydatid cysts unsuitable for percutaneous intervention. The absence of major complications in this preliminary series may relate to controlled operating room conditions and direct laparoscopic visualization. Larger comparative studies are warranted.

Is routine drain placement necessary in acute appendicitis? A single-center retrospective study

Buket Horoz, Murat Olcay Türk, Ömer Faruk Özkan, Muhammed Emre Ersü, Abdüsselam Ağcakoyun

University of Health Sciences Türkiye, Sultan 2. Abdulhamid Han Training and Research Hospital, İstanbul

Objective: Acute appendicitis is one of the most common causes of emergency abdominal surgery, and appendectomy remains one of the most frequently performed emergency surgical procedures. Intraoperative drain placement has traditionally been used during appendectomy to prevent postoperative intraabdominal infections and fluid collections. However, the routine use of drains remains controversial. Recent studies suggest that routine drain placement does not significantly reduce postoperative complications and may be associated with prolonged hospital stay. Despite this, drain usage is still commonly preferred, particularly in cases of complicated appendicitis, and there is no clear consensus regarding its necessity. The aim of this study was to evaluate the impact of intraoperative drain use on postoperative outcomes in patients undergoing surgery for acute appendicitis.

Material and Methods: A total of 50 patients who underwent appendectomy for acute appendicitis over a one-year period were included in this retrospective study. Patients were divided into two groups according to intraoperative drain usage: drain group and no-drain group. Demographic characteristics, type of appendicitis (complicated or uncomplicated), drain usage, duration of hospital stay, postoperative fever, and reoperation rates were analyzed and compared between the two groups.

Results: Drain placement was performed in 23 patients (46%), while 27 patients (54%) did not receive a drain. The mean length of hospital stay was 3 days in the drain group and 1.8 days in the no-drain group. Patients who received a drain had a longer hospital stay compared to those without drains. Reoperation rates were similar between the two groups, and no clear reduction in reoperation or postoperative complications was associated with drain usage. Postoperative fever rates did not differ significantly between groups. Drain placement was more frequently preferred in cases of complicated appendicitis.

Conclusion: Odur findings suggest that routine drain placement during appendectomy for acute appendicitis does not provide a significant benefit in reducing postoperative complications and may be associated with prolonged hospital stay. Therefore, drain usage should not be routine and should be selectively applied based on intraoperative findings and patient characteristics. Further prospective studies with larger patient populations are needed to support these findings.

Keywords: Acute appendicitis, drain placement, appendectomy, postoperative complications, length of hospital stay

[P-427]

Retrospective analysis of repair using the TEPP and TAPP techniques in patients diagnosed with bilateral inguinal hernia

Murat Tan

Ataşehir Florence Nightingale Hospital, İstanbul

Objective: There are many techniques available for the surgery of patients diagnosed with bilateral inguinal hernia. Laparoscopic techniques have many advantages over open surgical techniques. Less pain after surgery, smaller incisions, and less tissue trauma. Rapid recovery and return to work; most patients can return to daily activities within 1 week. Cosmetically superior, with smaller and more aesthetic scars. An advantage in bilateral hernias is that both sides can be repaired in a single session. Advantageous in recurrent hernias, especially if a hernia has recurred after open surgery. The only disadvantages are the need for general anesthesia and higher costs. Advantages of laparoscopic techniques over open surgical techniques.

Material and Methods: The files of patients diagnosed with bilateral inguinal hernia who underwent laparoscopic total extraperitoneal (TEP) and laparoscopic transabdominal preperitoneal (TAPP) surgery at Ataşehir Florence Nightingale Hospital between September 2022 and December 2025 were retrospectively reviewed. Patients were evaluated in terms of their surgery, postoperative data, and demographic characteristics. The data of patients operated on with these two techniques were compared with each other.

Results: A total of 77 patients were examined in this study. Of these patients, 55 (71.43%) underwent surgery using the laparoscopic TEP technique, and 22 patients (28.57%) underwent surgery using the laparoscopic TAPP technique. The reason for surgery using the TAPP technique was due to previous lower abdominal surgery in these patients. Of the 55 patients who underwent TEP, 20 (36.3%) were female and 35 (63.7%) were male, with an average age of 36.3 years. All 55 patients had a bilateral inguinal diagnosis. The average hospital stay was 1.07 days for the TEP technique and 1.23 days for the TAP technique. Ecchymosis was observed in 3 patients in the TEP technique and 2 patients in the TAP technique. Postoperative seroma was observed in 3 patients with the TEP technique and in 1 patient with the TAP technique. Wound site infection was observed in 1 patient with the TEP technique and in 2 patients with the TAP technique. There were no bilateral recurrences with either technique. Unilateral recurrence was observed in 2 patients with the TEP technique and in 1 patient with the TAP technique.

Conclusion: No significant difference was observed between laparoscopic TEP and laparoscopic TAPP hernia repair in terms of superiority. It is considered appropriate to decide which method to use based on the surgeon's experience and the patient's surgical history.

Keywords: Bilateral inguinal herni, TEP, TAPP

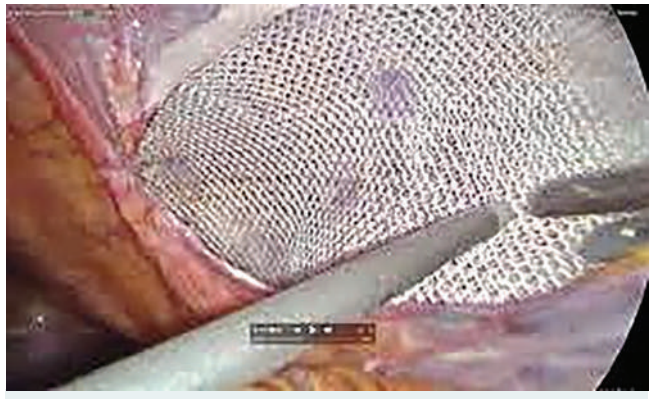

Figure 1. Retrospective analysis of repair using the TEPP and TAPP techniques in patients diagnosed with bilateral inguinal hernia.

Characteristics of recurrent gastrointestinal tumors

Yusuf İhsan Özdilek, Ömer Furkan Çelik, Ayşegül Ergün, Mehmet Sait Özsoy, Nuray Çolapkulu Akgül, Gürhan Baş, Orhan Alimoğlu

Department of General Surgery, İstanbul Medeniyet University, Göztepe Prof. Dr. Süleyman Yalçın City Hospital, İstanbul

Objective: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors originating from the gastrointestinal system. They originate from the precursors of the interstitial Cajal cells, located in and around the myenteric plexus, which regulate peristalsis. They are most commonly seen in the stomach, and less frequently in the small intestine, colon, rectum, and omentum.

Material and Methods: This article evaluates the gender, medical treatment use, age, tumor localization, elective/emergency status, time of recurrence, and follow-up period of 9 patients who experienced recurrence among 75 GIST patients treated between 2009 and 2025.

Results: Recurrence occurred in 75 patients (12%), 5 of whom were female and 4 male. All were receiving medical treatment for GIST. The mean age at the time of their first surgery for GIST was 61.5 (49-68). The primary tumor locations were jejunum, stomach, ileum, colon, and rectum. Seven patients (78%) underwent elective surgery, and two patients (22%) underwent emergency surgery. The mean time to recurrence was (26.3±23.8) months, and the mean follow-up period was 65 months.

Conclusion: In this study, the GIST recurrence rate was found to be 12%, and the mean time to recurrence was 26 months.

Keywords: GIST, gastrointestinal stromal tumor, surgical oncology

[2]*Department of General Surgery, Çukurova University Faculty of Medicine, Adana*

[3]*Department of Surgical Oncology, Çukurova University Faculty of Medicine, Adana*

[4]*Yozgat City Hospital, Yozgat*

Objective: The diagnosis and treatment of rectal cancer constitute a complex process requiring a multidisciplinary approach. Although there are certain differences between APR and ULAR in terms of clinical and surgical outcomes, tumor location, extent of invasion, and surgeon experience play key roles in patient selection. With advances in surgical techniques, both quality of life and oncological outcomes have improved. The choice of surgical method should be individualized in order to achieve optimal benefit for each patient.

Material and Methods: We compared the preoperative and postoperative outcomes of abdominoperineal resection and ultra-low anterior resection, performed in 63 patients aged 29-82 years who underwent surgery for rectal cancer at our clinic between 2015 and 2024, with each other and with the existing literature.

Results: Clinical and demographic differences were observed between APR and LAR surgical techniques; however, no statistically significant differences were found between the groups in terms of age (APR: 59.73±9.73; LAR: 59.48±14.11; p=0.935), sex distribution (APR: 72.50% male; LAR: 91.30% male; p=0.146), or BMI categories (p=0.149). Histopathological evaluation demonstrated similar rates of lymphatic invasion (APR: 58.97%; LAR: 63.64%; p=0.932), venous invasion (APR: 56.41%; LAR: 54.55%; p=1.000), and perineural invasion (APR: 38.46%; LAR: 36.36%; p=1.000) between the groups. Bowel obstruction was observed in 7.89% of APR patients and 13.04% of LAR patients (p=0.833). Stoma retraction occurred only in the APR group at a rate of 3.03% (p=1.000), whereas parastomal hernia was detected only in the LAR group at a rate of 10% (p=0.268). Regarding surgical approach, the open/laparoscopic surgery rates were 40%/60% in the APR group and 30.43%/69.57% in the LAR group (p=0.626). The distal surgical margin measured 4.00 (2.5-5.25) cm in APR patients and 2.00 (1.25-2.75) cm in LAR patients, demonstrating a statistically significant difference (p=0.008). Furthermore, the absence of local recurrence in any patient may be associated with improvements in surgical technique and increased surgical experience.

Conclusion: In patients with distal rectal cancer undergoing abdominoperineal resection or ultra-low anterior resection, no significant difference in oncological outcomes has been observed, consistent with the literature, and the choice of surgical technique appears to depend mainly on tumor localization and patient characteristics. Therefore, current approaches favor individualized treatment strategies that consider patient comfort and functional outcomes, with minimally invasive surgical techniques preferred whenever feasible to achieve optimal results.

Surgical and endoscopic treatment of colonic volvulus: our clinical experience and results, Bartın State Hospital

Tolga Girgin, Muzaffer Çapar, Yücel Doğrutürk, Hakkı Yılmaz, Yüksel Doğan

Bartın State Hospital, Bartın

Objective: Colon volvulus is an acute abdominal condition requiring prompt diagnosis and treatment. The treatment approaches, morbidity, mortality, and recurrence rates of cases operated on at Bartın State Hospital between 2010 and 2024 were evaluated and compared with the literature.

Material and Methods: Thirty-six patients diagnosed with KV and treated over a 10-year period were retrospectively examined. Age, gender, preoperative WBC, lactate, and CRP levels, colon diameter on abdominal CT (APCT), treatment protocols,morbidity and mortality rates, and recurrence at 1-year follow-up were compared. Twenty-five (69.4%) were female and 11 (30.6%) were male, with a mean age of 78 (range 48-95). Twenty-five (69.4%) had comorbidities (CVA, HT, DM, or severe CHF). Abdominal pain, distension, constipation, and vomiting were the most common symptoms. Approximately half of the cases had a history of previous attacks. ADBG (we believe it is not a definitive diagnostic tool due to its low sensitivity) was used to diagnose 70% of the cases, while APCT (superior to ADBG for diagnosis) was performed on all patients. Colon diameter was found to be 6-10 cm in those who underwent endoscopic procedures and ≥10 cm in those who underwent resection. Sigmoid colon volvulus was detected in 34 patients, cecal volvulus in 1 patient, and transverse colon volvulus in 1 patient.

Results: Surgical treatment was performed on 22 patients: 12 (54%) underwent resection and colostomy, 5 (22%) underwent resection and anastomosis (in patients with good general condition), 2 (9%) underwent detorsion, 1 (4%) underwent right hemicolectomy + ileotransversostomy (in cecal volvulus), 1 (4%) underwent detorsion and sigmoidopexy, and 1 (4%) underwent transverse colon resection and anastomosis. The remaining 14 patients were treated with endoscopic decompression. The mortality rate was 5.5% (2 patients, due to necrosis and delayed diagnosis). Endoscopic decompression was recorded at 20% and postoperative recurrence rates at 25%. Delayed presentation to the emergency department, high WBC, lactate, and CRP levels increased the need for resection. Emergency decompression and elective sigmoid resection resulted in low mortality; however, emergency resection in the presence of gangrene or perforation was associated with increased mortality and morbidity rates.

Conclusion: In the treatment of colonic volvulus, endoscopic interventions are the preferred choice in uncomplicated cases. Surgical treatment is required in patients with necrosis, perforation, or a transverse colon diameter >11 cm. Sigmoidopexy may be an appropriate option in cases without shock or necrosis. In patients with stable general condition, endoscopic decompression should be the first choice; however,in cases of gangrene, ischemia, or perforation, surgical intervention is mandatory along with optimal fluid resuscitation and preoperative preparation.

Keywords: Colonic volvulus, endoscopic decompression, sigmoidopexy

Obstructive defecation syndrome is a spectrum: Diagnosis-based surgical algorithm

Berkay Aksu, Salih Raşit Mizan, Ufuk Karabacak, Murat Derebey, İsmail Alper Tarim

Department of General Surgery, Ondokuz Mayıs University Faculty of Medicine, Samsun

Objective: Obstructive defecation syndrome (ODS) represents a heterogeneous clinical spectrum in which rectal prolapse, rectocele, and functional impairment coexist in varying degrees. This study aimed to determine the diagnostic surgical approach, the percentage distribution of the methods used, and the preferred surgeries after recurrence in patients who underwent surgery due to ODS.

Material and Methods: Retrospectively, a total of 44 patients who underwent surgical treatment for ODS at our clinic were evaluated. Patients were grouped according to the predominant anatomical pathology as rectal prolapse, pelvic relaxation, and rectocele. The surgical methods applied in each diagnostic group were analyzed in terms of number and percentage. In addition, secondary surgeries performed in patients who experienced recurrence after primary surgery were recorded.

Results: Of the 23 patients diagnosed with rectal prolapse, 82.6% underwent laparoscopic ventral mesh rectopexy (LVMR). In the remaining patients, altemeier (4.3%), laparoscopic suture rectopexy (4.3%), LAR + laparoscopic suture rectopexy (4.3%), and delorme (4.3%) procedures were preferred. Of the 14 patients diagnosed with pelvic organ prolapse, 85.7% underwent LVMR and 14.3% underwent ventral mesh rectopexy (VMR). In the 7 patients diagnosed with rectocele, all surgical approaches were transperineal rectocele repair; 42.9% used the mesh technique and 57.1% used the non-mesh technique. Three patients who developed recurrent ODS after LVMR or VMR underwent secondary surgery: two patients underwent stapler transanal rectal resection (STARR), and one patient underwent transperineal rectocele repair (without mesh). In one case where laparoscopic suture rectopexy was performed, full-thickness rectal injury developed intraoperatively, and primary repair was performed. This same patient underwent re-operation via laparotomy on the third day due to early postoperative bleeding. In one patient who underwent Delorme surgery, ileus and anal stricture developed, requiring emergency colostomy followed by elective LAR. In one patient who underwent LVMR, an enterocutaneous fistula developed, and fistula repair was performed via elective surgery.

Conclusion: ODS is not a homogenous disease that can be treated with a single surgical technique. The surgical approach should be individualized according to the dominant anatomical and functional phenotype of the disease, rather than isolated diagnoses. A diagnosis-based algorithmic approach facilitates the selection of appropriate surgery and contributes to the determination of rational secondary surgical strategies in cases of recurrence.

Keywords: Obstructive defecation syndrome (ODS), rectal prolapse, rectocele

Table 1. Surgical methods applied according to diagnosis

Diagnosis	Surgical method	n	%
Rectal prolapse (n=23)	LVMR	19	82.6
	Altemeier	1	4.3
	Laparoscopic suture rectopexy	1	4.3
	LAR + laparoscopic suture rectopexy	1	4.3
	Delorme	1	4.3
Pelvic organ prolapse (n=14)	LVMR	12	85.7
	VMR	2	14.3
Rectocele (n=7)	TP rectocele repair (with mesh)	3	42.9
	TP rectocele repair (without mesh)	4	57.1

In 3 patients who developed recurrent obstructive defecation syndrome after LVMR or VMR, secondary surgery was performed: STARR (Stapler Transanal Rectum Resection) in 2 patients and transperineal rectocele repair (without mesh) in 1 patient.

[P-432]

Retrospective analysis of patients operated on due to intestinal obstruction

Emrah Uludağ, Gökhan Posteki

Kocaeli State Hospital, Kocaeli

Objective: Mechanical intestinal obstruction is a surgical problem that still presents difficulties in terms of diagnosis and treatment modalities today. In this study, we aimed to examine the etiological analysis of our cases operated on due to intestinal obstruction.

Material and Methods: A retrospective analysis was performed on 54 patients who were admitted to our clinic with a diagnosis of intestinal obstruction between January 2019 and December 2023, and who underwent surgery after a mechanical cause was found through necessary physical examination and imaging methods. The patients' gender, age, cause of obstruction, previous surgeries (if any), postoperative complications, and mortality rates were recorded.

Results: Of the patients operated on, 30 were male and 24 were female. The average age of men was 55 and that of women was 50. The overall average age was 52, and the age range was determined as (20-95). When the causes of obstruction were examined, the most common waspostoperative adhesions (42 patients, 77.7%), followed by incarcerated hernias (inguinal and incisional, 6 patients, 11.1%), tumors (5 patients, 9.2%), and volvulus (1 patient, 1.8%). When the most frequent cause of adhesions was examined, it was determined that they were caused by previous operations (ulcus perforation, cholecystectomy, gastrectomies, gynecological operations, and appendectomy). The necessary surgical procedure was applied to the patients according to the cause of intestinal obstruction. The most important criterion affecting mortality and morbidity in patients was the timing of intervention and appropriate resuscitation performed preoperatively. Our complication rate in the postoperative period was 16.6%, and mortality was 5.5%. The most frequently encountered problems, especially in delayed cases, were infection (7.4%), paralytic ileus (3.7%), and anastomotic problems (5.5%).

Conclusion: In conclusion, when examining the causes of mortality and morbidity in intestinal obstruction, it was emphasized that early and accurate diagnosis, good preoperative resuscitation, and prompt surgery of patients presenting with mechanical intestinal obstruction are important in minimizing complications and mortality, and preventing intestinal damage.

Early outcomes of laser hemorrhoidoplasty in our series

Erdinç Tekel, Mehmet Arda Yıldırım, Muhammet Gündal, İlker Kızıloğlu, Bayram Çolak

Department of General Surgery, Bakırçay University Çiğli Training and Research Hospital, İzmir

Objective: Hemorrhoidal disease is one of the most common anorectal disorders worldwide and significantly affects individuals' quality of life. It is among the most frequently encountered conditions in patients presenting to general surgery outpatient clinics. Treatment options include medical management, minimally invasive interventions, and surgical procedures. This study aimed to evaluate the early outcomes of patients who underwent laser hemorrhoidoplasty in our clinic.

Material and Methods: The data of patients who underwent laser hemorrhoidoplasty for hemorrhoidal disease in our clinic between January 2025 and January 2026 were retrospectively analyzed. Treated patients were evaluated in terms of demographic characteristics, clinical features, operative details, and postoperative outcomes. A one-year follow-up was also analyzed.

Results: A total of 25 patients who underwent laser hemorrhoidoplasty for hemorrhoidal disease were included in the study. Of these, 19 were male and 6 were female, with a mean age of 50.6 years. Seventeen patients had grade III and 8 patients had grade II hemorrhoidal disease. The mean number of hemorrhoidal packages per patient was 2. Laser hemorrhoidoplasty was performed on each package using an average of 6-8 applications, with a power of 6 watts and a total energy of 18 joules per package. The mean hospital stay was 1 day, and no postoperative pain was observed. At the one-year follow-up, patients were re-evaluated, and persistent symptoms were noted in 5 patients. The gender, hemorrhoid stage, and one-year post-treatment symptom status of the 25 patients included in the study are presented as percentages

Conclusion: Laser hemorrhoidoplasty is a minimally invasive technique used in the surgical management of hemorrhoidal disease. Consequently, in appropriately selected patients, it can be considered a safe and effective treatment option, offering a short postoperative recovery period and minimal or no pain, thereby providing a comfortable therapeutic approach.

Keywords: Hemorrhoidal disease, laser hemorrhoidoplasty, recovery period

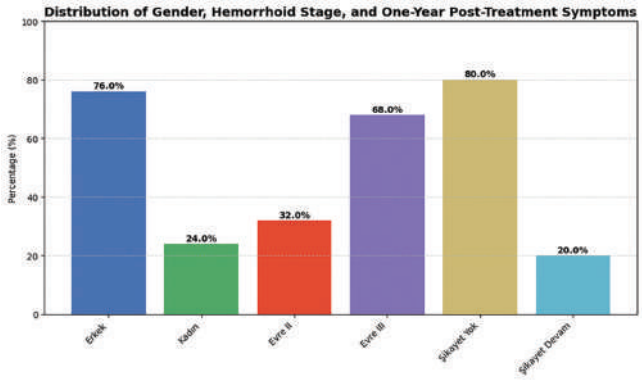

Figure 1. The gender, hemorhoid stage, and one-year post-treatment symptom status of the 25 patiens included in the study are presented as percentages.

The importance of laboratory parameters in the development of perianal fistula following perianal abscess

Ayşe Yosun Aydın, Sermet Terzi, Erdinç Çetinkaya

Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara

Objective: Perianal fistula development after perianal abscess is common and increases patient morbidity. This study aimed to evaluate the potential role of inflammatory and hematological laboratory parameters at the time of admission in predicting perianal fistula development in patients presenting with perianal abscess.

Material and Methods: This retrospective, single-center study included 15 patients who underwent surgical drainage for perianal abscess at Hacettepe University between 2020 and 2025. Patients were followed for one year and divided into two groups according to the development of perianal fistula: Those who developed fistula (n=11) and those who did not (n=4). Demographic characteristics, including age, sex, and presence of diabetes mellitus, were recorded. Laboratory parameters at admission included white blood cell count, neutrophil and lymphocyte counts, C-reactive protein (CRP), neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), and mean platelet volume (MPV). Data were analyzed using descriptive statistics.

Results: The mean age of the patients was 44.5 years, and 11 patients (73.3%) were male. During the follow-up period, perianal fistula developed in 73.3% of the patients. Higher white blood cell count, CRP, and NLR values were observed in patients who developed fistula. When a CRP cut-off value of 10 mg/L was applied, the majority of patients who developed fistula had CRP levels above this threshold. The mean CRP level in the fistula group was approximately 12 mg/L, and the mean NLR was 6.90. In contrast, patients without fistula development had lower CRP and NLR values. Changes in neutrophil and lymphocyte counts were consistent with the observed increase in NLR. No marked differences were observed between the groups in terms of PLR and MPV.

Conclusion: Elevated inflammatory laboratory parameters at admission in patients presenting with perianal abscess may serve as risk indicators for subsequent perianal fistula development. In particular, CRP ≥10 mg/L and elevated NLR appear to be practical and easily applicable parameters that may contribute to clinical decision-making. Prospective studies with larger patient cohorts are needed to further clarify the clinical utility of these findings.

Keywords: Perianal abscess, perianal fistula, C-reactive protein

Short- and mid-term outcomes of laser hemorrhoidoplasty: A single-center experience

Aytaç Selman, Begüm Irmak Çoban, Süleyman Toker

University of Health Sciences Türkiye, Haydarpaşa Numune Training and Research Hospital, İstanbul

Objective: Introduction hemorrhoidal disease is a common anorectal condition that significantly affects quality of life. Conventional surgical techniques are often associated with postoperative pain and prolonged recovery. Laser hemorrhoidoplasty has emerged as a minimally invasive alternative in recent years. This study aimed to evaluate the short- and mid-term clinical outcomes of laser hemorrhoid surgery.

Material and Methods: This retrospective, single-center study included 32 patients with grade I-III hemorrhoidal disease who underwent laser hemorrhoidoplasty. Demographic characteristics, postoperative pain (VAS), length of hospital stay, time to return to daily activities, postoperative bleeding, patient satisfaction, recurrence, and reoperation rates were analyzed. Data were obtained from medical records and telephone-based patient-reported outcomes. Descriptive statistical analysis was performed.

Results: The mean age was 46.3±14.1 years, and 71.9% of patients were male. Grade II-III hemorrhoidal disease was present in 81.2% of cases. The median postoperative VAS score was 2 (IQR: 0-3), with 78.1% of patients reporting VAS ≤3. Median length of hospital stay was 1 day, and median time to return to daily activities was 2 days. Postoperative bleeding occurred in only two patients, both of whom required early reoperation (6.3%). Additionally, six patients underwent reoperation due to recurrent hemorrhoidal symptoms (18.8%). Patient satisfaction was 90.6%, and 87.5% of patients would recommend the procedure. The recurrence rate was 25%.

Conclusion: Laser hemorrhoidoplasty provides low postoperative pain and rapid recovery. Although postoperative bleeding and reoperation rates require careful consideration, high patient satisfaction supports the feasibility of this technique in clinical practice.

Keywords: hemorrhoidal disease, laser hemorrhoidoplasty, minimally invasive surgery

[P-436]

Clinical outcomes of crystallized phenol application in patients with uncomplicated pilonidal sinus disease

Burak Etemoğlu

University of Health Sciences Türkiye, Erzurum City Hospital, Erzurum

Objective: Pilonidal sinus disease commonly affects young and active individuals and may result in considerable discomfort and work absenteeism. Although surgical techniques remain effective, they are associated with postoperative morbidity and extended recovery periods. Consequently, minimally invasive and outpatient treatment modalities have gained growing interest.

Material and Methods: In this retrospective study, 110 patients with uncomplicated pilonidal sinus disease containing a maximum of two pits were included. Twenty-seven patients (24.5%) were female and 83 (75.5%) were male, with a mean age of 24 years. Local anesthesia was achieved using lidocaine infiltration prior to the procedure. In patients with narrow sinus openings preventing clamp insertion, minimal incision was performed to widen the orifice. After mechanical curettage and removal of hair and debris, crystallized phenol was liquefied near body temperature and applied at an 80% concentration into the cavity. The mean procedure time was 10 minutes. No routine prophylactic antibiotics were administered. The first follow-up visit was scheduled 15-20 days after the initial session, and all patients were followed for 6 months.

Results: During the 6-month follow-up, recurrence was observed in 25 patients (22.7%), while 85 patients (77.3%) remained recurrence-free. Among the recurrence group, 16 patients (64%) had two pits. Single-session treatment was sufficient in 35 patients (31.8%). Complications included abscess formation in 7 patients (6.4%) and transient severe sacral pain in 2 patients (1.8%). Abscess cases were successfully managed with antibiotics and drainage.

Conclusion: Crystallized phenol application appears to be an effective, safe, and minimally invasive treatment option for uncomplicated pilonidal sinus disease when appropriate patient selection is applied. The short mean procedure time of 10 minutes, outpatient feasibility, and the absence of routine antibiotic requirement represent significant clinical advantages. The observed success rate of 77.3% and the manageable complication profile support the clinical applicability of this technique. An increased number of pits may be associated with a higher risk of recurrence. These findings suggest that crystallized phenol can be considered a viable alternative to surgical treatment in selected patients. Nevertheless, prospective and comparative studies with longer follow-up periods are required to further validate these results.

Keywords: Pilonidal sinus, crystallized phenol, minimally invasive treatment

Figure 1. A patient with a single pit treated with phenol.

Table 1. Patient demographic characteristics (n=110)
Variable value
Total number of patients 110

Breast hamartoma as a rare benign entity: Surgical outcomes, risk factors for concomitant malignancy, and follow-up results: A single-center retrospective study

Burak Dinçer[1], Emine Benzer[2], Cihangir Özaslan[1]

[1]*Department of Surgical Oncology, University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara*

[2]*Department of Pathology, University of Health Sciences Türkiye, Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Ankara*

Objective: Breast hamartomas are rare benign breast lesions with diagnostic challenges in imaging and histopathology. There is no consensus on the optimal management or follow-up strategy following excisional biopsy. The aim of our study was to evaluate the follow-up data of patients who were diagnosed with breast hamartoma by excisional biopsy in our center.

Material and Methods: This retrospective study included patients diagnosed with breast hamartoma after excisional biopsy between 2018 and 2024. Demographic, clinical, surgical, and pathological characteristics, along with follow-up outcomes, were analyzed.

Results: A total of 23 female patients (median age 46 years) were included. The most common symptom was a palpable mass (56%), and 30% were referred after lesion detection in screening. Radiological imaging revealed that 17 patients (72%) were categorized as BI-RADS 4a. Preoperative core biopsy showed fibroepithelial lesions in 52% of patients. Lumpectomy was performed in 21 patients, while the remaining two patients underwent reduction mammoplasty. The median lesion size was 40 mm. During a median follow-up of 42 months, no recurrence, *in situ* carcinoma, or breast cancer was observed.

Conclusion: Breast hamartomas exhibit a benign course, and no malignancy was detected during follow-up. Routine breast cancer screening protocols appear sufficient for these patients, and no additional follow-up strategy is necessary post-excision.

Clinical, biochemical, and surgical characteristics of patients with pheochromocytoma: A single-center retrospective study

Muhammed Metin Yüksel[1], Duray Şeker[1], Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazici[2], Melih Akıncı[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Pheochromocytoma is a rare endocrine tumor that requires a multidisciplinary approach due to its variable clinical presentation and challenges in perioperative management. This study aims to descriptively evaluate the demographic, clinical, biochemical, and surgical characteristics of patients who underwent surgery with a diagnosis of pheochromocytoma.

Material and Methods: Twenty-five patients who underwent surgical treatment for pheochromocytoma at our center were included in this retrospective descriptive study. Demographic data, admission findings, hypertension characteristics, biochemical diagnostic methods, tumor characteristics, preoperative preparation process, surgical approach, perioperative complications, and follow-up results were recorded. Continuous variables were presented as median and minimum-maximum values, while categorical variables were presented as numbers and percentages.

Results: The median age of the patients was 57 years; 72% were female, and 72% were classified as ASA III. The most common findings at admission were hypertension (44%) and incidentaloma (40%), while the distribution of symptoms included headache (40%), palpitations (40%), and sweating (32%). Sustained hypertension was observed in 84% of patients, while paroxysmal hypertension occurred in 16%. Diagnosis was established via plasma metanephrines in 52% and 24-hour urine analysis in 48% of cases; median metanephrine was 385.0 (min-max 4.4-4111.0), and median normetanephrine was 1400.0 (min-max 61.0-42880.0). While 48% of patients had a diagnosis of pheochromocytoma preoperatively, 52% were not preoperatively predicted. Of the tumors, 68% were located in the right adrenal gland with a median diameter of 40 mm (14-120); extra-adrenal localization was detected in 4%. In preoperative preparation, alpha-blockade was administered to 60% (median duration 20 days, 0-150) and beta-blockade to 40%. The surgical approach consisted of laparoscopic (56%) and open adrenalectomy (44%), with a median operative time of 120 minutes (45-315). Intraoperative hypertensive crisis occurred in 12%, while postoperative complications were observed in only one patient (Clavien-Dindo 3A); the median hospital stay was 6 days (3-11). Resolution of hypertension was achieved in 76% of patients postoperatively. No malignancy/metastasis, recurrence, or mortality was detected during a median follow-up of 21 months (2-32) (Table 1).

Conclusion: This retrospective series confirms the heterogeneous clinical presentation of pheochromocytoma, frequently manifesting as incidentalomas or via atypical symptoms. Nevertheless, guideline-concordant preoperative medical optimization and surgical management maintained low rates of intraoperative hypertensive crises and postoperative complications. The safe, frequent utilization of laparoscopic adrenalectomy aligns with the documented efficacy of minimally invasive surgery. Furthermore, postoperative hypertension resolution in most patients, alongside the absence of recurrence or mortality, underscores the favorable outcomes attainable in specialized centers. These descriptive findings emphasize the critical role of early diagnostic suspicion, meticulous preoperative preparation, and multidisciplinary management in pheochromocytoma care (Table 2).

The importance of preoperative parameters in detecting lymph node metastases in patients with medullary thyroid cancer

Vildan Ersöz, Hakan Ataş

University of Health Sciences Türkiye, University of Health Sciences Türkiye, Ankara Bilkent City Hospital, , Ankara

Objective: This study aims to establish objective criteria for surgical planning in patients diagnosed with medullary thyroid cancer (MTC). It evaluates the relationship between preoperative calcitonin (CT) and carcinoembryonic antigen (CEA) levels, as well as preoperative inflammation indices (NLR, PLR, and SII), with the clinicopathological and molecular characteristics of MTC. Additionally, it assesses the utility of these parameters in predicting lymph node (LN) metastases. Accurate prediction of LN metastases may help unnecessary extensive surgical dissections, improve patient comfort, and reduce complications while enhancing survival outcomes.

Material and Methods: A retrospective analysis was conducted on patients aged 18-90 who underwent surgery for MTC at Ankara Bilkent City Hospital between 2019 and 2024. The patients' clinical examination findings, laboratory results, surgical notes, pathology reports, imaging data, age, and gender were reviewed. A total of 54 patients diagnosed with MTC (2.25% of all thyroid cancers) were identified. After excluding four patients due to missing laboratory results, surgical notes, or pathology reports, the study proceeded with 50 patients. Preoperative and postoperative CT, CEA, NLR, PLR, and SII values, pathological staging, immunohistochemical staining results, and surgical notes were meticulously examined and recorded. Patients were categorized into groups with and without LN metastases, and the effect of the analyzed parameters on LN metastasis was statistically evaluated. Statistical analyses were performed by BUİSTDAM.

Results: No statistically significant relationship was found between LN metastases and patient age, gender, preoperative CT, CEA, NLR, PLR, or SII levels. However, the presence of LN metastases was significantly higher in nodules with microcalcifications detected ultrasonography ($p=0.010$) and in nodules that stained positively for chromogranin A in pathology reports ($p=0.031$).When comparing preoperative and postoperative CT, CEA, and hemoglobin (Hb) levels, a statistically significant decrease was observed regardless of the type of surgery performed ($p=0.004$, $p=0.039$, and $p=0.002$, respectively). Biochemical improvement was detected in 68.75% of patients postoperatively. Among patients who underwent only total thyroidectomy (BTT), 93.3% achieved biochemical improvement and were included in a follow-up program.In stage 1-2 patients (those without LN metastases), postoperative CT levels were significantly lower ($p=0.003$).

Conclusion: This study demonstrates the relationship between preoperative CT and CEA levels, as well as inflammation scores, with LN metastases in MTC patients. It also highlights the significance of postoperative biomarker changes in evaluating surgical success and patient recovery. However, considering the study's limitations, larger-scale and prospective studies are needed to validate these findings. This approach could contribute to the development of multidisciplinary treatment protocols and help improve long-term survival rates while minimizing complications in MTC patients.

Intraoperative parathyroid hormone dynamics in predicting surgical cure in double parathyroid adenomas in primary hyperparathyroidism

Işık Çetinoğlu, Ozan Çalışkan, Mehmet Taner Ünlü, Zerin Şengül, Ahmet Faruk Yener, Nurcihan Aygün, Mehmet Uludağ

University of Health Sciences Türkiye, Şişli Hamidiye Etfal Training and Research Hospital, İstanbul

Objective: The incidence of double adenomas in primary hyperparathyroidism (pHPT) ranges between 2-20% and represents an important cause of persistent disease. In this study, we aimed to evaluate intraoperative parathyroid hormone (iPTH) dynamics in predicting surgical cure in patients with double adenomas.

Material and Methods: We retrospectively analyzed patients who underwent parathyroidectomy for pHPT between 2015 and 2025 and achieved surgical cure after removal of two pathological glands. In all operations, peripheral venous blood samples for iPTH measurement were obtained pre-excision and at the 10th and 20th minutes after excision. A ≥50% decrease in PTH compared to the pre-excision value was considered sufficient for surgical success. For the 8 patients with persistent disease after the first operation, iPTH values from both the first and second surgeries were evaluated. Among patients cured after the first surgery, iPTH measurements were analyzed separately in 19 patients in whom measurements were obtained after removal of both pathological glands, and in 7 patients in whom iPTH was measured after removal of the first gland and again after removal of the second gland. In total, 49 iPTH measurements were evaluated. Normocalcemia at 6 months was defined as surgical cure. Two criteria were assessed for predicting surgical cure: •Method 1: >50% decrease in iPTH at the 10th and/or 20th minute compared to the pre-excision value. •Method 2: >50% decrease in iPTH at the 10th and/or 20th minute plus a decline to within or below the normal reference range (PTH <65 ng/mL). Sensitivity, specificity, positive predictive value (PPV), negative predictive value, and overall accuracy were calculated. False-positive and false-negative rates were compared.

Results: Thirty-four patients (mean age 57 years) were included; 28 (82.4%) were female and 6 were male. Surgical cure was achieved with a single operation in 26 patients, while 8 (23.5%) required reoperation due to persistent disease. Of the second adenomas, 20 (59%) were located contralaterally and 14 (41%) ipsilaterally. For predicting surgical cure, Method 1 had 6 (12.2%) false positives, whereas Method 2 had none (p=0.0312). False-negative rates were 1 (2.9%) and 2 (4.1%) patients for Methods 1 and 2, respectively (p=1). Although Method 2 showed slightly lower sensitivity (94.1% vs. 97.1%), it demonstrated higher specificity (100% vs. 60%), PPV (100% vs. 84.6%), and overall accuracy (95.9% vs. 85.7%).

Conclusion: Double adenomas carry a high risk of persistent disease, with most second adenomas located contralaterally. In addition to a >50% decrease in iPTH, a decline into the normal reference range improves overall performance, significantly reduces false positives, and may help minimize the risk of persistent disease.

The relationship between tumor size and hounsfield unit values in adrenal masses and their correlation with pathological results

Oğuzhan Hakan Topgül[1], Arslan Ali Kurban[1], Ahmet Zahit Kaan[2], Hüda Ümit Gür[1], Meliha Atay[1], Gamze Çıtlak[1]

[1]*University of Health Sciences Türkiye, İstanbul Haseki Training and Research Hospital, İstanbul*

[2]*Derecik State Hospital, Hakkari*

Objective: Tumor size and computed tomography (CT) Hounsfield Unit (HU) values are used as key criteria in predicting malignancy risk in the management of adrenal masses. However, in selected patient populations who undergo surgery, it is unclear to what extent these parameters predict pathological outcomes. In this study, we aimed to evaluate the relationship between tumor size and HU values and pathological results in patients who underwent adrenal surgery.

Material and Methods: Seventy-eight patients who underwent adrenal surgery were retrospectively analyzed. Tumor size was classified based on the largest diameter as <4 cm, 4-6 cm, and ≥6 cm. CT attenuation values were categorized as <10 HU and ≥10 HU. Pathological results were grouped as adrenocortical adenoma and non-adenoma lesions (pheochromocytoma, myelolipoma, cysts, and malignant tumors). Chi-square and Fisher's exact tests were used for comparisons between groups.

Results: Among the 78 cases, adrenocortical adenoma was detected in 37 patients (47.4%) and non-adenoma pathology in 41 patients (52.6%). Seven cases (9.0%) were malignant. The rate of non-adenoma pathology increased significantly in parallel with tumor size (<4 cm: 32.4%; 4-6 cm: 52.9%; ≥6 cm: 86.4%; p=0.00032). All malignant cases were in the ≥6 cm group, and no malignancy was detected in masses <6 cm (p=0.00034). No significant association was found between HU value and pathological results (<10 HU: 55.4% non-adenoma; ≥10 HU: 33.3% non-adenoma; p=0.405). When size and HU were evaluated together, the non-adenoma rate was 30.8% in the <4 cm and <10 HU group, whereas it increased to 76.7% in the ≥4 cm and <10 HU group (p=0.001).

Conclusion: In patients undergoing adrenal surgery, increasing tumor size is strongly associated with non-adenoma pathology and malignancy. Malignancy was detected only in masses ≥6 cm. HU values provided limited contribution in predicting pathological outcomes in this selected surgical population. Tumor size remains the most decisive factor in the surgical decision-making process for adrenal masses.

Keywords: Adrenal mass, tumor size Hounsfield unit

Table 1. Combined analysis of tumor size and Hounsfield unit (HU) values with pathological outcomes. Table showing the comparative analysis of tumor size, size cut-off value, CT attenuation (HU) values, and size + HU combinations with adenoma, non-adenoma, and malignant pathology rates in patients undergoing adrenal surgery. Increasing tumor size is significantly associated with non-adenoma pathology and malignancy, whereas HU value alone shows limited predictive value for pathological outcomes

Diagnostic challenges in gallbladder adenomyomatosis: A retrospective analysis of clinical, radiological, and histopathological findings

Sena Özgül[1], Faruk Yazıcı[2], Serkan Demir[1], Muhammed salih Süer[1], Serhat Tokgöz[1], Şener Balas[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Adenomyomatosis is a benign lesion of the gallbladder; however, it poses diagnostic challenges. Clinically, it is frequently associated with cholelithiasis and may often be overlooked in the preoperative period due to its non-specific symptoms. This study aimed to evaluate the demographic, clinical, radiological, and pathological characteristics of patients who underwent cholecystectomy at the University of Health Sciences Türkiye, Ankara Etlik City Hospital General Surgery Clinic between October 2022 and October 2025 and were histopathologically diagnosed with adenomyomatosis, as well as to assess the concordance between radiological diagnosis and histopathological findings.

Material and Methods: A total of nine cases that underwent laparoscopic cholecystectomy during the specified period and were reported as adenomyomatosis on pathological examination were retrospectively analyzed. The patients' age, sex, presenting symptoms, indication for surgery, presence of gallstones, radiological findings (US and MRI/MRCP), type of adenomyomatosis, localization, gallbladder wall thickness, associated pathologies, and radiology-pathology concordance were evaluated.

Results: Seventy-seven point eight percent of the cases were female, and the mean age was 53.3±8.7 years. The most common presenting symptom was abdominal pain (77.8%), and the most frequent indication for surgery was cholelithiasis (77.8%). All patients underwent laparoscopic cholecystectomy. Gallstones were present in 77.8% of the patients. On ultrasonography, the most common diagnoses were adenomyomatosis (44.4%) and cholelithiasis (44.4%), whereas no significant findings were detected in 66.7% of the cases who underwent MRI/MRCP. Histopathological examination revealed that 77.8% of the cases were of the focal type, and 66.7% were located in the fundus. The mean gallbladder wall thickness was 3.25 mm. The most common associated pathology was cholelithiasis (22.2%). No dysplasia or malignancy was detected in any of the cases. Radiology-pathology concordance was achieved in only 44.4% of the cases.

Conclusion: Despite its benign nature, adenomyomatosis is a gallbladder pathology that is frequently overlooked in the preoperative period and may be confused with malignancy. As reported in the literature, imaging modalities may not always accurately reflect the type and extent of adenomyomatosis. This is consistent with the low radiology-pathology concordance rate observed in our study. In our series, the predominance of the focal type and fundus localization supports the most commonly reported morphological pattern in the literature. These findings once again emphasize that, despite the benign nature of adenomyomatosis, routine histopathological examination of surgical specimens is indispensable for clinical safety.

Serum vitamin B12 levels and etiological distribution before liver transplantation a single-center experience

Emin Kırkıncı, Davuthan Haydar, Mustafa Özsoy

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Vitamin B12 levels are frequently altered in liver diseases. Markedly elevated serum Vitamin B12 levels may be observed in advanced cirrhosis, hepatocellular carcinoma (HCC), and fulminant hepatitis. The aim of this study was to evaluate pre-transplant serum vitamin B12 levels and their relationship with underlying disease etiology in patients undergoing liver transplantation.

Material and Methods: This retrospective study included 60 patients who underwent liver transplantation at our center between 2024 and 2025. Pre-transplant serum vitamin B12 levels (pg/mL) and etiological diagnoses were recorded from patient files. Etiologies were classified as HBV, HBV + HCC, alcoholic cirrhosis, NASH, autoimmune hepatitis, cryptogenic cirrhosis, fulminant hepatitis, HCC, and other causes. Descriptive statistics and intergroup comparisons were performed. A p-value <0.05 was considered statistically significant.

Results: Serum Vitamin B12 levels ranged between 197 and 771 pg/mL. Patients with fulminant hepatitis and alcoholic cirrhosis had significantly elevated vitamin B12 levels (>2000 pg/mL) ($p<0.05$). High levels were also observed in patients with HCC. In contrast, NASH, cryptogenic cirrhosis, and some HBV-related cases showed relatively lower vitamin B12 levels. A statistically significant difference in serum vitamin B12 levels was found among etiological groups.

Conclusion: Pre-transplant serum vitamin B12 levels differ significantly according to liver disease etiology. Extremely high levels were detected in fulminant hepatitis and advanced HCC, whereas relatively lower levels were observed in NASH and cryptogenic cirrhosis. Preoperative vitamin B12 measurement may serve as a supportive biomarker in assessing disease severity and prognosis in liver transplant candidates.

Keywords: Liver transplantation, vitamin B12, etiology

Risk stratification approach based on clinical and imaging findings in patients with invasive and premalignant lesions in cholecystectomy specimens

Cenap Erdoğan[1], Sezer Sel[1], Umutcan Aydoğan[1], Özgür İbiş[1], Nurettin Kahramansoy[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir*

Objective: Gallbladder carcinoma is a clinically important malignancy due to its aggressive course and late diagnosis, despite its low incidence. Invasive malignancy and true premalignant gallbladder lesions may be detected incidentally following cholecystectomy performed for benign indications; however, in most cases, no specific preoperative clinical or imaging findings suggestive of malignancy are observed. The aim of this study was to evaluate the clinical and imaging characteristics of invasive and true premalignant lesions detected in cholecystectomy specimens and to identify meaningful patterns for risk stratification.

Material and Methods: This single-center, retrospective, observational study reviewed the pathology reports of 1,588 adult patients who underwent cholecystectomy for benign indications between 1, January, 2024 and 31, December, 2025. Cases with invasive gallbladder malignancy or true premalignant lesions—defined as biliary intraepithelial neoplasia (BilIN), epithelial dysplasia, or adenoma—were identified. Demographic characteristics, clinical presentation, laboratory findings, imaging results, surgical data, and pathological outcomes of these patients were analyzed in detail. Descriptive statistics were used, and proportion comparisons and binomial testing were applied where appropriate.

Results: Among 1,588 cholecystectomy specimens, one invasive gallbladder adenocarcinoma (0.06%) and nine true premalignant lesions (0.57%) were identified, yielding a combined invasive/premalignant incidence of 0.63%. The majority of premalignant lesions were low-grade BilIN, with only one case of adenoma; no high-grade dysplasia was observed. The invasive malignancy was a 20 mm adenocarcinoma staged as pT3, with lymphovascular invasion present. All invasive and premalignant cases occurred in female patients, and 80% were aged 50 years or older (median age: 57). The exclusive female distribution was statistically significant compared with the expected sex distribution (binomial test, $p<0.05$). Most patients (90%) underwent elective surgery for biliary colic. Acute cholecystitis was uncommon, and no cholestatic laboratory pattern was observed. On ultrasonography, gallbladder wall thickening ≥5 mm was detected in 60% of cases, while no patient demonstrated a mass or imaging-based suspicion of malignancy. All invasive and premalignant lesions were detected incidentally (100%).

Conclusion: Although invasive and true premalignant gallbladder lesions are rare in cholecystectomies performed for benign indications, they may remain completely silent clinically and radiologically and can be detected incidentally even at advanced stages. The incidence rates observed in our center appear to be consistent with those reported in the literature (0.1-0.4%) and in national series from Türkiye (approximately 0.2-0.3%). These findings suggest that reliance on a single clinical or radiological alarm sign may be insufficient, and that risk stratification approaches incorporating female sex, older age, and non-specific imaging findings may improve preoperative awareness.

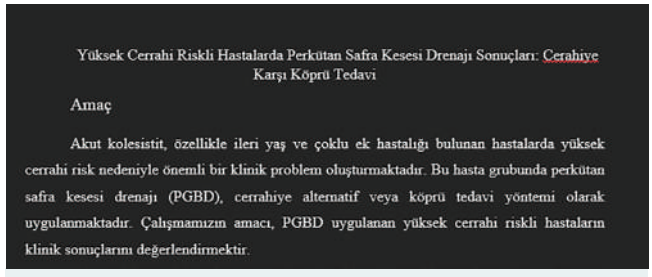
Outcomes of percutaneous gallbladder drainage in high-risk surgical patients: A bridge treatment vs. surgery

Murat Yıldırım, Muhammed Emin Gideroğlu

Tokat Gaziosmanpaşa University, Tokat



Objective: Acute cholecystitis poses a significant clinical problem, particularly in elderly patients with comorbidities, due to its high surgical risk. In this patient group, percutaneous gallbladder drainage (PGBD) is used as an alternative or bridging treatment to surgery. The aim of our study is to evaluate the clinical outcomes of high-surgical-risk patients undergoing PGBD.

Material and Methods: This study included patients who underwent PGBD and were followed up in our Interventional Radiology unit between April 2021 and July 2025. Demographic characteristics, comorbidities, indications for the procedure, procedure-related complications, mortality rates, and the need for surgery during the follow-up period were evaluated.

Results: The mean age was 71.9, with an age range of 33-94. 46 patients (45.54%) were male and 55 (54.45%) were female. The most common comorbidities were diabetes mellitus (32.6%, n=33), hypertension (28.7%, n=29), and coronary artery disease (19.8%, n=20). A large proportion of patients had multiple comorbidities. Regarding the indications for the procedure, acute cholecystitis was found in 84.1% (n=85), gallbladder perforation in 9.9% (n=10), and emphysematous cholecystitis in 6.9% (n=7). Fifteen patients died before being discharged from the hospital. The mean hospital stay was 21 (1-56) days, the mean catheter removal time was 27.2 (1-60) days, and the mean follow-up period was 36 (0-48) months. Procedure-related complications were observed in 15.8% (n=16) of patients. Complications included severe post-procedure pain (n=5), intra-gallbladder hemorrhage (n=4), catheter displacement (n=4), and intra-abdominal bile leakage (n=3). Additional intra-abdominal drains were placed in patients who developed intra-abdominal bile leakage. The overall mortality rate was 14.8%. The majority of patients who died were those followed in the intensive care unit due to comorbidities and had a higher mean age. During the follow-up period, 19.8% (n=20) of patients were discharged, and 15.8% (n=16) underwent cholecystectomy. The mean cholecystectomy time was 2 months. In four of the patients who underwent surgery, laparoscopic surgery was converted to open surgery. Of these patients, one underwent partial cholecystectomy, one underwent choledoch-jejunostomy due to choledochal injury, and two underwent open cholecystectomy.

Conclusion: PGBD is a safe and effective method for managing acute cholecystitis and its complications in elderly patients and those with high surgical risk. Thanks to its acceptable complication rates and the advantages it provides as a bridging treatment to surgery, it can be considered an effective treatment option in the appropriate patient group.

Yüksek Cerrahi Riskli Hastalarda Perkütan Safra Kesesi Drenajı Sonuçları: Cerrahiye Karşı Köprü Tedavi

Amaç

Akut kolesistit, özellikle ileri yaş ve çoklu ek hastalığı bulunan hastalarda yüksek cerrahi risk nedeniyle önemli bir klinik problem oluşturmaktadır. Bu hasta grubunda perkütan safra kesesi drenajı (PGBD), cerrahiye alternatif veya köprü tedavi yöntemi olarak uygulanmaktadır. Çalışmamızın amacı, PGBD uygulanan yüksek cerrahi riskli hastaların klinik sonuçlarını değerlendirmektir.

Bibliometric analysis of subtotal cholecystectomy publications

Yalçın Sönmez, Ali Cihat Yıldırım, Nebi Acar, Sezgin Zeren, Faik Yaylak, Mehmet Fatih Ekici

Kütahya Health Science University, Kütahya

Objective: Subtotal cholecystectomy has emerged as a critical damage-control strategy for managing difficult gallbladders when complete cholecystectomy poses unacceptable risk of bile duct injury. Despite growing clinical adoption, no comprehensive bibliometric analysis has characterized the scholarly landscape of this technique. This study aimed to quantify publication trends, identify leading contributors, and map the evidence base for subtotal cholecystectomy.

Material and Methods: A bibliometric analysis was conducted using PubMed-indexed publications on subtotal cholecystectomy. Data extracted included publication year, journal, first author, title, and open access status. Temporal trends were analyzed across decades (pre-1990, 1990s, 2000s, 2010s, 2020s). Study types were classified based on title keywords into categories including case reports/series, reviews/meta-analyses, cohort studies, technique papers, and clinical trials. Descriptive statistics summarized publication patterns, journal distribution, and author productivity.

Results: A total of 567 publications spanning 1954-2026 were identified, contributed by 509 unique first authors across 196 journals. Publication activity demonstrated exponential growth: only 21 papers appeared before 1990, compared to 302 (53.3%) in the 2020s alone. Annual output peaked at 63 publications in 2025. Surgical Endoscopy was the leading journal with 55 publications (9.7%), followed by Cureus (n=28, 4.9%) and American Surgeon (n=26, 4.6%). The most prolific first authors were Lucocq J (n=7), Lunevicius R, Ramírez-Giraldo C, and Kohga A (n=6 each). Title-based classification revealed case reports/series (n=43, 7.6%), reviews/meta-analyses (n=39, 6.9%), technique/method papers (n=36, 6.3%), and cohort studies (n=34, 6.0%). Notably, only 3 publications (0.5%) were identified as clinical trials. Open access availability was 40.7% (n=231 with PMC indexing).

Conclusion: The literature on subtotal cholecystectomy has expanded significantly, with more than half of all publications appearing in the last decade. This increase reflects the growing acceptance of subtotal cholecystectomy as a safe salvage procedure for difficult cholecystectomies. However, the evidence base remains limited due to the predominance of case reports and retrospective studies and the striking lack of randomized controlled trials. Future research priorities should include prospective multicenter studies comparing fenestration and reconstruction subtypes, standardized outcome reporting, and randomized trials evaluating long-term outcomes. The concentration of publications in surgical endoscopy journals highlights the relevance of this technique to minimally invasive surgical practices.

Keywords: Difficult cholecystectomy, subtotal cholecystectomy, bibliometric analysis, minimally invasive surgery

Gastric diverticula: Diagnostic challenges, adrenal lesion mimicry, and conservative management outcomes - a single-center case series

Faruk Yazıcı[1], Mete Üçdal[1], Serkan Demir[2], M. Salih Süer[2], Alican Arslan[1], Şener Balas[2]

[1]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hosspital, Ankara*

Objective: Gastric diverticula are among the rarest forms of gastrointestinal diverticular disease and are most often detected incidentally. Although symptoms are frequently attributed to coexisting gastric pathology rather than the diverticulum itself, data regarding diagnostic pitfalls and optimal management strategies remain limited. This study aimed to evaluate the clinical characteristics, diagnostic challenges, and outcomes of conservative management in patients diagnosed with gastric diverticula.

Material and Methods: This single-center retrospective case series included adult patients who underwent upper gastrointestinal endoscopy between September 2024 and December 2025. Patients in whom gastric diverticula were identified during endoscopic evaluation were included. Demographic characteristics, presenting symptoms, diverticulum location and type, associated gastric pathology—particularly *Helicobacter pylori* infection—imaging findings, management strategies, and clinical outcomes during follow-up were reviewed.

Results: Five patients (three females and two males; median age 67 years, range 35-81) were identified. Two patients were asymptomatic, with diverticula detected incidentally. Three patients presented with epigastric pain and/or dyspepsia. Diverticula were located in the fundus in two patients and in the antrum in three patients. Four diverticula were classified as true diverticula. In one patient, an ulcer-related antral pseudodiverticulum associated with significant food retention was identified, resulting in severe symptoms. Despite its size and symptomatic presentation, this lesion regressed both clinically and morphologically following medical therapy. *Helicobacter pylori* infection was detected in four patients, including all symptomatic cases. In one case, a posterior fundal gastric diverticulum mimicked a left adrenal mass on abdominal computed tomography, prompting endocrine evaluation before endoscopic confirmation. All patients were managed conservatively, and no surgical intervention was required.

Conclusion: This case series highlights the heterogeneous presentation of gastric diverticula and underscores several important clinical lessons. Posterior fundal diverticula may mimic adrenal lesions on cross-sectional imaging, representing a significant diagnostic pitfall. Ulcer-related antral pseudodiverticula with food retention may represent a reversible condition rather than a fixed structural abnormality and can be successfully managed with medical therapy. Overall, symptoms are often driven by associated gastric pathology, and an individualized conservative management strategy is appropriate for most patients.

Keywords: Adrenal lesion mimicry, conservative management, food retention, gastric diverticulum, pseudodiverticulum

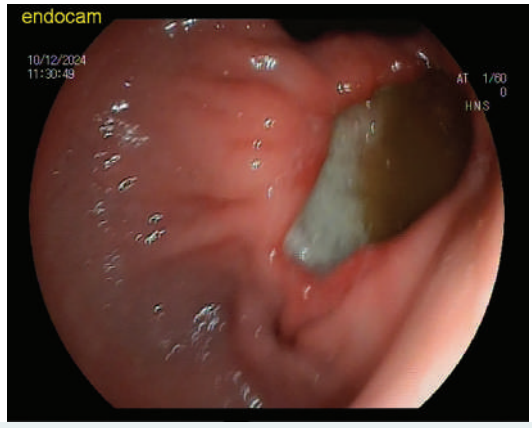

Figure 1. Ulcer-related antral pseudodiverticulum with food retention. Upper gastrointestinal endoscopy demonstrating an ulcer-related antral pseudodiverticulum. Marked food retention is observed within the diverticular cavity. This finding suggests that clinical symptoms may be driven by the associated ulcer disease rather than the diverticulum itself.

Figure 2. Computed tomography appearance of an antral pseudodiverticulum. Abdominal computed tomography demonstrating an ulcer-related antral pseudodiverticulum (red box). The cystic configuration and location of the lesion may mimic other intraabdominal masses, highlighting the importance of endoscopic correlation for accurate diagnosis.

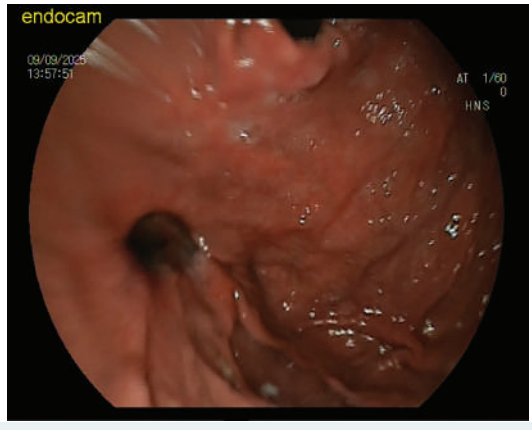

Figure 3. Endoscopic appearance of a posterior fundal gastric diverticulum. Upper gastrointestinal endoscopy demonstrating a true (congenital) gastric diverticulum located on the posterior wall of the gastric fundus. Due to its posterior fundal location, this lesion may mimic left adrenal pathology on cross-sectional imaging, representing an important diagnostic pitfall.

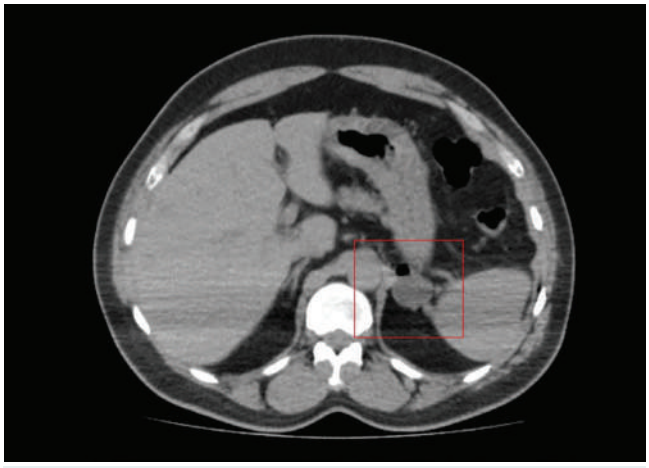

Figure 4. Computed tomography appearance of a posterior fundal gastric diverticulum. Abdominal computed tomography demonstrating a gastric diverticulum arising from the posterior wall of the gastric fundus (red box). Due to its retrogastric location and cystic appearance adjacent to the left adrenal gland, this lesion may mimic an adrenal mass, representing an important diagnostic pitfall. Endoscopic correlation is essential for accurate diagnosis.

[P-449]

Frailty-based risk stratification in emergency general surgery: A systematic review and meta-analysis of 30-day mortality and patient-centered outcomes

Mehmet Oğuzhan Polat, Türker Kaymak, Veysel Barış Turhan, Bahadır Kartal

Department of General Surgery, Hitit University Faculty of Medicine, Çorum

Objective: Emergency general surgery is associated with substantial mortality and morbidity, particularly among older patients and those with significant comorbidity. Chronological age alone may fail to capture physiologic reserve and vulnerability to surgical stress. Accordingly, frailty assessment has gained prominence for preoperative risk communication, planning the required level of care, and supporting shared decision-making. We aimed to synthesize the evidence on the association between frailty and early clinical outcomes in emergency general surgery, and to quantify this relationship through meta-analysis.

Material and Methods: Following a PRISMA-based approach, we searched for studies assessing frailty in emergency general surgery populations and included eligible reports. Frailty instruments (Clinical Frailty Scale, modified Frailty Index, and other validated tools) were recorded. The primary outcome was 30-day mortality. Secondary outcomes included major complications, length of stay, and escalation of post-discharge care needs/loss of independence. Data suitable for pooling were synthesized using a random-effects model, with effects reported as odds ratios (OR).

Results: Across included studies, frail patients consistently experienced higher early mortality. Frailty was also associated with clinically meaningful patient-centered outcomes beyond death, including major postoperative complications, prolonged hospitalization, and increased need for post-discharge support or loss of independence. In the pooled analysis, frailty was significantly associated with increased 30-day mortality (pooled OR: 2.91; 95% CI: 2.00-4.23, p<0.001). The direction of effect remained consistent across different frailty instruments, supporting frailty as a broadly applicable risk marker within heterogeneous emergency surgical indications.

Conclusion: Frailty is a strong predictor of adverse short-term outcomes in emergency general surgery. Incorporating rapid, pragmatic frailty tools into routine risk stratification may enhance the quality of risk communication, facilitate proactive planning of perioperative care level, and strengthen shared decision-making. Prospective studies with standardized definitions and patient-centered endpoints are warranted to refine instrument selection and establish actionable clinical thresholds.

Comparison of quality of life and general health status in kidney transplant recipients and hemodialysis patients

Baha Tolga Demirbaş, Zeynep Özel, Alp Tanman, Kıvanç Kardaş, Seyhan Hıdıroğlu

Marmara University Pendik Training and Research Hospital, İstanbul

Objective: End-stage renal disease (ESRD) is a serious health condition that significantly affects individuals' quality of life in multiple dimensions. Dialysis and kidney transplantation are the primary treatment modalities for sustaining the lives of patients with ESRD. The effects of these treatments on quality of life vary, and existing literature suggests that kidney transplant recipients generally report higher quality of life compared to hemodialysis patients. This study aims to compare and evaluate the quality of life of transplant and dialysis patients followed at Marmara University Pendik Training and Research Hospital in specific domains.

Material and Methods: This cross-sectional study was conducted with patients undergoing kidney transplantation and hemodialysis at Marmara University Pendik Training and Research Hospital. Ethical approval (dated 19.11.2024) and institutional permission were obtained. Data were collected through face-to-face surveys after receiving written informed consent from participants. The questionnaire consisted of two parts: the first included socio-demographic questions, and the second utilized the Turkish-validated version of the SF-36 form. SF-36 is a reliable and validated scale composed of eight subdomains that assess physical and mental health. Data were analyzed using SPSS software through the Mann-Whitney U and Kolmogorov-Smirnov tests, with a significance level set at "p<0.05".

Results: The study reached 88% of the target sample (n=155), including 59 dialysis and 96 transplant patients. Significant differences were found in 7 of the 8 SF-36 subdomains (physical functioning, role limitations due to physical health, role limitations due to emotional problems, vitality, mental health, bodily pain, and general health), with transplant patients scoring higher than dialysis patients (p-values respectively: <0.001, <0.001, <0.001, <0.001, <0.001, 0.003, 0.024). No statistically significant difference was observed in the "social functioning" subdomain (p=0.093).

Conclusion: The findings indicate that kidney transplant patients have higher quality of life in both physical and psychological dimensions compared to hemodialysis patients. However, no significant difference was found between the two groups in terms of social functioning. These results highlight kidney transplantation as a more favorable treatment option in improving quality of life among ESRD patients.

Keywords: Kidney transplantation, hemodialysis, quality of life

Clinical habits or medical necessity? Safety and cost analysis of discontinuing routine postoperative tests (hemogram-biochemistry) in elective laparoscopic cholecystectomy

Hüseyin Bayram, Selin Irmak, Kağan Mete Uzan

University of Health Sciences Türkiye, İzmir Tepecik Education and Research Hospital, İzmir

Objective: Conventional surgical practice frequently involves the request of routine blood counts and biochemical tests in the postoperative period, irrespective of the patient's clinical condition. Nevertheless, "Choosing Wisely" campaigns and ERAS protocols advocate the utilisation of evidence-based and cost-effective strategies for patient management. The objective of this study is to evaluate the impact of discontinuing routine haematology and biochemistry monitoring on patient safety and the resulting cost-effectiveness in uncomplicated elective laparoscopic cholecystectomy cases.

Material and Methods: The files of 956 patients who underwent elective laparoscopic cholecystectomy were retrospectively reviewed. In order to ensure the homogeneity of the study, cases with major intraoperative complications or conversion to open surgery were excluded from the analysis. The patients' ASA scores, the early postoperative clinical findings (tachycardia, hypotension, etc.), and the 30-day postoperative major events (need for ERCP, reoperation, biliary tract injury) were examined. The indications for postoperative laboratory tests were categorised as either "clinical suspicion" or "routine". The rates at which these tests influenced clinical decisions, including imaging, prolonged hospitalisation and reoperation, were then compared. The presence of events such as readmission within 30 days, delayed bleeding, and biliary tract injury was also examined.

Results: Of 956 patients (mean age: 50.4±13.7, 70.2% female), 98.3% were postoperatively stable. Labs were omitted in 698 patients and requested in 230 (199 routinely, 31 upon clinical suspicion). Symptom-driven tests altered management in 10 patients, whereas routine tests merely prolonged hospitalization in 38 (p=0.009). These prolongations reflected defensive medicine addressing isolated anomalies, generating unnecessary costs. No major surgical complications occurred in the routine group; the sole event was an unpredictable cardiac pathology. Multivariate analysis identified advancing age (OR: 1.013, 95% CI: 1.002-1.025, p=0.027) and higher ASA scores as independent predictors for unnecessary testing, while gender was insignificant (p=0.301). Patients with ASA ≥3 were 2.3 times more likely to undergo routine testing, regardless of clinical status (OR: 2.298, 95% CI: 1.447-3.649, p<0.001).

Conclusion: The request for routine tests in stable patients following uncomplicated elective laparoscopic cholecystectomy does not represent a medical necessity, but rather a defensive habit that results in the inefficient use of resources. The present study demonstrates that tests only influence decisions when there is clinical suspicion. In the interest of patient safety and cost-effectiveness, this conventional routine should be wholly discontinued in favour of a symptom-driven clinical approach.

A rare cause of acute abdomen: Perforated jejunal diverticulitis and surgical management

Hikmet Kadakal, Enes Şahin, Nihat Zafer Utkan

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Small bowel diverticulosis is a rare clinical entity, most commonly seen in the jejunum after the duodenum, and is typically classified as acquired "false" diverticula. While usually asymptomatic, complications such as diverticulitis, perforation, hemorrhage, or obstruction may develop in 10-30% of cases. Among these, perforation is one of the most serious complications, with mortality rates reaching up to 40%. The aim of this study is to present the surgical management of a case admitted with signs of acute abdomen and diagnosed with perforated jejunal diverticulitis.

Material and Methods: A 64-year-old male patient with a history of lung cancer with brain metastasis presented to the emergency department with severe abdominal pain lasting for 2 hours. The diagnostic workup included physical examination, laboratory tests (WBC, CRP), and multi-slice contrast-enhanced abdominal computed tomography (CT). The patient was diagnosed with acute abdomen and underwent exploratory laparotomy, with the surgical procedure determined based on intraoperative findings.

Results: Physical examination revealed tenderness in all four quadrants and defense in the left quadrant; laboratory tests showed WBC: 5 and CRP: 35. CT imaging revealed multiple diverticula reaching 2.5 cm in diameter in jejunal loops, stranding in peridiverticular fat tissue, and free air in the left upper quadrant. Surgical exploration identified a perforated diverticulum 60 cm distal to the Treitz ligament, accompanied by fibrinopurulent exudate in the surrounding tissues. Due to the wide base of the diverticulum and extensive inflammation, a 10 cm segmental small bowel resection with end-to-end anastomosis was performed. Pathological examination confirmed serosal active chronic inflammation. The patient was discharged without complications on the 6th postoperative day.

Conclusion: Jejunal diverticulitis should be considered in the differential diagnosis of acute abdominal pain, particularly in the elderly population. CT is the gold standard for diagnosis. In the presence of perforation, simple diverticulectomy carries risks of leakage and recurrence; therefore, segmental resection of the affected segment with primary anastomosis is the safest surgical approach to reduce morbidity and mortality.

Keywords: Acute abdomen, jejunal diverticulum, perforation

Evaluation of the necessity of re-excision in patients with positive surgical margins after breast-conserving surgery: Analysis of residual malignancy in re-excision specimens

Ayşe Yosun Aydın, Sermet Terzi, Ömer Cennet, Ali Konan

Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara

Objective: Although re-excision is the standard approach for patients with positive surgical margins after breast-conserving surgery (BCS), residual malignancy is not detected in all re-excision specimens. This situation may lead to potentially unnecessary surgical interventions, increased morbidity, and additional patient burden. The aim of this study was to compare the clinicopathological characteristics of patients with and without residual malignancy in re-excision specimens, to identify potential factors associated with residual malignancy, and to contribute to more rational and individualized clinical decision-making regarding the necessity of re-excision.

Material and Methods: This retrospective, single-center study was conducted at Hacettepe University and included patients who underwent re-excision due to positive surgical margins following BCS between 2018 and 2026. A total of 37 patients were evaluated. A positive surgical margin was defined as the presence of invasive carcinoma or ductal carcinoma *in situ* (DCIS) at the inked surgical margin. Patients who received neoadjuvant therapy were excluded from the study. Patients were divided into two groups according to the presence (Group 1) or absence (Group 2) of residual malignancy in the re-excision specimen. Continuous variables were expressed as mean ± standard deviation, and categorical variables as numbers and percentages. Group comparisons were performed using descriptive statistical methods.

Results: The mean age of the study population was 51.9 years. Residual malignancy was detected in 14 patients (37.8%), while no malignancy was identified in 23 patients (62.2%). The mean age was lower in patients with residual malignancy compared with those without residual malignancy (48.1 vs. 54.2 years). The rate of concomitant DCIS was 85.7% in patients with residual malignancy and 95.7% in those without residual malignancy. High tumor grade (Grade 3) was more frequently identified in patients without residual malignancy than in those with residual malignancy (60.9% vs. 28.6%). A low rate of residual malignancy was identified in patients with single positive surgical margins and a limited invasive component. Among the 14 patients with residual malignancy, five required a second re-excision due to persistent positive surgical margins in the re-excision specimen.

Conclusion: Routine re-excision in all patients with positive surgical margins after BCS may result in unnecessary surgical procedures in a substantial proportion of patients. An individualized patient selection strategy based on clinicopathological risk factors may contribute to a more accurate determination of the necessity for re-excision. This approach may help reduce patient morbidity and improve clinical decision-making. Further prospective studies with larger patient cohorts are warranted to validate these findings.

Keywords: Breast-conserving surgery, positive surgical margin, re-excision

[P-480]

Impact of treatment approaches on recurrence in granulomatous mastitis cases: A single-center experience

Merve Tok[1], Özden Yülek[2], Kenan Çetin[3]

[1]*Çanakkale Onsekiz Mart University, Çanakkale*

[2]*Department of Pathology, Çanakkale Onsekiz Mart University, Çanakkale*

[3]*Department of General Surgery, Çanakkale Onsekiz Mart University, Çanakkale*

Objective: Granulomatous mastitis is a chronic inflammatory breast disease that can clinically and radiologically mimic malignancy and presents a challenge for clinicians due to high recurrence rates during treatment. Although recent consensus studies recommend individualizing treatment decisions according to the clinical subtype of the disease and advise against the routine use of surgery as first-line therapy, surgical treatment is still frequently used as an initial approach in daily clinical practice. This study aimed to evaluate the clinical outcomes and the effect of medical and surgical treatment approaches on recurrence in patients with granulomatous mastitis followed at our center.

Material and Methods: Patients diagnosed with granulomatous mastitis and followed at our center over the past five years were retrospectively evaluated. Demographic characteristics, presenting symptoms, diagnostic methods, treatment approaches, and follow-up outcomes were analyzed. Treatment approaches were classified into two groups: medical treatment (topical and/or oral corticosteroids) and surgical treatment (segmental excision). Recurrence was defined as the development of a new lesion in the same breast after achieving clinical and/or radiological remission. Treatment groups were compared in terms of recurrence rates.

Results: A total of 26 patients were included in the study. Unilateral breast involvement was observed in 23 patients (88.5%), and the most common presenting complaints were breast mass (n=13, 50%) and pain (n=13, 50%). Diagnosis was predominantly established by tru-cut biopsy (n=19, 73.1%). Surgical treatment was performed in 11 patients (42.3%), while 15 patients (57.7%) received medical treatment. The median follow-up duration was 22 months (range, 4-60 months). Recurrence occurred in 7 of the 11 surgically treated patients (63.6%) and in 4 of the 15 medically treated patients (26.7%). Although recurrence rates were higher in the surgical treatment group, no statistically significant difference was observed between the treatment groups due to the limited sample size (p=0.06).

Conclusion: The higher recurrence rates observed in patients undergoing surgical treatment support the view that surgery should not be reflexively used as first-line therapy in granulomatous mastitis. Treatment decisions should be individualized according to disease stage and clinical subtype.

Early postoperative outcomes and oncologic safety of video endoscopic nipple-sparing mastectomy and axillary evaluation with immediate breast reconstruction in breast cancer patients

Kazım Şenol

Division of Breast Surgery, Department of General Surgery, Bursa Uludağ University Faculty of Medicine, Bursa

Objective: Video endoscopic nipple-sparing mastectomy (VENSM) with axillary evaluation and immediate breast reconstruction (IBR) is an evolving technique in the surgical management of breast cancer. This study aims to evaluate the oncological safety, cosmetic outcomes, and early postoperative results of this minimally invasive approach.

Material and Methods: Between January 2021 and December 2025, a prospective cohort of breast cancer patients underwent VENSM with axillary evaluation (sentinel lymph node biopsy or axillary lymph node dissection) and IBR at Bursa Uludağ University Faculty of Medicine, General Surgery Department. Patient demographics, tumor characteristics, surgical details, oncological outcomes, and early postoperative results were collected and analyzed.

Results: A total of 224 patients underwent mastectomy where 57 (25.4%) were bilateral, 167 (74.6%) were unilateral. 103 (46%) had implant-based reconstruction. A total of 22 patients (9.82%) had VENSM in the cohort and 40 mastectomy and implant-based reconstructions were performed. The median follow-up period was 8 months. The mean age of the patients was 48 years. Pathological analysis confirmed positive margins in one case (4.5%). The sentinel lymph node biopsy was performed in all patients, and 3 patients underwent axillary lymph node dissection. The mean operative time was 210 minutes, and the median hospital stay was 1 days. Early postoperative complications included minor wound complications in one breast (2.5%) and nipple areola complex in three breasts (7.5%), all of which were managed conservatively. In total two implants (5%) were lost during follow-up. Overall complication rates were higher in conservative mastectomy and reconstruction group (n=32, 15.84%, p=0.81), with higher implant loss rates (n=8, 7.76%, p=0.84). The cosmetic outcomes were rated with Breast-Q.

Conclusion: The early results of this study demonstrate that VENSM with axillary evaluation and IBR is an oncologically safe and cosmetically favorable option for selected breast cancer patients. The technique is associated with minimal complications and excellent cosmetic outcomes. Further studies with longer follow-up are needed to confirm these findings and assess long-term oncological safety.

Keywords: Breast cancer, early outcomes, video endoscopic nipple-sparing mastectomy

Small intestine and vermiform appendix lengths in healthy adults: Intraoperative morphometric data from a living donor cohort

Emrah Şahin[1], Adem Tuncer[1], Cüneyt Kayaalp[2], Abuzer Dirican[1], Bülent Ünal[1], Servet Karagül[2]

[1]*Department of General Surgery, İstanbul Aydın University Faculty of Medicine, İstanbul*

[2]*Department of General Surgery, Atlas University Faculty of Medicine, İstanbul*

Objective: Small intestine and vermiform appendix lengths are critical anatomical parameters in bariatric surgery and short bowel syndrome management. However, reliable normative data from direct *in vivo* measurements in healthy individuals are limited. This study aimed to establish reference values in healthy living liver donors and investigate the potential morphometric relationship between these structures.

Material and Methods: Data from 99 healthy living liver donors representing a multi-ethnic population were analyzed retrospectively. Intraoperative measurements were performed using a standardized technique: small intestine length (SIL) from the ligament of Treitz to the ileocecal valve, and appendix length from base to tip. Relationships between morphometric and anthropometric variables were evaluated.

Results: The mean SIL was 630±104.7 cm, and the mean appendix length was 84.8±21.1 mm. SIL was significantly greater in males (654.8 cm vs. 601.5 cm, p=0.011), while no sex-based difference was found for appendix length (p=0.389). A weak but significant positive correlation was found between SIL and appendix length (r=0.237, p=0.021). An appendix length ≥8 cm was associated with a higher probability of SIL >600 cm. Additionally, Meckel's diverticulum was incidentally detected in 2.0% (n=2) of donors. Notably, the retrocecal appendix position was observed in only 4.0% of donors, which is significantly lower than rates reported in appendicitis series.

Conclusion: This study provides reference values for SIL and appendix length based on direct measurements in healthy individuals. The weak relationship between SIL and appendix length suggests a biological continuum based on shared embryological origin and immunological roles but should not be used as a standalone clinical predictor.

Keywords: Appendix, living donors, small intestine

Figure 1. Meckel's diverticulum. Intraoperative view of an incidental Meckel's diverticulum detected during surgery in a healthy living donor (prevalence: 2.0%).

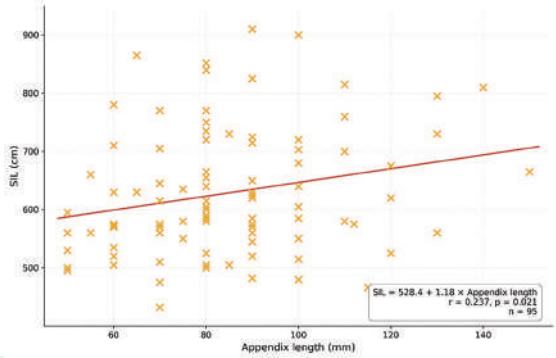

Figure 2. Correlation between small intestine length (SIL) and appendix length. Scatter plot illustrating the relationship between SIL and appendix length (n=95). The linear regression equation is SIL=528.4+1.18×appendix length (mm). The plot demonstrates a weak but statistically significant positive correlation (r=0.237, p=0.021).

Table 1. Small intestine and appendix length measurements by sex

Parameter	Entire cohort	Female	Male	p-value*
SIL (cm)	630.0±104.7	601.5±91.1	654.8±110.2	**0.011**
Appendix (mm)	84.8±21.1	82.8±21.4	86.5±21.0	0.389

Data are presented as mean ± standard deviation. * Differences between groups were evaluated using Student's t-test. SIL: Small intestine length.

[P-483]

Approach to splenic artery aneurysm - a single-center 13-year retrospective analysis

Sadiye Akbaş[1], Sefa Ergün[1], Başar Can Turgut[2], Yasemin Pekmezci[1], Salih Pekmezci[1]

[1]*Department of General Surgery, İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İstanbul Training and Research Hospital, İstanbul*

Objective: Splenic artery aneurysm is an abnormal dilatation of the splenic artery and is usually asymptomatic; however, rupture may present with sudden abdominal pain, hemorrhagic shock, and high mortality. Clinical significance increases particularly in female patients, pregnancy, and conditions such as portal hypertension.

Material and Methods: Patients diagnosed with splenic artery aneurysm at İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine between 2013 and 2026 were evaluated retrospectively. Demographic data; clinical presentation, imaging modality, aneurysm diameter, location, multifocality, treatment applied, and follow-up outcomes were obtained from medical records.

Results: Of the 41 patients, 34 were female, and the age range was 27-80 years. The median aneurysm diameter was 18 mm (range: 5-70). The mean follow-up duration was 42.5 months. Twenty-nine patients were asymptomatic, while 12 were symptomatic with abdominal pain. The management strategy was determined according to the patient's clinical status and aneurysm characteristics. One patient was evaluated emergently due to rupture; one patient was diagnosed during pregnancy. Surgical treatment was performed in eight patients; transcatheter coil embolization was used in three patients (definitive treatment in two patients and a preoperative attempt prior to surgery in one patient). The remaining patients were managed with conservative follow-up. Aneurysm diameter was significantly larger in patients who underwent an intervention compared with the follow-up group (median 45 mm vs. 13.5 mm). Postoperative collection was observed in two patients.

Conclusion: In conclusion, splenic artery aneurysms present with a broad clinical spectrum. While regular imaging follow-up may be an appropriate option for small and asymptomatic aneurysms, active treatment with surgery or embolization can be safely applied in symptomatic or large aneurysms, as well as in high-risk situations such as pregnancy and rupture.

Bibliometric analysis of machine learning and artificial intelligence applications in postoperative pancreatic fistula (2020-2026)

Begüm Aytaş Nazar[1], Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Melih Akıncı[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hosspital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Postoperative pancreatic fistula (POPF) remains a major determinant of morbidity and mortality after pancreaticoduodenectomy (Whipple procedure). In recent years, machine learning (ML) and artificial intelligence (AI)–based predictive models have increasingly been applied to surgical complication forecasting. This study aimed to bibliometrically evaluate publication trends, thematic structure, and scientific production dynamics of ML/AI applications in POPF following pancreaticoduodenectomy.

Material and Methods: Publications between 2020 and 2026 were retrieved from PubMed using the following query: ("pancreaticoduodenectomy" OR "Whipple procedure") AND ("postoperative pancreatic fistula" OR "pancreatic fistula" OR "POPF") AND ("machine learning" OR "artificial intelligence" OR "deep learning" OR "neural network"). Data were analyzed using Bibliometrix/Biblioshiny. Annual scientific output, country and institutional contributions, author productivity (Lotka's law), core journals (Bradford's law), keyword co-occurrence networks, thematic mapping, and temporal keyword trends were assessed.

Results: A total of 31 publications were included. Output markedly increased after 2023, peaking in 2024-2025. The studies involved 289 authors (≈10 authors per article), with no single-author publications. The international collaboration rate was 19.35%. China emerged as the leading contributor, particularly after 2023, followed by the United States, the Netherlands, Italy, and Germany. The University of Zurich and several Chinese institutions were prominent at the institutional level. Frequently occurring keywords included "retrospective studies," "risk factors," "humans," "pancreaticoduodenectomy/adverse effects," and "ROC curve," indicating a predominantly retrospective, risk-modeling-based methodology. Thematic mapping identified "machine learning" and "postoperative complications/etiology" as motor themes, whereas "deep learning" and "neural networks" appeared as low-density, emerging themes. These findings suggest a transitional phase from conventional clinical risk assessment toward ML-driven predictive modeling.

Conclusion: Between 2020 and 2026, AI/ML research in POPF after pancreaticoduodenectomy accelerated significantly, yet remains concentrated in a limited number of countries and institutions and is largely retrospective in design. Thematic analysis indicates that ML has become the field's driving theme, while deep learning and neural networks are still in early developmental stages. By quantitatively delineating growth patterns and methodological orientations, this study highlights priority gaps—multicenter datasets, prospective validation, standardization, and generalizable modeling—thereby providing a roadmap for future research.

Comparison of preoperative, perioperative and postoperative outcomes of emergency and elective inguinal hernia surgery in geriatric patients using antiaggregants

Onur Ağ

University of Health Sciences Türkiye, Elazığ Fethi Sekin City Hospital, Elazığ

Objective: The proportion of the geriatric population is increasing worldwide, leading to continuous updates in medical management for elderly patients. Polypharmacy is common in this group, and antiplatelet therapy is among the most frequently prescribed treatments. However, these agents complicate surgical decision-making due to increased perioperative bleeding risk and potential rises in morbidity and mortality. This study aimed to compare preoperative characteristics and postoperative outcomes of elective and emergency inguinal hernia repair in patients over 65 years of age receiving antiplatelet therapy.

Material and Methods: This retrospective study included patients over 65 years who underwent inguinal hernia surgery between January 2025 and February 2026 while receiving regular antiplatelet therapy (acetylsalicylic acid, clopidogrel, P2Y12 receptor antagonists, GPIIb/IIIa receptor antagonists, or combination therapy). Patients were divided into two groups: Group 1 (emergency surgery) and Group 2 (elective surgery). Preoperative evaluation included age, gender, ASA score, and comorbidities. Postoperative complications were assessed using the Clavien-Dindo classification. Postoperative bleeding, seroma, hematoma, wound infection, chronic pain, recurrence, and length of hospital stay were compared.

Results: A total of 101 male patients were included; 29 (28%) underwent emergency surgery and 72 (72%) underwent elective surgery. The mean age was 75 years, with no significant age difference between groups ($p<0.35$). However, the ASA score was significantly higher in the emergency group ($p<0.001$). Operative time was significantly longer in the emergency group (mean 88 minutes) compared to the elective group (mean 62 minutes) ($p<0.001$). Postoperative complications showed no statistically significant differences between groups. Seroma occurred in 3.6% of emergency cases and 6.9% of elective cases ($p=1$). Hematoma was observed in 21.4% of emergency patients and 9.7% of elective patients ($p<0.18$). Chronic pain occurred in 32.1% of emergency patients and 16.7% of elective patients ($p<0.15$). Recurrence was detected in 7.1% of emergency cases and 4.2% of elective cases ($p<0.61$).

Conclusion: Elective inguinal hernia repair in geriatric patients receiving antiplatelet therapy can be performed safely with acceptable complication rates in patients with an appropriate preoperative risk profile. Delaying surgery may result in emergency presentation, higher preoperative risk, and increased morbidity. Therefore, elective surgery under optimal conditions may improve postoperative outcomes in this patient population.

Keywords: Inguinal hernia, geriatrics, antiplatelet

ANTİAGREGAN KULLANAN GERİATRİK HASTALARDA ACİL VE ELEKTİF İNGÜİNAL HERNİ CERRAHİSİNİN PREOPERATİF,PERİOPERATİF VE POSTOPERATİF SONUÇLARININ KARŞILAŞTIRILMASI

Onur Ağ

Sağlık Bilimleri Üniversitesi ,Elazığ Fethi Sekin Şehir Hastanesi ,Genel Cerrahi Kliniği,ELAZIĞ

GİRİŞ

Dünya genelinde geriatrik popülasyonun oranı normal popülasyona göre artmakta ve geriatrik hastalarda tıbbi operasyon ve medikasyonların sürekli güncellenmesine neden olmaktadır.Geriatrik hastalarda polifarmasi sık görülmekle birlikte en sık kullanılan ilaç gruplarından olan antiagregan tedaviler ,perioperatif kanama riski açısında cerrahi karar sürecini zorlaştırırken morbidite ve mortalitede de artışa neden olmaktadır .Bu çalışmada antiagregan kullanan 65 yaş üstü hastalarda elektif ve acil ingüinal herni cerrahisinin preoperatif ,perioperatif ve postoperatif sonuçlarının karşılaştırılması amaçlanmıştır.

YÖNTEMLER

Bu retrospektif çalışmaya Ocak 2025-Şubat 2026 yılları arasında kliniğimizde ingüinal herni nedeniyle opere edilen ,düzenli antiagregan tedavi alan (asetilsalisik asit,klopidogler, P2Y12 (ADP) Reseptör Antagonistleri, GPIIb/IIIa Reseptör Antagonistleri veya multiple tedavi)hastalar dahil edildi . Çalışmaya dahil edilen hastalar grup 1 (acil) ,grup 2 (elektif) olarak 2 gruba ayrılmıştır Hastaların preoperatif değerlendirmede yaş ,cinsiyet ,ASA skorları ,ek hastalıkları değerlendirilirken,postoperastif komplikasyonlar Clavien-Dindo sınıflamasına göre analiz edildi .Postoperatif kanama,seroma ,yara yeri enfeksiyonu,hastanede kalım süresi ,kronik ağrı ve nüks açısından karşılaştırılarak değerlendirildi .

BULGULAR

Çalışmaya dahil edilen 101 hastanın 29'u (%28) acil, 72'si (%72) elektif cerrahi geçirmiştir.Tüm hastalar erkek cinsiyete sahiptir.Yaş ortalaması 75'tir (72.8 ±77.0). Gruplar arasında yaş açısından istatistiksel olarak anlamlı bir fark saptanmamıştır($p<0.35$) .Buna karşın ASA skoru acil grupta 3,0 (3,0±4,0) ile elektif gruba kıyasla 2,0 (2,0 ±4,0) istatistiksel olarak anlamlı biçimde daha yüksek bulunmuştur ($p<0,001$)..

Operatif parametreler incelendiğinde cerrahi süresinin acil grupta elektif gruba kıyasla istatistiksel olarak anlamlı düzeyde daha uzun olduğu görülmüştür. Cerrahi süresi acil grupta ortalama 88,0(77.8 ± 103.2) dakika iken elektif grupta medyan 62,0 (53.8 –±72.0) dakika olup istatistiksel olarak anlamlı bulunmuştur ($p<0,001$).

Postoperatif komplikasyonlar değerlendirildiğinde acil cerrahi yapılan 1 hastada (%3.6) elektif cerrrahi yapılanlarda 5 hastada (%6,9) seroma , acil cerrahi yapılanlardan 6 hastada (%21.4),elektif cerrahi yapılanlardan 7 hastada (%9.7) hematom , acil cerrahi yapılan 9 hastada (%32.1) ,elektif cerrahi yapılan 12 hastada (%16.7) kronik ağrı ve acil cerrahi yapılan 2 hastada (%7.1elektif cerrahi yapılan 3 hastada (%4.2) nüks saptanmış olup bu bulgular istatistiksel olarak anlamlı bulunamamıştır ($p<1,p<0.18,p<015,p<0.61$).

SONUÇLAR

Antiagregan kullanan geriatrik hastalarda elektif inguinal herni onarımı, preoperatif risk profili uygun hastalarda kabul edilebilir postoperatif komplikasyon oranları ile güvenli bir şekilde uygulanabilmektedir. Buna karşılık cerrahinin ertelenmesi acil başvuruya, daha yüksek preoperatif risk profiline ve belirgin şekilde artmış postoperatif morbiditeye yol açmaktadır. Bu nedenle geriatrik antiagregan kullanan hastalarda, uygun koşullarda elektif cerrahinin tercih edilmesi postoperatif sonuçları iyileştirebilir.

Three port laparoscopic sleeve gastrectomy: One year single center results

Sangar Abdullah, Hanım Esra Çoksürer

University of Health Sciences Türkiye, Sancaktepe Şehit Prof. Dr. İlhan Varank Training and Research Hospital, İstanbul

Objective: Laparoscopic sleeve gastrectomy (LSG) is a widely performed and effective procedure in the surgical management of morbid obesity. The conventional technique typically requires four to five ports. This study aimed to evaluate the safety, feasibility, and early clinical outcomes of the three-port LSG technique.

Material and Methods: Patients who were scheduled for three-port LSG between January 2024 and January 2025 were retrospectively analyzed. A total of 54 patients were initially planned for a three-port approach. Due to intraoperative technical requirements, a fourth port was inserted in three patients, and these cases were excluded from the final analysis. The study cohort consisted of 51 patients. The evaluated parameters included: demographic characteristics, operative time, number of staplers used, length of hospital stay, intraoperative and postoperative complications, Clavien-Dindo classification, percentage of excess weight loss (%EWL), percentage of total weight loss (%TWL), comorbidity response. All procedures were performed by the same surgical team.

Results: The mean age of the patients was 35.7±9.4 years, and the mean body mass index (BMI) was 43.3±3.0 kg/m^2. Females constituted 70.5% of the study population. The mean operative time was 61.3±5.4 minutes. No intraoperative complications were observed. The overall postoperative morbidity rate was 5.8% (3/51). According to the Clavien-Dindo classification: One patient developed a Grade I complication, one patient required blood transfusion due to postoperative bleeding (Grade II), one patient underwent reoperation under general anesthesia due to a Veress needle-related injury (Grade IIIb). The major complication rate was 1.9%. No staple-line leakage or mortality was observed. A fourth port was required in 3 patients (5.5%). The mean length of hospital stay was 2-3 days. The mean %EWL was 77.6%, and the mean %TWL was 33%. A complete response was achieved in the majority of obesity-related comorbidities.

Conclusion: Three-port LSG demonstrated a low major complication rate (1.9%), acceptable operative time, and satisfactory early weight loss outcomes in this series. When performed by an experienced surgical team in appropriately selected patients, the three-port approach may represent a safe and feasible alternative to the conventional multi-port technique.

Does debridement technique affect bacterial load? A comparison of jet lavage and surgical debridement

Muhammet Halil Duru, İsmail Sezikli, Ramazan Topcu, Murat Kendirci

Hitit University Faculty of Medicine, Erol Olçok Training and Research Hospital, Çorum

Objective: Diabetic foot ulcers are among the most serious and costly complications of diabetes mellitus. The development of infection in these patients prolongs the healing process and increases the risk of major amputation. Debridement is a cornerstone in infection control, as it facilitates both the removal of necrotic tissue and the reduction of bacterial load. In recent years, jet lavage-assisted debridement has emerged as a technique that enhances mechanical cleansing. However, the effect of this method on bacterial load, in comparison with conventional surgical debridement, remains unclear. The aim of this study is to compare the effects of jet lavage-assisted debridement and conventional surgical debridement on bacterial load in diabetic foot ulcers.

Material and Methods: This study was designed as a prospective, randomized controlled trial. Patients diagnosed with Wagner grade 2-3 diabetic foot ulcers were included in the study. The patients were randomized into two groups: Group A: Jet lavage-assisted debridement. Group B: Conventional surgical debridement. From each patient, tissue biopsy samples were obtained from the wound bed both before debridement and after debridement. Microbiological evaluation was performed using a quantitative culture method, and the results were expressed as colony-forming units per gram (CFU/g). A p-value of <0.05 was considered statistically significant.

Results: According to the findings obtained at the end of the study, a statistically significant reduction in bacterial load after debridement was observed in the jet lavage group ($p<0.001$). The reduction in bacterial load was significantly greater compared to the conventional surgical debridement group.In addition, the need for repeat debridement was lower in the jet lavage group. Clinically, the wound bed appeared cleaner and more suitable for granulation tissue formation.

Conclusion: According to the results of our study, jet lavage-assisted debridement may be a more effective method than conventional surgical debridement in reducing bacterial load in diabetic foot ulcers. This technique may contribute positively to infection control, wound healing, and the overall success of surgical treatment. We believe that integrating jet lavage-assisted debridement into surgical practice, in appropriately selected patients, may be beneficial.

Keywords: Chronic wound, diabetic foot

Use of cadaveric iliac vein graft in recipient after laparoscopic right donor nephrectomy

Özgür Yıldırım, Veli Kılıç, Edip Akpınar

Department of General Surgery and Organ Tranplantation, University of Health Sciences Türkiye, Adana Faculty of Medicine, Adana City Training and Research Hospital, Adana

Objective: In living donor kidney transplants, laparoscopic harvesting of the right kidney is technically challenging due to the short and thin-walled nature of the right renal vein. This anatomical limitation can increase the risk of vascular complications and graft failure during implantation. Various venous lengthening techniques are used to overcome these challenges and ensure a tension-free, safe anastomosis. The aim of this study is to evaluate the technical feasibility and clinical outcomes of using a cadaver iliac vein graft for lengthening the right renal vein in cases undergoing laparoscopic right donor nephrectomy.

Material and Methods: Consecutive laparoscopic donor nephrectomy cases performed at our center were retrospectively reviewed. In this study, cases undergoing right donor nephrectomy were analyzed in terms of recipient and donor demographic characteristics, the anatomical structure of the renal vein, and the vascular reconstruction techniques applied. In cases where the right renal vein was found to be thin-walled and of insufficient length for anastomosis during the operation, venous lengthening was performed using a cadaveric iliac vein segment during the "back-table" preparation phase. Technical success was evaluated using parameters such as hot and cold ischemia times, peroperative vascular complications, and long-term graft survival.

Results: Of the 96 laparoscopic donor nephrectomy cases examined, 13 (13.5%) were from right donor nephrectomy. The mean age of recipients was 43 (27-69; 5 women, 8 men), and the mean age of donors was 49 (24-63; 10 women, 3 men). Due to right renal vein anatomy, reconstruction with a cadaveric iliac vein graft was performed in 10 cases (77%). No intraoperative complications occurred in any of the cases that underwent vascular reconstruction, and cold ischemia times remained within clinically acceptable limits despite the additional time spent in back-table preparation. No renal vein thrombosis, vascular stenosis, or primary graft failure related to the use of venous lengthening grafts was observed in the postoperative period. During a median follow-up period of 20 months (1-60 months), two patients died due to COVID-19 and one patient died due to pulmonary mycosis. The kidney function of the 10 surviving patients is within normal limits.

Conclusion: Venous lengthening with a cadaveric iliac vein graft after laparoscopic right donor nephrectomy offers a reliable and permanent solution to the technical challenges posed by a short renal vein. This approach allows for the safe expansion of the donor pool for centers that traditionally prefer the left kidney due to surgical difficulties.

The diagnostic value of mammography in young breast cancer patients

Mahmut Ayvazoğlu, Saliha Karagöz Eren

University of Health Science Türkiye, Kayseri City Training and Research Hospital, Kayseri

Objective: Currently, mammography is the most commonly used imaging method for breast cancer screening in the population over 40 years of age. While it is not routinely used for screening in the population under 40, its use is recommended for identifying and supporting diagnoses of lesions with a high suspicion of malignancy during physical examination. Current studies show that mammography has high sensitivity, particularly in less dense breasts.

Material and Methods: Based on this information, in order to evaluate the contribution of mammography to diagnosis in breast cancer patients diagnosed under the age of 40, 65 patients under the age of 40 who underwent surgery at University of Health Science Türkiye, Kayseri City Training and Research Hospital between 2023 and 2025 were retrospectively evaluated.

Results: Mammography was not performed in 35 operated patients (53.8%), whereas 30 patients (46.2%) underwent mammographic evaluation. Among those who underwent mammography, 3 patients (10%) were reported as BI-RADS 0, while 27 patients (90%) had BI-RADS 4-6 findings. Of the 16 patients classified as BI-RADS 6, mammography was performed after histopathological confirmation and prior to treatment, following breast ultrasound and magnetic resonance imaging (MRI) by breast surgery specialists. In contrast, cases without mammography were managed by surgeons without breast surgery subspecialization. These findings indicate that mammography use in young patients may vary according to physician specialization. At initial diagnosis, 39 patients (60%) were in advanced stages. Specifically, 29 patients (44.6%) were stage III and 10 patients (15.4%) stage IV. Early-stage breast cancer (stage I-II) was observed in 26 patients (40%). When stratified by stage, the diagnostic contribution of mammography appeared independent of disease stage.Regarding surgical management, 25 patients (38.5%) underwent mastectomy, while 40 patients (61.5%) received breast-conserving surgery. No statistically significant association was found between mammography use during diagnosis and surgical treatment. Among mastectomy patients, mammography was not used in 17 (26.16%) and was used in 8 (12.31%). Similarly, among breast-conserving surgery patients, mammography was not performed in 18 (27.69%) and was performed in 22 (33.84%). Breast MRI was performed in all patients who did not undergo mammography.

Conclusion: Current guidelines recommend clinical mammography for all patients aged 30 and over with palpable masses and suspicious findings for breast cancer. In our cases, it was observed to contribute to the diagnosis. Mammography should not be avoided due to young breasts or dense breast tissue.

Keywords: Mammography, young breast cancer

Table 1. Preference for mammography in diagnosis of breast cancer in patients under 40 years of age

Viewing preference	n	%
Mammogram taken	35	53.8
Mammogram not performed	30	46.2
Total	**65**	**100**

Table 2. Mamografi çekilen hastalar BI-RADS dağılımı (n=30) (2023-2025)

Mammography result	n	%
BI-RADS 0	3	10.0
BI-RADS 4	5	16.7
BI-RADS 5	6	20.0

BI-RADS 4-6 constitutes the patient group in which mammography supports diagnosis (n=27, 90%).

[P-501]

The role of preoperative CA19-9 in predicting resectability and survival in intrahepatic cholangiocarcinoma: A single-center retrospective study

Yunus Sür, Ceren Yavuz, Feride Mustafayeva, Furkan Karahan, Örgün Güneş, Arif Atay, Fevzi Cengiz

Department of General Surgery, İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir

Objective: Intrahepatic cholangiocarcinoma (ICC) is a primary liver malignancy known for its aggressive clinical course and low surgical resectability rates. Surgical resection remains the only curative treatment option. In this study, we aimed to evaluate the clinicopathological characteristics, surgical outcomes, and the impact of tumor marker levels on survival in patients diagnosed with ICC at our center over the last 10 years.

Material and Methods: A total of 43 patients (21 males, 22 females) diagnosed with ICC between 2015 and 2025 at our center were retrospectively analyzed. Patients were divided into two groups: Surgical resection (Group 1, n=10) and inoperable/advanced disease (Group 2, n=33). Demographic data, preoperative CA19-9 levels, and overall survival were analyzed and compared between the groups.

Results: The median age of the entire cohort was 68 years (range: 35-84). Eleven patients underwent surgical exploration, and one patient was deemed inoperable intraoperatively, resulting in a resectability rate of 23.2%. R0 resection was achieved in 80% (n=8) of the patients in Group 1. The median overall survival was 28.5 months (range: 2-56 months) in Group 1, whereas it was significantly shorter at 3 months (range: 1-26 months) in Group 2. The median CA19-9 level was 138.5 U/mL in Group 1, while marker levels in Group 2 showed a wide distribution, reaching extremely high values up to 920,926 U/mL in some cases. In Group 1, 20% of patients (n=2, at 24 and 56 months) were still alive at the time of analysis and continued follow-up. In contrast, 85% of patients in Group 2 died within the first 6 months after diagnosis.

Conclusion: Our findings demonstrate that surgical resection, particularly achieving R0 margins, is the most important determinant of survival in patients with ICC. Overall survival was markedly longer in patients who underwent curative resection compared to those with unresectable disease. Significantly elevated preoperative CA19-9 levels in the inoperable group suggest that this marker may reflect increased tumor burden and aggressive tumor biology. However, CA19-9 alone is insufficient to determine surgical resectability and should be considered as an adjunctive biomarker in preoperative risk stratification and clinical decision-making. Larger prospective multicenter studies are needed to validate these findings.

Keywords: Intrahepatic cholangiocarcinoma, CA19-9, surgical resectability

The effect of intracorporeal knot-tying in laparoscopic appendectomy on the learning curve of laparoscopic intracorporeal suturing

Mehmet Zafer Sabuncuoğlu[1], İsa Sözen[2], Bilal Turan[2], Serdar Acar[2], İsa Karaca[2], Büşra Rabia Çam[2]

[1]*Akdeniz University Faculty of Medicine, Antalya*

[2]*Süleyman Demirel University Faculty of Medicine, Isparta*

Objective: For surgeons engaged in laparoscopic surgery, suturing and knot-tying techniques are of critical importance. With the development and widespread adoption of reconstructive surgeries in the new century, laparoscopic suturing has gained even greater significance. Laparoscopic suturing techniques are more technically demanding than conventional open surgical suturing techniques, and the learning curve is considerably longer. This is primarily because, unlike in open surgery, the surgeon operates using a two-dimensional image in laparoscopic surgery and lacks depth perception. In addition, the tactile feedback that allows assessment of suture tension in open surgery is largely absent in laparoscopic procedures. During the operation, patient positioning, trocar placement, and the surgeon's stance often restrict both the surgeon's movements and the maneuverability of the suturing instruments. In most cases, surgical manipulation is limited to the angles permitted by the trocars. Furthermore, factors beyond the surgeon's direct control-such as camera angle, the movements of the assisting surgeon, and patient respiratory motion-also contribute to movement limitations. These and similar challenges encountered in advanced laparoscopic procedures may sometimes make such operations difficult or even impossible to perform. Therefore, learning and effectively applying intracorporeal knot-tying techniques in laparoscopic appendectomy is of great importance for achieving laparoscopic proficiency prior to performing advanced laparoscopic surgeries.

Material and Methods: In our clinic, 801 laparoscopic appendectomy surgeries have been performed by residents over the past 10 years. In 670 of these laparoscopic appendectomy cases, the appendix was secured using intracorporeal surgical knot tying, with two intracorporeal knots placed proximally and one placed distally. These cases were evaluated in terms of their contribution to resident training prior to advanced laparoscopic surgeries.

Results: Before starting laparoscopic surgery, surgeons must know basic entry and suturing techniques, both in theory and practice. By learning intracorporeal knot tying during laparoscopic appendectomy in our clinic, residents develop key skills: seeing in 3D on a 2D screen, hand-eye coordination, working with limited touch sensation, operating in a small space, handling the camera, placing trocars, and controlling instruments with both hands for intracorporeal suturing. Keeping up with new technology and combining it with open surgery experience makes even complex laparoscopic procedures possible and successful.

Conclusion: Intracorporeal suturing is one of the most difficult skills in laparoscopic surgery. The goal is to create an ideal suture, and attention to detail is essential. With experience, even complex intracorporeal anastomoses can be performed. Mastering safe laparoscopic suturing techniques helps surgeons gain experience before advanced procedures and improves their success in advanced laparoscopic surgery.

Postoperative pain management approach in patients undergoing anti-reflux surgery for hiatal hernia

Ali Önder Devay[1], Ala Elcircevi[2]

[1]*Medicana Bursa Hospital, Bursa*

[2]*Kocaeli Atakent Cihan Hospital, Kocaeli*

Objective: Postoperative pain following laparoscopic hiatal hernia repair significantly impacts patient recovery, hospital length of stay, andhealthcare resource utilization. Traditional opioid-based anesthesia protocols are associated with substantial complications including postoperative nausea and vomiting (PONV), respiratory depression, delayed discharge, and potential for dependence. Recent advancesin regional anesthesia techniques, long-acting local anesthetic formulations, and multimodal opioid-sparing protocols havedemonstrated promising outcomes in reducing opioid consumption while maintaining effective analgesia. This comprehensive review examines contemporary evidence-based pain management strategies for hiatal hernia repair surgery.

Material and Methods: A systematic literature review was conducted acrossfive databases (SciSpace Deep Search, Google Scholar, and PubMed), retrieving 636 articles. Following artificial intelligence-powered relevance ranking and deduplication, 125 unique paperswere identified. Studies were filtered to include only publicationsfrom 2019 onwards to ensure maximum currency of evidence. The top 30 most relevant studies were analyzed in detail, including randomized controlled trials, cohort studies, and systematic reviews evaluating regional anesthesia techniques (crural blocks, fascial plane blocks), local anesthetic infiltration strategies, opioid-free anesthesia protocols (OFAP), and multimodal systemic analgesic regimens.

Results: OFAP demonstrated superior clinical outcomes compared to opioid-based protocols (OBAP). OFAP achieved 94.3% same-day discharge rates versus 60.7% with OBAP ($p<0.001$), with median length of stay of 0 days versus 1 day ($p=0.006$). OFAP significantly reducedperioperative nausea and retching (0% versus 15.6%, $p=0.020$) while maintaining comparable pain control. Post-discharge opioid requirements were significantly lower with OFAP (66.7% versus 100%, $p<0.001$), with odds of same-day surgery 8.21 times greater (95% CI: 3.10-21.71; $p<0.001$). Regional anesthesia showed opioid-sparing effects: crural blocks reduced daily morphine requirements by 2 mg with decreased peak pain scores. A systematic review of 12 studies (983 patients) demonstrated that multimodal opioid-free anesthesia significantly reduced early postoperative pain, PONV incidence, and analgesic consumption while improving quality of recovery (QoR-40) scores. Combination systemic regimens provided superior analgesia: at 45 minutes post-surgery, acetaminophen monotherapy resulted in mean pain scores of 7.91, while acetaminophen plus pethidine achieved 5.99 and acetaminophen plus parecoxib achieved 6.87 on the numeric rating scale.

Conclusion: Contemporary evidence supports a paradigm shift toward multimodal, opioid-sparing approaches. Opioid-free anesthesia protocols facilitate same-day discharge, reduce opioid-related complications, and decrease post-discharge opioid requirements while maintaining effective pain control. Regional anesthesia demonstrate opioid-sparing benefits as valuable adjuncts. Multimodal systemic analgesic combinations consistently outperform monotherapy. Implementation of individualized, evidence-based multimodal pain management strategies should beprioritized to optimize patient outcomes, enhance recovery, andminimize healthcare resource utilization in clinical practice.

Bibliometric analysis of the literature on splenic endometriosis: A PubMed-based evaluation

Şükran Çavdar[1], Faruk Yazıcı[3], Muhammed Salih Süer[2], Serkan Demir[2], Alper Yavuz[2]

[1]*Hatay Payas State Hospital, Hatay*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[3]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Splenic endometriosis is an extremely rare clinical entity, and its diagnosis and treatment are often established through postoperative histopathological examination. This study aimed to systematically analyze the bibliometric characteristics of the literature addressing the relationship between splenic endometriosis and splenectomy and to reveal the dynamics of scientific production in this field.

Material and Methods: Publications retrieved using the keywords (endometriosis [Title/Abstract]) AND (spleen OR splenic) AND (splenectomy OR surgery OR histopathology) in the PubMed database were evaluated using bibliometric analysis methods. Publications were examined in terms of production by year, journal and author distribution, country and institutional contributions, keyword trends, and within the framework of Bradford and Lotka laws. Analyses were performed using Bibliometrix/Biblioshiny software.

Results: A total of 31 publications published between 1976 and 2026 across 30 journals were analyzed, involving 136 authors with a mean of 4.42 authors per paper and no single-author publications. The international collaboration rate was low (3.23%), with an annual publication growth rate of 1.4% and a marked increase after 2015. Source analysis demonstrated a highly dispersed publication pattern, with no core journal identified; the Journal of Minimally Invasive Gynecology was the most frequent source (n=2), while most journals contributed only a single article. Lotka analysis revealed predominantly single-publication authorship, with the most productive author contributing only two publications. Country output was mainly concentrated in the United States, Italy, China, Israel, and France. Keyword analysis identified "humans," "female," "adult," and "diagnosis, differential" as the most frequent terms, with increasing prominence over time of themes related to endometriosis diagnosis and magnetic resonance imaging.

Conclusion: Splenic endometriosis is an exceptionally rare entity, most often diagnosed only by postoperative histopathology, and to date lacks a dedicated bibliometric evaluation. To our knowledge, this study is among the first to systematically map the splenic endometriosis literature using PubMed-based bibliometric indicators. The low publication volume and dispersed authorship and journal distribution suggest that a mature research ecosystem has not yet developed, which may partly explain the lack of standardized clinical management. Keyword and trend analyses indicate a temporal shift in focus from surgical techniques toward diagnostic challenges, differential diagnosis, and imaging, particularly magnetic resonance imaging. The concentration of contributions within a limited number of institutions further reflects the fragmented and case-based nature of the field. Overall, this study delineates the current structure of the literature and highlights the need for future multicenter, standardized research to improve diagnostic approaches.

High trauma score accidents: Tractor accidents

Cansu Alyeşil Özturan[1], Barış Tüzün[2], Sumru Beril Çetintaş Atak[2], Murat Burç Yazıcıoğlu[2], Büşra Balkan[2], Murat Özdamar[2]

[1]*Clinic of Emergency Medicine, Kocaeli City Hospital, Kocaeli*

[2]*Clinic of General Surgery, Kocaeli City Hospital, Kocaeli*

Objective: Tractor accidents typically occur in rural areas, involving drivers and passengers without protective equipment, and exhibiting characteristics of both in-vehicle and out-of-vehicle traffic accidents, often resulting in high trauma scores. Given our hospital's characteristics as a regional referral hospital for traumatology, we believe that trauma scoring systems and evaluation based on these scores are crucial, as we can conduct detailed examinations and provide necessary consultations.

Material and Methods: Between January 1, 2024, and December 31, 2025, 10 cases evaluated in our hospital's emergency department or referred to our emergency department from other centers were assessed. The patients' age, gender, trauma ultrasound (e-FAST) results (if performed), CT scans taken in the emergency department and after admission, and surgical notes were evaluated to determine their current pathologies, clinical or intensive care unit needs, and mortality rates. Based on these findings, the new injury severity score (NISS) was calculated.

Results: The mean age of the patients included in the study was 55.5 (21-83), and all 10 patients were male (100%). e-FAST was applied in 6 (60%) cases, with 4 (66.7%) cases being positive and 2 (33.3%) cases being negative. Of the 4 cases that were considered positive for e-FAST, 3 (75%) were due to hemothorax and 1 (25%) case was due to widespread intra-abdominal fluid. The mean NISS score in the cases was 25.3 (13-41), and 4 (40%) cases were admitted to the thoracic surgery clinic and 6 (60%) cases were admitted to the intensive care unit. Mortality occurred in 2 cases with a NISS score of 41 in the intensive care unit. The mean NISS scores of the 4 patients admitted to the thoracic surgery clinic were 13.2 (9-18), while the mean NISS scores of the patients admitted to the intensive care unit were 35 (13-41).

Conclusion: The NISS score indicates the need for intensive care and is a highly accurate indicator of mortality. Tractor injuries, occurring frequently in rural areas due to the lack of protective equipment and the common occurrence of being crushed under the vehicle, are cases with high morbidity and mortality and should be rapidly referred to tertiary healthcare centers.

Keywords: Traffic accident, tractor, NISS

Biliary obstruction after deceased donor liver transplantation: Incidence and risk factors

Kağan Karabulut[1], Oğuzhan Özşay[1], Mehmet Can Aydın[2]

[1]*Department of General Surgery, Ondokuz Mayıs University Faculty of Medicine, Samsun*

[2]*Clinic of Gastroenterology Surgery, University of Health Sciences Türkiye, Bursa City Hospital, Bursa*

Objective: Biliary complications remain a significant source of morbidity following liver transplantation (LT). Among these, biliary anastomotic stricture (BAS) has been reported in some series at rates as high as 40%. BAS is commonly attributed to biliary ischemia, small bile duct diameter, and the need for multiple anastomoses. In addition, several recipient- and donor-related factors -including demographic characteristics, etiology, MELD-Na score, donor age, graft-to-recipient weight ratio, and cold/warm ischemia times- have been investigated as potential risk factors. In contrast to the extensive literature on BAS after living-donor LT, studies focusing on deceased-donor LT are limited. This study aimed to evaluate the incidence of BAS after deceased-donor LT and to analyze potential recipient- and donor-related risk factors.

Material and Methods: Patients who underwent deceased-donor LT at our center between January 1, 2019, and February 6, 2025, were included. Prospectively recorded data were retrospectively reviewed. Patients with follow-up shorter than 12 months, those undergoing living-donor LT, patients who died within 90 days, and those who developed rejection were excluded. Recipient and donor age, age difference, sex and Rh incompatibility, body mass index, MELD-Na score, cold and warm ischemia times, and intraoperative transfusion volume were evaluated. Time to BAS development and follow-up duration were recorded. In all patients, duct-to-duct biliary anastomosis was performed using interrupted 6/0 polypropylene sutures. Patients presenting with signs of biliary obstruction and/or cholangitis underwent CT to assess graft vascularity and MRCP for biliary evaluation. The cohort was divided into BAS and non-BAS groups for comparison.

Results: A total of 48 patients met the inclusion criteria. Fifteen (31.3%) were female, and the mean age was 56 (18-69) years. BAS developed in 16 patients (33%), with a median time to diagnosis of 4.7 (0.3-20) months. Median follow-up was 50 (12-85) months. In the final study year, only one case of BAS was observed. None of the evaluated variables were statistically significant predictors of BAS in univariate analysis.

Conclusion: The incidence of BAS in this series was relatively high (33%), and no significant risk factors were identified. This may be related to the limited sample size and evaluated parameters. The marked reduction in BAS during the final study year suggests a potential effect of increasing institutional experience and technical refinement. Larger, multicenter prospective studies are needed to better define risk factors for BAS following deceased-donor LT.

Parathyroid adenoma located between the bifurcated branches of the recurrent laryngeal nerve: A rare case of primary hyperparathyroidism

Kübra Nur Doğru, Mehmet Zeki Buldanlı

University of Health Sciences Türkiye, Gülhane Training and Research Hospital, İstanbul

Objective: Primary hyperparathyroidism (PHPT) is most commonly caused by a solitary parathyroid adenoma and is curatively treated by surgery, the success of which depends on precise localization and careful dissection. Extralaryngeal bifurcation or trifurcation of the recurrent laryngeal nerve (RLN) represents a clinically significant variation, as preservation of all branches is crucial to prevent vocal cord paralysis. When early branching occurs, localization of a parathyroid adenoma between the nerve branches complicates dissection and increases the risk of injury. We present a rare case of a parathyroid adenoma located between bifurcated RLN branches and discuss the surgical approach in light of the literature.

Material and Methods: A 29-year-old female patient presented with complaints of fatigue and muscle weakness. Preoperative laboratory evaluation revealed a serum calcium level of 11.5 mg/dL, 25-OH vitamin D level of 17 ng/mL, and PTH level of 210 pg/mL. The findings were consistent with PHPT. SPECT/CT imaging demonstrated focal increased radiotracer uptake in a mildly hypodense nodular lesion measuring approximately 12×8 mm, located posterior to the mid-inferior portion of the right thyroid lobe. Neck ultrasonography revealed a 13×16 mm iso- to hypoechoic nodular lesion inferior to the right thyroid gland, outside the thyroid capsule. Both imaging modalities were considered compatible with a parathyroid adenoma. Minimally invasive parathyroid adenoma excision was planned. In the preoperative period, the lesion was marked by the department of nuclear medicine using the radioguided occult lesion localization technique. During intraoperative exploration, early bifurcation of the RLN was observed, and the parathyroid adenoma was found to be located between the two nerve branches. Under intraoperative nerve identification and monitoring, and with gamma probe guidance, the parathyroid adenoma was carefully dissected and completely excised. Postoperatively, serum calcium decreased to 9.2 mg/dL and PTH to 32.1 pg/mL. No postoperative hoarseness or vocal cord paralysis developed. Biochemical normocalcemia was achieved, and the patient's symptoms resolved.

Results: RLN bifurcation increases the risk of nerve injury during surgery. Although parathyroid glands may lie medial or posterior to the nerve due to embryologic migration, localization between its branches is exceedingly rare. As preoperative imaging cannot reliably predict nerve variations, selective excision under intraoperative nerve monitoring is recommended. Intraoperative view demonstrating early extralaryngeal bifurcation of the RLN, with the parathyroid adenoma located between the two nerve branches. The adenoma was excised under careful microdissection and intraoperative nerve monitoring. This rare anatomical variation increases the risk of nerve injury, highlighting the importance of meticulous surgical technique and anatomical awareness.

Conclusion: Parathyroid adenoma located between the bifurcated branches of the RLN represents a rare anatomical variation. Careful dissection and intraoperative nerve monitoring are critical for surgical success. Reporting such cases contributes to increased surgical awareness and prevention of potential complications.

An alternative approach in acute inguinal hernia: Hernioscopy

Serkan Giray[1], Utku Özgen[2]

[1]*Silopi State Hospital, Şırnak*

[2]*Pamukkale University Faculty of Medicine, Denizli*

Objective: Inguinal hernia repair is one of the most frequently performed surgical procedures in general surgery, using both open and laparoscopic techniques. However, postponement of elective surgery by some patients leads to an increased number of emergency admissions. In patients presenting with acute incarcerated inguinal hernia, mechanical obstruction may necessitate emergency bowel resection, resulting in a significant increase in morbidity and mortality. On the other hand, when spontaneous reduction of the hernia sac occurs after induction of anesthesia, evaluation of the abdominal organs contained within the sac is often not feasible. In such cases, the inability to exclude potential pathological processes may force the surgeon to proceed with diagnostic laparotomy. At this point, hernioscopy, as a less invasive alternative to diagnostic laparotomy, gains clinical importance.

Material and Methods: Hernioscopy is a technique that enables diagnostic laparoscopy through a single trocar inserted via the hernia sac, performed under low insufflation pressure without the need for additional incisions. A review of the literature reveals that hernioscopy was first described in 1992; however, subsequent reports remain limited.

Results: In our clinic, hernioscopy was performed in selected patients. Following standard open surgical technique, the hernia sac was dissected free, a purse-string suture was placed on the peritoneum, and a 10-mm trocar was inserted to allow laparoscopic evaluation. In our practice, hernioscopy was performed in a total of seven patients who underwent surgery for incarcerated inguinal hernia in whom the contents of the hernia sac could not be clearly evaluated intraoperatively. No pathological findings were detected in the bowel loops in any of the cases. In the presence of pathological findings, continuation with laparoscopic intervention using additional ports or conversion to laparotomy based on a risk-benefit assessment was considered. Particularly in patients with hemodynamic instability or significant comorbidities, in whom laparotomy was expected to increase morbidity and mortality, diagnostic laparoscopy performed via the hernia sac provides an important alternative approach that supports and accelerates the surgeon's intraoperative decision-making process.

Conclusion: In patients undergoing emergency surgery with a preliminary diagnosis of incarcerated hernia, in whom the contents of the hernia sac cannot be clearly evaluated and there is a risk of underlying bowel pathology, hernioscopy using the hernia sac should be considered, especially in situations where laparotomy may lead to a significant increase in morbidity and mortality or when laparoscopic surgery cannot be continued due to patient-related comorbidities.

Our 7-year clinical experience with parastomal hernias

Halil Çınar, Burak Uçaner, Ömer Kılıç, Oğuz Hançerlioğulları

Department of General Surgery, University of Health Sciences Türkiye, Gülhane Training and Research Hospital, Ankara

Objective: Parastomal hernias are uncommon but clinically significant complications that may develop following stoma creation. There is no clear consensus in the literature regarding the optimal management and treatment of these patients. This study aimed to retrospectively evaluate the demographic and clinical characteristics of patients who underwent surgery for parastomal hernia in our clinic.

Material and Methods: This retrospective study included 45 patients who underwent surgical treatment for parastomal hernia at the General Surgery Department of University of Health Sciences Türkiye, Gülhane Training and Research Hospital between January 2018 and January 2025. Patient demographics, including age and sex, were recorded. Preoperative laboratory parameters, including hemoglobin, leukocyte, platelet, and albumin levels, were evaluated to assess baseline clinical status. Imaging modalities used for diagnosis, stoma type, mesh use during surgical repair, and whether the operation was performed under elective or emergency conditions were reviewed using patient files and the hospital information system. The mean age of the patients was 62 years (range: 28-86), and 22 patients (48.9%) were male and 23 (51.1%) were female.

Results: Evaluation of stoma types revealed loop ileostomy in 25 patients (55.6%), loop colostomy in 9 patients (20%), end ileostomy in 2 patients (4.4%), end colostomy in 8 patients (17.8%), and urostomy in 1 patient (2.2%). The mean preoperative hemoglobin level was 12.59 g/dL, mean leukocyte count was 7.02×10^9/L, mean platelet count was 226.5×10^9/L, and mean albumin level was 3.98 g/dL. Computed tomography was the most commonly used imaging modality, performed in 35 patients (77.8%), while ultrasonography was used in 10 patients (22.2%). All patients underwent surgical repair for parastomal hernia. The majority of procedures were performed under elective conditions in 44 patients (97.8%), whereas only 1 patient (2.2%) required emergency surgery. Repair without mesh was performed in 41 patients (91.1%), while mesh reinforcement was used in 4 patients (8.9%).

Conclusion: Parastomal hernias represent clinically important complications with heterogeneous clinical presentations and management strategies. The fact that all patients in this study underwent surgical treatment and that most procedures were performed electively highlights the central role of surgery in their management. The relatively limited use of mesh suggests that surgical decision-making was individualized based on patient-specific and intraoperative factors. These findings emphasize the importance of tailored surgical planning in the management of parastomal hernias. Further prospective studies with larger patient populations are needed to establish standardized treatment protocols and optimize surgical outcomes.

The effect of anti-thymocyte globulin (ATG) use on postoperative surgical complications and graft function in living donor renal transplant patients

Mert Can Polat[1], Eren Gülşahin[1], Müzeyyen Aleyna Ayhan[1], Sudenaz Çıtak[1], Baha Tolga Demirbaş[2]

[1]*Marmara University Faculty of Medicine, İstanbul*

[2]*Clinic of General Surgery, Marmara University Pendik Training and Research Hospital, İstanbul*

Objective: Renal transplantation is considered to be the most effective treatment option compared to dialysis for patients with end-stage renal failure. One of the commonly used agents as an induction immunosuppressive after transplantation is anti-thymocyte globulin (ATG). In this study, the effects of ATG use on postoperative surgical complications and graft functions are evaluated.

Material and Methods: The data of 76 patients who underwent living donor kidney transplantation at Marmara University Pendik Training and Research Hospital between 2015 and 2020 and met the research criteria were retrospectively examined. Surgical complications, graft function (serum creatinine, eGFR) were examined. The chi-square test, Fisher's exact test, t-test, ANOVA test and Mann-Whitney U test were used for statistical analyses, and the significance level was determined as $p<0.05$.

Results: Thirty-three (43.42%) of the patients received ATG and 43 (56.58%) received basiliximab. A total of 22 patients (28%) developed surgical complications. These complications were observed in 7 patients (21.2%) in the ATG group and in 15 patients (34.9%) in the basiliximab group. These complications include hemorrhage (n=5), vascular complications (renal artery or vein thrombosis or stenosis) (n=3), urinary complications (ureteral stenosis, hematuria, bladder dysfunction, vesicoureteral reflux) (n=8), lymphocele (n=2) and surgical site infections (n=5). There was no significant relationship between ATG use and the development of surgical complications ($p=0.193$). There was a significant change in serum creatinine levels over time ($p=0.024$), but ATG use did not show a significant effect on creatinine ($p=0.780$) and eGFR ($p=0.660$). The bacterial infection rate was found to be low in the ATG group and CMV positivity was found to be high; however, these differences are not statistically significant.

Conclusion: There was no significant effect of ATG use on surgical complications, graft function and delayed graft function. ATG was preferred more often in recipients with a high immunological risk (PRA positive, high HLA missmatch number, pretransplant DSA positive). Therefore, when interpreting the results obtained, it should be taken into account that patients who were given ATG initially had a higher immunological risk profile.

Rare but critical: Our clinical experience in the diagnosis and surgical management of Spigelian hernia

Muhammed Hallaç[1], Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Bahattin Bayar[1], Şener Balas[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Spigelian hernia is an important abdominal wall hernia that is prone to diagnostic delay due to its rarity, variable clinical presentation, and often inconspicuous findings on physical examination, carrying a risk of emergency presentation and complications. The aim of this study was to present the clinical characteristics, diagnostic process, surgical management, and outcomes of patients with Spigelian hernia who underwent emergency surgical treatment at the General Surgery Department of University of Health Sciences Türkiye, Ankara Etlik City Hospital, and to compare our findings with the literature.

Material and Methods: Five patients who underwent emergency surgical treatment for Spigelian hernia at University of Health Sciences Türkiye, Etlik City Hospital were retrospectively analyzed. Demographics, comorbidities, and risk factors; clinical presentation and diagnostic delay; imaging modalities and CT reports; surgical approach and repair technique; postoperative complications, hospital stay, follow-up,and recurrence data were evaluated using descriptive statistics.

Results: The mean age of the patients was 64.0±14.6 years, with 80% being female. All patients had comorbidities, with a mean ASA score of 2.6±0.9. A history of previous abdominal surgery was present in 80%, and chronic constipation in 60% of cases. All patients presented with abdominal pain. The mean time from symptom onset to diagnosis was 45.6±27. Four hours, with diagnostic delay (≥48 hours) observed in 60% of cases. A palpable mass was noted in 80% of patients, while in one case (20%) the diagnosis was made solely through imaging. Incarceration occurred in 60% and strangulation in 20%. CT imaging was crucial, diagnosing 80% of cases, although the explicit mention of "Spigelian hernia" in reports was low. All patients underwent open surgical repair, with mesh used in 60% (most commonly in the IPOM position). Postoperatively, seroma developed in one patient (20%), while surgical site infection and ileus were not observed. ICU admission was required in 40%, the mean hospital stay was 5.0±3.0 days, and no recurrence was observed during a mean follow-up of 20.4±8.8 months.

Conclusion: The experience at University of Health Sciences Türkiye, Etlik City Hospital demonstrates that, despite its rarity, Spigelian hernia is a clinically significant pathology, particularly in emergency presentations, with a high risk of diagnostic delay (60%) and complications such as incarceration and strangulation. Although CT played a decisive role in diagnosis in our series,the low frequency of explicit mention of "Spigelian hernia" in CT reports suggests that diagnostic success depends not only on imaging but also on clinical suspicion and radiological reporting awareness. From a surgical perspective, mesh repair was performed in 60% of cases under emergency conditions; no surgical site infections were observed, and no recurrence was noted during follow-up exceeding 20 months. These findings align with the diagnostic challenges emphasized in the literature, highlighting the need for increased awareness for early diagnosis and supporting that, with proper patient selection and technique, mesh repair can be a safe and effective option even in emergency cases. This series, providing real-world data on the diagnosis and management of this rare pathology, offers a practical guide for clinicians and underscores the need for further support from larger case series.

Laparoscopic transabdominal preperitoneal inguinal hernia repair (TAPP) in a young training clinic: Two-year experience

Mehmet Arda Yıldırım, Rona Cansu Kavar Ağcabay, Sunguralp Farsak, Murat Akalın, Mete Numan Etlik, Cem Tuğmen

Department of General Surgery, İzmir Bakırçay University Çiğli Training and Research Hospital, İzmir

Objective: Inguinal hernias are among the most commonly encountered surgical conditions in general surgery practice. Surgical repair is recommended for their treatment, and various surgical techniques are currently employed for this purpose. One of these techniques is laparoscopic inguinal hernia repair.

Material and Methods: The aim of this study was to present the early outcomes of transabdominal preperitoneal (TAPP) inguinal hernia repair performed on patients in a newly established general surgery clinic.

Results: A retrospective analysis was conducted on 102 patients who underwent TAPP inguinal hernia repair at our general surgery clinic between January 2024 and January 2026. Of these patients, 98 (96.1%) were male and 4 (3.9%) were female. The mean age was 55.6 years, and the mean body mass index was 26.8 kg/m^2. According to preoperative anesthesia assessment, 18 patients were classified as ASA I (17.6%), 72 as ASA II (70.6%), and 12 as ASA III (11.8%). Regarding hernia laterality, 51 patients (50%) had right-sided, 31 (30.4%) left-sided, and 20 (19.6%) bilateral inguinal hernias. Intraoperative findings revealed 48 (47.1%) direct, 46 (45.1%) indirect, 7 (6.9%) pantaloon, and 1 (1%) femoral hernia. The mean operative time was 60.9 minutes. The mean postoperative hospital stay was 1.67 days. During a two-year follow-up period, hernia recurrence was observed in 2 patients. Early postoperative complications included inguinal seroma in 2 patients, scrotal edema in 1 patient, inguinal hematoma in 2 patients, trocar site bleeding in 1 patient, and subcutaneous ecchymosis. All patients received appropriate medical management and follow-up during the postoperative period.

Conclusion: The TAPP procedure has recently become a commonly preferred method for inguinal hernia repair due to its advantages of reduced postoperative pain and shorter hospital stay, which facilitate a faster return to daily activities. In our clinic, laparoscopic inguinal hernia repair was successfully performed during the learning curve with low complication and recurrence rates, and these results support its dissemination within the general surgery residency training program.

Minimally invasive pancreatic surgery: Our robotic and laparoscopic experiences

Sinan Şener, Fatih Türkoğlu, Hüseyin Yılmaz

Selçuk University Faculty of Medicine, Konya

Objective: Pancreatic cancers remain among malignancies with high mortality rates due to both theiraggressive biological behavior and the limited chance of curative surgical treatment at thetime of diagnosis. In recent years, minimally invasive approaches including laparoscopic androbotic techniques have been increasingly preferred because of their potential benefits onintraoperative and postoperative morbidity and mortality. However, comprehensive data, particularly regarding long-term outcomes and complication profiles, remain limited.

Material and Methods: In this study, laparoscopic and robotic pancreatic surgeries performed in our clinic between 2020 and 2025 were retrospectively reviewed. Various parameters were compared, including operative duration, anesthesia induction and extubation times, intraoperative blood loss andblood product transfusion requirements. Postoperative outcomes such as thromboembolic events, atelectasis, surgical site infections and mortality were analyzed. Conversion rates tolaparoscopic or open surgery and length of stay in the intensive care unit were also evaluated. In light of similar studies reported in the literature, the current status of laparoscopic and robotic pancreatic surgery and potential future trends were assessed. The aim was toprovide data that may help clarify the advantages and limitations of minimally invasive pancreatic surgery and contribute to surgical decision-making processes.

Results: In robotic pancreatic surgery cases, parameters related to surgical and anesthesiological processes were observed to improve significantly over time. A gradual reduction in operative duration was noted in later cases, indicating more efficient perioperative management. In accordance with learning curve data reported in the literature, increasing team experience led to a more predictable and stable surgical workflow. Postoperative complication rates in robotic pancreatic surgery were found to be lower compared to laparoscopic surgery. Anastomotic leakage, thromboembolic events and mortality were observed in a limited number ofcases. These findings may be associated with the precise dissection capability and stable visualization provided by robotic surgical systems.

Conclusion: Robotic pancreatic surgery appears to be a safe and feasible approach in our clinic withrespect to early surgical and clinical outcomes. The improvement observed in operative processes over time and the trend toward shorter operative durations are consistent with reports from other experienced centers. Increasing surgical and anesthesiological team experience and improved perioperative coordination support the role of robotic surgery as aneffective and sustainable option in pancreatic surgery.

Stove burn complicated as diabetic foot: Case presentation

Emine Acar[1], Tuğçe Gizem Coşgun[1], Zeliha Aydın[1], Canan Bulut Ayaz[1], Ali Cihat Yıldırım[2]

[1]*Unit of Chronic Wound, Kütahya City Hospital, Kütahya*

[2]*Department of General Surgery, Kütahya Health Sciences University, Kütahya*

Objective: Diabetes mellitus (DM) is a systemic disease that negatively affects the wound healing process and significantly increases the risk of chronic wound formation in patients with burn. Microvascular circulation disorders, peripheral neuropathy, prolonged inflammation, and susceptibility to infection in diabetic individuals can hinder the normal healing process of burn wounds.

Material and Methods: This case report aims to examine the progression of a chronic wound in a diabetic patient and the effect of an interdisciplinary approach to wound care on wound healing.

Results: Fifty-one-year-old male patient with a history of DM and hypertension presented to the burn unit with a second-degree burn on the plantar surface of his left foot due to a thermal burn. The burn occurred approximately 5 days earlier as a result of contact with a stove. The patient's HbA1C value was determined to be 9.6% and his blood glucose value was 282 mg/dL; findings of peripheral neuropathy and circulatory disorders were evaluated. The patient had a history of peripheral neuropathy and smoking. The patient's wound was followed up and treated by the burn unit on an outpatient basis for approximately two weeks. Due to possible uncontrolled DM, the patient's burn wound did not heal and had complicated as diabetic foot, so the patient was transferred to the Chronic Wound Care Team. The Chronic Wound Care Team sequentially applied autolytic debridement and epithelialization-supporting products to the patient's wound. At the same time, the patient's glycemic control was ensured, and signs of infection were closely monitored. The patient's wound completely healed after approximately three weeks of follow-up and treatment in outpatient clinic conditions.

Conclusion: Following the wound care applied, an increase in granulation tissue in the wound bed and a significant acceleration in the epithelialization process were observed. This case demonstrates that burn wounds in diabetic individuals carry a high risk of chronicity and that successful wound healing is possible through interdisciplinary collaboration. It should always be kept in mind that coordinated work between Burn and Chronic Wound Care Teams is critical for the effectiveness of wound management.

Characteristics of recurrent retroperitoneal soft tissue sarcomas

Yusuf İhsan Özdilek, Ömer Furkan Çelik, Doğaç Demir, Mehmet Sait Özsoy, Arda Işık, Özgür Ekinci, Orhan Alimoğlu

Department of General Surgery, İstanbul Medeniyet University, Göztepe Prof. Dr. Süleyman Yalçın City Hospital, İstanbul

Objective: Retroperitoneal soft tissue sarcomas constitute approximately 12-15% of all soft tissue sarcomas. Mortality is generally due to unresectable recurrent tumor complications rather than distant metastasis. In this study, the characteristics of patients with recurrent retroperitoneal soft tissue sarcoma were investigated.

Material and Methods: In this study, gender, age, presenting complaint, length of hospital stay, tumor diameter, histopathological type, type of resection, organ resection, and time of recurrence were evaluated in 30 of 49 retroperitoneal soft tissue sarcoma patients who experienced recurrence and were treated between 2009 and 2025.

Results: Recurrence occurred in 30 (61%) of the 49 patients, 17 (57%) of whom were female and 13 (43%) were male. The mean age at the time of the first surgery for retroperitoneal soft tissue sarcoma was 55 (28-81). Abdominal pain was the most frequent presenting complaint, occurring in 46.6% of patients. The mean postoperative hospital stay was 9 (2-24) days. The mean tumor diameter was 16.4 (3.5-36) cm. Thirteen different histopathological types were identified, the most frequent being dedifferentiated liposarcoma, seen in ten patients (33%). R0 resection was performed in nineteen patients (64%), R1 resection in ten patients (33%), and R2 resection in one patient (3%). Organ resection was performed in sixteen patients (53%) due to invasion. The mean time to recurrence was 40 (5-220) months.

Conclusion: In this study, the recurrence rate in retroperitoneal soft tissue sarcoma was found to be 61%, and the mean time to recurrence was 40 months.

Retroperitoneal tumors: A review of six cases

Hazar Berkay Yavru, Zekerya Pelen, Kutay İşçen, Doğan Gönüllü

University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul

Objective: The retroperitoneal region is a complex potential space bordered by vital organs: anteriorly by the peritoneum, colon and mesocolon, liver, pancreas, and stomach. Posteriorly, it is bounded predominantly by muscular structures: the psoas, quadratus lumborum, transversus abdominis, and iliac muscles. Depending on tumor location, the diaphragm, ipsilateral kidney, ureter, and gonadal vessels may be adjacent. Medially, the boundaries may be defined by the vertebrae, paraspinal muscles, inferior vena cava, and aorta.

Material and Methods: The clinical findings, imaging modalities used for diagnosis, surgical course, and final histopathological characteristics of patients operated on in our clinic between 2023 and 2025 with a prediagnosis of "retroperitoneal tumor" were reviewed.

Results: A total of 6 (six) patients underwent surgery; mean age was 60.2 (56-67) years, and the female-to-male ratio was 4:2. Three patients had primary retroperitoneal tumors; the remaining three had secondary tumors, two presented with recurrence in the setting of prior total hysterectomy and oophorectomy, and one had a recurrence of a chordoma with very low malignant potential. The tumors primarily diagnosed were "high-grade malignant mesenchymal tumor (with areas showing rhabdomyosarcoma and leiomyosarcoma differentiation)"; high-grade liposarcoma; and retroperitoneal fibrosis. Among the secondary tumors, one patient, who had been operated on 7-8 times in the neurosurgery clinic due to chordoma, had an invasive 8.5 cm mass over the left iliopsoas; the other two had previously been operated on by the obstetrics and gynecology clinic 8 years and 2 years earlier for "granular cell ovarian tumor" and "mesonephric adenocarcinoma," respectively. The mean longest tumor diameter was 18.3 (8.5-30) cm; the largest measured 30×29×14 cm and weighed 14.5 kg. Surgical margins were negative in all patients, and they have continued their lives without recurrence to date.

Conclusion: All retroperitoneal tumors we operated on were large-volume lesions. Due to the retroperitoneal location, a multidisciplinary approach is required, and survival can be prolonged by achieving negative surgical margins and by close follow-up for recurrence.

[P-530]

Initial interpretation of symptoms in acute appendicitis and the decision process for hospital admission

Emin Kırkıncı, Alper Yavuz

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: The aim of this pilot study is to evaluate the effect of symptom duration, initial interpretation of pain, home interventions, and social factors on the decision-making process for hospital admission in patients diagnosed with acute appendicitis; and to explore perceptual and behavioral factors that may be associated with delayed admission.

Material and Methods: This single-center, descriptive, and exploratory pilot study involved administering a closed-ended questionnaire to 30 patients diagnosed with acute appendicitis or perforated appendicitis. The questionnaire examined the duration of symptoms, the initial assessment of pain, actions taken at home, the influence of the social environment and information sources, and the decision-making process leading to hospital admission. Clinical information was recorded by the physician. The study did not include any personally identifiable data, and all analyses were performed on an anonymized dataset. Delayed referral was dichotomized as "delay present" for all options except the "no delay" response. Categorical variables were presented with descriptive statistics. Fisher's exact test was used for exploratory comparisons, and $p<0.05$ was considered statistically significant.

Results: Twenty-three patients (76.7%) were diagnosed with acute appendicitis, and 7 (23.3%) with perforated appendicitis. %53.3 patients (n=16) had symptoms lasting more than 12 hours. Sixteen patients (53.3%) said they "did not take the pain seriously at first," 10 (33.3%) said they took it "somewhat seriously," and 4 (13.3%) said they took it "seriously from the beginning." Twenty-seven patients (90%) stated that they did not consider the possibility of appendicitis at the onset of symptoms. Twelve patients (40%) researched their symptoms on the internet. Forty percent of families (n=12) accelerated the referral process, while 53.3% (n=16) reported no effect, and 6.7% (n=2) reported delaying the referral. Thirteen patients (43.3%) stated that they delayed going to the hospital because they felt better after taking painkillers. No statistically significant relationship was found between delayed presentation and not taking the pain seriously at first ($p>0.99$), not considering the possibility of appendicitis ($p=0.43$), and relief after taking painkillers ($p>0.99$). There was a trend toward less delay in seeking medical attention among patients who assessed their pain as "severe from the outset" ($p=0.119$).

Conclusion: In conclusion, this study suggests that delayed presentation in patients with acute appendicitis may be related to the initial interpretation of symptoms and patient perception rather than clinical findings. The findings indicate that the effect of patient perception and decision-making processes on delayed presentation could be more clearly demonstrated in prospective studies with larger samples.

Keywords: Appendicitis, delay, application

Table 1. Patients' perceptual and behavioral characteristics related to symptom recognition and the decision-making process for seeking hospital care (n=30)

Perceptual/behavioral characteristics	n (%)
Didn't take the pain seriously at first	16 (53.3)
Not considering the possibility of appendicitis at first	27 (90.0)
Searching for symptoms online	12 (40.0)
Relieved after taking painkillers and postponing the application	13 (43.3)
Not making the decision to go to the hospital on their own (family/environmental influence)	14 (46.7)

Surgical site infections after ileostomy and colostomy closure: A single-center experience

Şerife Rümeysa Şahin, Şara Janset Kuş, Mehmet Sercan Candan, Fevzi Cengiz

İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir

Objective: The creation of an ostomy or colostomy may be required temporarily or permanently for the management of various pathological conditions, including congenital anomalies, colonic obstruction, inflammatory bowel disease, bowel trauma, and gastrointestinal malignancies. One of the most common complications following ostomy closure is surgical site infection (SSI). Compared to many other surgical procedures, the risk of SSI is relatively higher in ostomy closure operations. Therefore, meticulous adherence to sterile techniques by both the surgeon and operating room nurse is strongly recommended. In this study, we aimed to analyze the data of patients who developed SSI after ostomy closure.

Material and Methods: This retrospective study included 34 patients who underwent ostomy or colostomy closure between January 1, 2023, and January 1, 2026, at İzmir Katip Çelebi University, Atatürk Training and Research Hospital. Demographic characteristics, comorbidities, and length of hospital stay were evaluated.

Results: Among the 34 patients, 18 underwent ostomy closure and 16 underwent colostomy closure. Fourteen patients (41.2%) were female and 20 (58.8%) were male. In the colostomy closure group, 4 of 16 patients (25%) developed SSI. Two were female and two were male. All infected patients had at least one comorbidity. The mean hospital stay was 8.75 days (range: 6-11) in infected patients and 6.0 days (range: 3-8) in non-infected patients. In the ostomy closure group, 7 of 18 patients (38.9%) developed SSI. Two were female (28.6%) and five were male (71.4%). All infected patients had at least one comorbidity, and three had three or more comorbidities. The mean hospital stay was 13.14 days (range: 8-23) in infected patients and 5.36 days (range: 4-7) in non-infected patients. Additionally, one patient developed an anastomotic leak, resulting in a mortality rate of 2.94%.

Conclusion: SSI after ostomy closure is a common complication that significantly prolongs hospital stay. The presence of comorbidities appears to increase the risk of infection. Strict adherence to sterile techniques and strong collaboration between surgeons and nurses may help reduce this complication.

Outcomes of stoma closure after emergency resection in patients operated for perforated diverticulitis

Mehmet Sefa Uludağ, Mehmet Sercan Candan, Hakan Kul, Cengiz Tavusbay, Fevzi Cengiz

İzmir Katip Çelebi University, Atatürk Training and Research Hospital, İzmir

Objective: The choice between Hartmann's procedure and resection with primary anastomosis plus diverting loop ileostomy in patients undergoing emergency surgery for perforated diverticulitis remains controversial. It is well established that stoma reversal rates are lower and closure times are significantly longer in patients undergoing Hartmann's procedure compared to those with loop stomas. In this study, we aimed to compare stoma closure rates and timing in patients who underwent emergency surgery with stoma formation due to diverticular perforation.

Material and Methods: We retrospectively analyzed patients who underwent emergency surgery for perforated diverticulitis with stoma formation at İzmir Katip Çelebi University Atatürk Training and Research Hospital between January 1, 2021, and January 1, 2026. Data regarding stoma closure status and timing were evaluated.

Results: A total of 36 patients underwent emergency surgery for perforated diverticulitis. Stoma formation was performed in 29 patients. Five patients who died in the postoperative period were excluded from the study. Among the remaining 24 patients, 5 underwent resection with primary anastomosis and diverting loop ileostomy, while 19 underwent Hartmann's procedure. Stoma closure was achieved in all patients (100%) with loop ileostomy. In contrast, 7 of the 19 patients (36.8%) who underwent Hartmann's procedure had not undergone stoma reversal at the time of analysis. In the Hartmann group, stoma closure was performed between 4 and 60 months postoperatively. In the loop ileostomy group, closure was achieved significantly earlier, between 8 and 14 weeks.

Conclusion: Stoma formation is frequently required in emergency surgery for perforated diverticulitis. Our findings suggest that resection with primary anastomosis and protective loop ileostomy may provide higher stoma closure rates and significantly shorter time to reversal compared to Hartmann's procedure. This approach may reduce the likelihood of permanent stoma and improve postoperative outcomes.

Clinicopathological comparison of perforated and non-perforated acute appendicitis cases

Sinem Yumurtacılar Gördebil[1], Sefa Ergün[1], Başar Can Turgut[2], Şadiye Akbaş[1], Salih Pekmezci[1]

[1]*İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul*

[2]*University of Health Sciences Türkiye, İstanbul Training and Research Hospital, İstanbul*

Objective: Acute appendicitis is one of the most common surgical abdominal pathologies. Approximately 20-30% of cases present as complicated appendicitis with perforation. Appendiceal perforation can significantly increase morbidity and mortality rates. The aim of this study was to compare the clinical, laboratory, intraoperative, and histopathological data of patients who underwent surgery for appendicitis, both perforated and non-perforated.

Material and Methods: The data of 521 patients with acute appendicitis who underwent surgery between January 2016 and June 2025 were retrospectively reviewed. Patients were grouped according to the status of appendix perforation (non-perforated, perforated, plastron). Parameters such as age, duration of symptoms, laboratory values (WBC, CRP, neutrophil, lymphocyte, bilirubin), and radiological findings (appendix diameter) were compared between groups.

Results: The rates of perforation and plastron increased significantly with increasing age and duration of symptoms ($p<0.001$). In patients with perforation and plastron, preoperative leukocyte, neutrophil, CRP, total bilirubin, and indirect bilirubin levels were significantly higher than in the non-perforated group ($p<0.001$). Lymphocyte levels were significantly lower in patients with perforation and plastron. The appendix diameter was significantly smaller in non-perforated patients compared to those with perforation and plastron ($p<0.001$).

Conclusion: Advanced age, prolonged symptom duration, and elevated inflammation markers (WBC, CRP, neutrophil) along with decreased lymphocyte and elevated bilirubin levels are important clinical and pathological indicators of perforation risk in acute appendicitis cases. These findings may assist clinicians in assessing perforation risk earlier and optimizing treatment management.

Keywords: Non-perforated appendicitis, perforated appendicitis

[P-534]

A new surgical approach to incisional hernia; simultaneous hernia repair and abdominoplasty

Hasan Doğru, Emil Hüseyinoğlu, Mehmet Akif Üstüner

University of Health Sciences Türkiye, Bursa City Hospital, Bursa

Objective: Simultaneous ventral hernia repair and abdominoplasty is a combined surgical approach that provides aesthetic improvement along with restoration of abdominal wall function. This study aimed to evaluate the clinical outcomes, complications, and wound management strategies of 42 patients who underwent concurrent ventral hernia repair and abdominoplasty, in light of the relevant literature.

Material and Methods: A total of 42 patients who underwent simultaneous ventral hernia repair and abdominoplasty were retrospectively analyzed. Demographic characteristics, types of hernia, concomitant surgical procedures, postoperative complications, and follow-up outcomes were assessed. Reconstructive surgical interventions and wound care strategies applied in patients who developed skin necrosis were also evaluated.

Results: Skin necrosis occurred in 5 of the 42 patients (11.9%). One of these patients was treated with a free skin graft harvested from the anterolateral thigh region, while the remaining cases were successfully managed using vacuum-assisted closure therapy. Concurrent cholecystectomy was performed in eight patients. During the mean follow-up period, no ventral hernia recurrence was observed. No major morbidity or mortality was recorded.

Conclusion: With appropriate patient selection and meticulous surgical technique, the simultaneous application of ventral hernia repair and abdominoplasty is a safe and effective approach. Skin necrosis is the most common serious complication; however, it can be successfully treated using modern wound management techniques.

Keywords: Abdominoplasty, combined surgery, skin necrosis, ventral hernia repair, wound management

False decrease in oxygen saturation following subareolar isosulfan blue dye injection

Ali İmran Küçük, Bülent Toksöz, Mehmet Aziret

University of Health Sciences Türkiye, Balıkesir Atatürk City Hospital, Balıkesir

Objective: Sentinel lymph node biopsy (SLNB) is a widely used and reliable method for axillary staging in early-stage breast cancer surgery, with a low morbidity rate and a reported accuracy exceeding 90%. The most commonly used dyes during SLNB are isosulfan blue and methylene blue. Although rare, clinically noteworthy complications following isosulfan blue administration include a decrease in oxygen saturation due to methemoglobinemia or false readings related to pulse oximetry interference. Such events may lead to unnecessary interventions and concern during the perioperative period. In this study, we aimed to investigate whether the perioperative decrease in oxygen saturation observed after subareolar injection of isosulfan blue dye for sentinel lymph node identification was attributable to true hypoxemia or to a false measurement caused by pulse oximetry.

Material and Methods: A total of 30 patients who underwent surgery for a diagnosis of breast cancer and received SLNB were included in the study. Patients' demographic characteristics, histopathological diagnoses, surgical procedures performed, and perioperative oxygen saturation values were recorded. SpO_2 values measured by pulse oximetry before and after dye injection were compared. In patients who were found to have a decrease in oxygen saturation, arterial blood gas analysis was performed to assess true oxygen saturation.

Results: Invasive ductal carcinoma was present in 27 patients, invasive lobular carcinoma in 2 patients, and ductal carcinoma *in situ* in 1 patient. The mean age was 53.8 years (range: 32-75). Breast-conserving surgery plus SLNB was performed in 21 patients, modified radical mastectomy in 4 patients, and simple mastectomy plus SLNB in 5 patients. Fifteen patients underwent surgery following neoadjuvant chemotherapy. The mean SpO_2 value measured prior to dye injection was 99.1%, which decreased to 91.5% after injection. However, arterial blood gas analysis performed during the same period revealed a mean oxygen saturation of 97.4%. No postoperative respiratory complications were observed in any of the patients.

Conclusion: The decrease in oxygen saturation observed on pulse oximetry following isosulfan blue dye injection during SLNB does not reflect true hypoxemia. This phenomenon should be considered a measurement artifact, and in cases of clinical suspicion, confirmation with arterial blood gas analysis is recommended. Recognition of this condition may help prevent unnecessary interventions.

Keywords: Sentinel lymph node biopsy, isosulfan blue dye, breast cancer

Bilateral mastectomy with immediate reconstruction in a single stage

Arash Azadijouyan[1], Ali Ertan Çapar[2], Mahmut Sertan Kapaklı[1], Sina Mokhtare[1], Uğur Deveci[1], İlayda Şentürk[2], Manuk Norayik Manukyan[1]

[1]*Department of General Surgery, Maltepe University Faculty of Medicine, İstanbul*

[2]*Department of Plastic and Reconstructive Surgery, Maltepe University Faculty of Medicine, İstanbul*

Objective: At Maltepe University Faculty of Medicine Hospital, the outcomes of immediate silicone-based breast reconstruction performed in the same session for patients undergoing mastectomy due to a cancer diagnosis were investigated.

Material and Methods: The data of 313 patients who underwent surgery for a diagnosis of breast cancer between 2020 and 2025 were reviewed. Patients who underwent axillary dissection following sentinel lymph node biopsy were excluded from the study, and the remaining patients were divided into three groups: segmental mastectomy, simple mastectomy, and bilateral mastectomy with silicone-based reconstruction. Postoperative hospital stay duration, pain levels, and patient satisfaction were evaluated.

Results: As expected, the shortest time to discharge was observed in patients who underwent segmental mastectomy alone (median 1 day), whereas the median hospital stay was 3 days in the silicone-based reconstruction group, and the difference was statistically significant. Postoperative wound-site complications were found to be more frequent in patients who underwent reconstruction, and visual analog scale pain scores were significantly higher in this group. When patients' postoperative aesthetic satisfaction was assessed on a 10-point scale, the simple mastectomy group was found to be dissatisfied, while the other two groups showed no significant difference, with satisfaction scores of 7.8/10 in the segmental mastectomy group and 8.1/10 in the reconstruction group.

Conclusion: Although segmental mastectomy still appears to be the best option in terms of patient satisfaction, the option of silicone-based reconstruction should be offered preoperatively, taking into account the patient's age, family history, and expectations.

The effect of parathyroid autotransplantation on parathyroid hormone levels during total thyroidectomy

Tolga Sislituna, Halil Özkan, Ali Demir, Sabri Özden

Konya City Hospital, Konya

Objective: Hypocalcemia due to hypoparathyroidism after total thyroidectomy is one of the common complications of surgery and may follow a transient or permanent course. Permanent hypoparathyroidism negatively affects patients' quality of life and may require long-term calcium and active vitamin D supplementation. Parathyroid autotransplantation is considered a salvage strategy aimed at preserving the function of parathyroid tissue that is thought to be devascularized intraoperatively or inadvertently excised. However, the effect of this approach on the parathyroid hormone (PTH) recovery process remains controversial in the literature. This study aimed to compare the postoperative PTH recovery process in patients with and without parathyroid autotransplantation.

Material and Methods: This retrospective comparative cohort study included 152 patients who underwent total thyroidectomy at the Endocrine Surgery Clinic of Konya City Hospital. Patients were divided into a parathyroid autotransplantation group (PAT, n=70) and a control group without autotransplantation who developed hypoparathyroidism at postoperative 24 hours (n=82). Serum PTH and calcium levels were measured preoperatively and at postoperative 24 hours, 1 month, 6 months, and 12 months. Biochemical recovery was defined as serum calcium ≥8.5 mg/dL and PTH ≥15 pg/mL. Groups were compared using appropriate statistical tests, with $p<0.05$ considered significant.

Results: The study population consisted of 20 males (13.1%) and 132 females (86.9%). Mean age was similar between the PAT and control groups (49.4±13.1 vs. 48.7±12.7 years, $p>0.05$). PTH levels at postoperative 24 hours were significantly higher in the PAT group ($p<0.001$). At 1 month, biochemical recovery was observed in 65% of the PAT group and 40% of the control group ($p=0.01$). Although median PTH and calcium levels were comparable, recovery rates were higher in the PAT group based on threshold analysis. No significant differences were observed at 6- and 12-month follow-up. Biochemical recovery was defined as a serum calcium level ≥8.5 mg/dL and a parathyroid hormone (PTH) level ≥15 pg/mL at the corresponding follow-up time point. The proportion of patients (%) meeting the recovery criteria at each follow-up time point was calculated, and intergroup comparisons were performed using the chi-square test or Fisher's exact test, as appropriate.

Conclusion: Parathyroid autotransplantation accelerates the biochemical recovery of parathyroid function after total thyroidectomy, particularly in the early postoperative period. However, similar recovery rates are achieved in both groups during long-term follow-up. In light of these findings, autotransplantation of parathyroid glands that are considered devascularized intraoperatively or inadvertently excised may be regarded as an effective surgical approach for preserving parathyroid function and facilitating early biochemical recovery.

Keywords: Parathyroid autotransplantation, parathyroid hormone recovery, total thyroidectomy

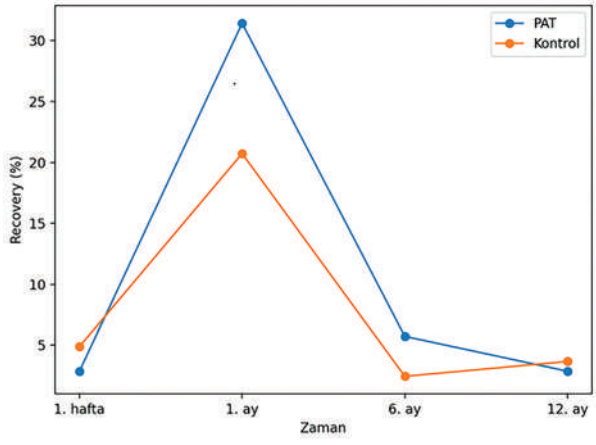

Figure 1. Time course of biochemical recovery in patients with and without parathyroid autotransplantation.

Table 1. Calcium and PTH levels over time

Variable	PAT	Control	p
Calcium-preoperative	9.40 (9.10-9.70)	9.40 (9.10-9.60)	0.798
PTH-preoperative	33.95 (21.72-43.85)	47.10 (38.55-50.25)	0.300
Calcium-24th hour	7.85 (7.40-8.30)	7.75 (7.50-8.10)	0.452
PTH-24th hour	10.30 (3.94-25.10)	5.57 (2.45-8.80)	p<0.001
Calcium-1st week	8.55 (8.00-8.80)	8.45 (7.60-8.85)	0.867
PTH-1st week	11.90 (10.60-19.25)	15.45 (7.39-39.95)	0.711
Calcium-1st month	9.10 (8.70-9.62)	8.80 (8.25-9.40)	0.188
PTH-1st month	23.25 (18.28-39.57)	27.05 (14.90-33.88)	0.731

The road to total pancreatectomy: Preoperative planning or peroperative necessity?

Ömer Kişi, Veysel Yazar

Necmettin Erbakan University Faculty of Medicine, Konya

Objective: Pancreatic surgery is one of the most complex fields of general surgery due to its high mortality and morbidity rates and technical challenges. Postoperative pancreatogenic diabetes mellitus (DM) (type 3c DM) is one of its most significant complications. The absence of both insulin and glucagon makes glycemic regulation difficult. Deciding between pancreatoduodenectomy, distal pancreatectomy, and total pancreatectomy (TP) techniques can sometimes be complex process. TP is surgical procedure applied in multifocal lesions, particularly in intraductal papillary mucinous neoplasm (IPMN). Furthermore, it may be preferred to avoid anastomosis in patients at high risk of developing postoperative pancreatic fistula.

Material and Methods: TP cases performed in our clinic between January 2021 and December 2025 were evaluated. We analyzed whether the decision for TP was made based on preoperative radiological assessment or peroperative surgical findings and presented the reasons behind these decisions.

Results: Fifteen TP cases were performed in our clinic over the last five years. Of these patients, 8 were male and 7 were female. The mean age was 56 (min-max: 42-78). TP was planned for seven patients based on preoperative evaluations. Radiological imaging in these patients revealed lesions involving both the caput and the corpus or cauda of the pancreas. In eight patients, TP was performed due to peroperative findings and technical reasons. In 4 of 8 patients,the decision for TP was made because contrary to preoperative radiological tests the lesion size was larger, the locations were multiple, or the lesion extended toward the body and tail of the pancreas. TP was preferred in one patient due to severe pancreatic atrophy and the inability to clearly identify the Wirsung duct. In another patient, TP was chosen because the mass invaded the portal and splenic veins, necessitating vascular reconstruction. In the remaining 2 patients, TP was preferred to avoid postoperative pancreatic fistula. A common feature of these two patients was the need for gastrectomy in addition to pancreatic surgery. One patient had second center as gastric mass, and total gastrectomy was added to the surgery. In the other patient, the pancreatic mass was adherent to the posterior corpus of the stomach and distal subtotal gastrectomy was added. For these reasons, Roux-en-Y anastomosis was preferred in these patients in order to avoid pancreatic anastomosis.

Conclusion: TP is procedure rarely preferred among pancreatic surgeries but can be inevitable in selected patients. Although its indications are still not clearly defined, it is preferred in lesions that can involve the entire pancreas, such as IPMN, and in patients with high risk of developing postoperative pancreatic fistula. Determining the decision for TP in either the preoperative or peroperative period is challenging; multidisciplinary evaluation and intraoperative surgical experience plays decisive role in this process.

Keywords: Pancreas, pancreatectomy, peroperative, preoperative, total

From the emergency department to general surgery: Clinical course and management of traumatic pancreatic injuries

Zeynep İlayda Işı[1], Salih Süer[1], Serkan Demir[1], Şener Balas[1], Gürkan Değirmencioğlu[1], Faruk Yazıcı[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut State Hospital, Ankara*

Objective: Traumatic pancreatic injuries are rare but complex lesions associated with significant morbidity. This study aimed to evaluate the demographic characteristics, injury severity, surgical management strategies, and clinical outcomes of patients with pancreatic trauma admitted to the emergency department and treated in the general surgery clinic.

Material and Methods: Patients hospitalized for pancreatic trauma at University of Health Sciences Türkiye, Ankara Etlik City Hospital, Department of General Surgery, were retrospectively reviewed. Demographic data, mechanism of injury, laboratory and imaging findings, AAST pancreatic injury grade, surgical procedures, postoperative complications, ICU and hospital length of stay, and mortality rates were analyzed.

Results: Eight patients were included. The median age was 33 years, and 87.5% were male. Blunt and penetrating trauma were equally distributed. Concomitant extra-pancreatic organ injury was present in 75% of patients, and major vascular injury in 25%. Blood transfusion within 24 hours was required in 37.5%. The median Glasgow Coma Scale score was 15, and hypotension occurred in 25%. Amylase and lipase levels varied widely. FAST examination was negative in all patients. Computed tomography (CT) was performed in 87.5%, suggesting pancreatic injury in 37.5% and ductal injury in 25%. The median AAST grade was 1. Drainage alone was the most common surgical approach (62.5%), while distal pancreatectomy was performed in 25%. No patient required pancreaticoduodenectomy or necrosectomy. Drains were placed in all patients, and no damage control surgery was performed. All patients were managed in the ICU (median 3 days); median hospital stay was 14 days. The overall complication rate was 75%, most commonly pancreatic fistula (50%), followed by pancreatitis (37.5%) and intra-abdominal abscess (25%). No sepsis, organ failure, delayed hemorrhage, or mortality was observed.

Conclusion: Traumatic pancreatic injuries remain diagnostically challenging and are associated with substantial morbidity, even in low-grade injuries. Despite the predominance of low AAST grades in this cohort, complication rates were high, highlighting the clinical burden of pancreatic trauma. While mortality rates of 10-30% have been reported in the literature, often related to major associated injuries and delayed diagnosis, no mortality occurred in our series. Early surgical evaluation, appropriate patient selection, limited surgical strategies, and effective intensive care management may explain these favorable outcomes. In selected cases, organ-preserving approaches such as drainage alone may be sufficient. Close monitoring and management in experienced centers remain essential.

Clinical characteristics, treatment approaches, and outcomes of common bile duct injuries following cholecystectomy over the last five years: A single-center experience

Neslihan Alıcı, Ömer Faruk Özkan, Elif Didem Terzi, Merve Karadağ, Muhammed Emre Ersü

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Cholecystectomy is one of the most commonly performed surgical procedures in general surgery for the treatment of gallbladder diseases. Although the widespread use of laparoscopic techniques has reduced overall surgical morbidity, common bile duct injuries remain rare but potentially serious complications. These injuries are associated with prolonged hospital stay, the need for additional interventions, and long-term biliary complications. Early diagnosis and appropriate management are the most important factors determining prognosis in common bile duct injuries. The type of injury, timing of recognition, and initial management in experienced centers have a direct impact on long-term outcomes. In this study, we aimed to evaluate the clinical characteristics, treatment strategies, and outcomes of patients who developed common bile duct injury following cholecystectomy at our center over the last five years.

Material and Methods: In this retrospective study, six patients who were diagnosed with common bile duct injury following cholecystectomy within the last five years at our institution were analyzed. Patient age, sex, body mass index (BMI), ASA scores, whether the surgery was performed under elective or emergency conditions, surgical approach (laparoscopic/open), timing of injury recognition (intraoperative/postoperative), type of injury, and distribution according to the Strasberg classification were recorded. Diagnostic modalities, treatment strategies (endoscopic, percutaneous, and surgical), postoperative complications, and follow-up outcomes were evaluated.

Results: The mean age of the patients was 57.5 years, and the mean BMI was 26.8 kg/m². All patients underwent elective cholecystectomy. Common bile duct injury was recognized intraoperatively in one patient, whereas in the remaining patients, the diagnosis was established postoperatively based on clinical findings. The main reasons for postoperative presentation included bile leakage, jaundice, abdominal pain, and cholangitis. Injuries were distributed among Strasberg types B, C, D, and E. Ultrasonography, MRCP, and ERCP were used during the diagnostic process. Treatment modalities included ERCP with stent placement, percutaneous drainage, primary surgical repair, T-tube placement, and hepaticojejunostomy, depending on the clinical condition of the patient and the type of injury. Some patients required additional interventions and experienced prolonged hospital stay. Long-term follow-up revealed complications such as biliary stricture and recurrent cholangitis.

Conclusion: Common bile duct injuries are rare but serious complications of cholecystectomy, and early diagnosis and appropriate treatment are the most important factors determining prognosis. The type of injury, timing of diagnosis, and initial management in experienced centers have a significant impact on long-term outcomes. A multidisciplinary approach and individualized treatment strategies are essential to reduce morbidity.

Our experience with pancreaticogastrostomy as a reconstruction technique after pancreaticoduodenectomy

Nami Ünal Polat, Muhammet Gündal, Eyüp Kababçı, Bayram Çolak, Nuri Emrah Göret, Cem Tuğmen

Department of General Surgery, İzmir Bakırçay University Çiğli Training and Research Hospital, İzmir

Objective: One of the most important complications that may occur after pancreaticoduodenectomy is the development of a pancreatic fistula. One of the reconstruction techniques used after pancreatic resection is pancreaticogastrostomy. In this study, we aimed to present the clinical outcomes of patients who underwent pancreaticogastrostomy reconstruction for pancreatic drainage following pancreaticoduodenectomy and to compare the results with the existing literature.

Material and Methods: In this study, 13 patients who underwent pancreaticogastrostomy reconstruction following pancreaticoduodenectomy for periampullary tumors between January 2023 and January 2026 in the Department of General Surgery at İzmir Bakırçay University Çiğli Training and Research Hospital were evaluated in terms of demographic data, postoperative complications, and length of hospital stay.

Results: Of the 13 patients included in our study, 6 were female and 7 were male. The ASA scores of the patients were determined to be II-III. The mean age of the patients was 59.3 years. Morbidity was observed in 3 patients. Among these patients, one developed gastrointestinal bleeding, one experienced evisceration, and one had a leak from the hepaticojejunostomy anastomosis. The overall morbidity rate was 38%. One patient died on postoperative day 4 due to pulmonary embolism, resulting in a mortality rate of 7%. The mean operative time was 252 minutes, and the mean length of hospital stay was 8.3 days. According to the International Study Group on Pancreatic Surgery (ISGPS) classification, postoperative pancreatic fistula (POPF) Grade A biochemical leak was observed in 2 patients; these patients had no clinical findings and recovered with conservative management. These results are comparable to the morbidity and mortality rates reported in the literature following pancreaticoduodenectomy. No clinically relevant pancreatic fistula developed in our patients according to the ISGPS classification.

Conclusion: In our country, pancreaticogastrostomy reconstruction is not commonly performed after pancreaticoduodenectomy. In this study, our morbidity and mortality rates were found to be comparable to those reported in the literature. No clinically significant pancreatic fistula was observed. Although larger case series are needed to further evaluate the safety of this reconstruction technique in patients undergoing pancreaticoduodenectomy, we believe that it may represent a viable alternative method due to its technical simplicity and low morbidity and mortality rates.

Long-term outcomes and quality of life following surgical management of gastrointestinal bezoars

Onur Yorgun, Edip Akpınar

Department of General Surgery, University of Health Sciences Türkiye, Adana Faculty of Medicine, Adana City Training and Research Hospital, Adana

Objective: Gastrointestinal bezoars are relatively rare but can lead to serious complications such as obstruction or perforation, often requiring surgical intervention. While acute surgical outcomes are well-documented, long-term post-operative quality of life and nutritional status are less frequently studied. This study evaluates the long-term follow-up results and patient satisfaction in a cohort of patients operated on for bezoars.

Material and Methods: We conducted a retrospective survey study of patients who underwent abdominal surgery in our tertiary care surgical center for bezoars between 2020 and 2024. Data were collected via a structured questionnaire assessing post-operative symptoms (pain, nausea, vomiting), nutritional difficulties, general health status, and overall surgical satisfaction (scored 1-5). Collected data are analysed, numerical values, categorical variables are presented in percentages and statistical evaluations were done using the R package.

Results: The cohort consisted of 24 patients. Follow-up duration ranged from 1 to 5 years. At the time of follow-up, 65% (n=16) reported no current gastrointestinal complaints, while 35% (n=8) experienced intermittent symptoms, most commonly nausea or mild abdominal pain. Regarding nutritional habits, 53% (n=10) reported experiencing difficulties post-operatively. The most frequent nutritional issues identified were heartburn/reflux (48%), weight loss (25%), early satiety (21%), and dysphagia (12%). Despite these symptoms, the mean general health assessment score was 3.8/5. Patient satisfaction with the surgical outcome was high, with a mean score of 4.3/5. Notably, 80% of patients reported satisfaction scores of 4 or 5. Only 20% (n=5) of the cohort required follow-up or additional treatment at other healthcare facilities following their initial discharge.

Conclusion: Surgical treatment of gastrointestinal bezoars provides high long-term patient satisfaction and good general health outcomes. However, a significant portion of patients experience long-term nutritional sequelae, particularly reflux and early satiety. These findings suggest that postoperative management should include detailed nutritional counseling and long-term monitoring for reflux-related symptoms to improve the quality of life in this patient population.

A hidden mimicker in the acute abdomen: Omental infarction-clinical characteristics, treatment approach, and outcomes (single-center experience)

Sena Özgül, Ender Ergüder, Muhammed Salih Süer, Faruk Yazıcı, Serkan Demir, Alper Yavuz

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Omental infarction is a rare condition in patients presenting with acute abdomen, yet it can mimic common surgical pathologies both clinically and radiologically, making it diagnostically challenging. This study aimed to evaluate the clinical characteristics, laboratory and imaging findings, treatment approaches, and clinical outcomes of patients diagnosed with omental infarction, with a particular focus on the role of computed tomography (CT) in the diagnostic and clinical decision-making process.

Material and Methods: A total of 11 patients diagnosed with omental infarction in our clinic were included in the study. The patients were retrospectively analyzed based on demographics, presentation, clinical findings, laboratory parameters, imaging methods, CT findings, treatment approach (conservative or surgical), and clinical outcomes. Descriptive statistics were presented as mean ± standard deviation, median (interquartile range), and percentages.

Results: The mean age of the 11 patients was 44.4±13.1 years, with 63.6% being male. All presented with subacute abdominal pain, most commonly in the right lower quadrant (36.4%). Rebound and guarding were absent, and fever and nausea/vomiting were rare (9.1%). Laboratory results showed a mean leukocyte count of 10.8±3.6×10³/μL and CRP of 48.4±57.0 mg/L. Imaging revealed that 63.6% of patients underwent only CT, while 36.4% had both CT and ultrasound. Omental infarction was diagnosed preoperatively in 90.9% of cases. Lesions were mostly right-sided (72.7%), with an average diameter of 32.8±13.9 mm. Treatment was conservative in 63.6% and surgical in 36.4%, with diagnostic uncertainty being the main surgical indication. The CT-based approach helped avoid unnecessary surgery in 63.6%. The median hospital stay was 3 days, and all patients experienced pain relief without complications or recurrences.

Conclusion: Omental infarction, although it mimics appendicitis and other causes of acute abdomen, can generally be managed safely without surgery when diagnosed accurately with CT. Literature emphasizes CT's role in reducing unnecessary surgeries by clarifying the diagnosis, with conservative treatment being sufficient in most cases. Surgery is only needed in selected patients with persistent pain, clinical deterioration, or diagnostic uncertainty. Our series supports this approach, with a high preoperative diagnostic rate (90.9%) and successful conservative management in 63.6% of cases. The absence of complications suggests that conservative management has a high safety profile. However, surgery may shorten hospital stays, and factors like high leukocyte counts could indicate conservative treatment failure. Therefore, a strategy of "CT diagnosis + close monitoring + surgery in selected cases" seems reasonable. Early CT use and selective surgery can reduce unnecessary operations and optimize resource use.

Primary repair of penetrating gluteal and sphincteric injury due to ceramic fracture in a domestic setting

Mehmet Fatih Öztürk[1], Fatih Türkoğlu[1], Ömer Faruk Genç[2], Sinan Şener[1], Ülkü Birnas Aşıroğlu[1]

[1]*Department of General Surgery, Selçuk University Faculty of Medicine,*

[2]*Department of Plastic, Reconstructive and Aesthetic Surgery, Selçuk University Faculty of Medicine, Konya*

Objective: Penetrating gluteal and perianal injuries secondary to domestic accidents are uncommon and require careful evaluation due to the potential risk of anal sphincter damage. We present a case of penetrating trauma occurred after falling onto a ceramic structure, which fractured upon impact, leading to a gluteal injury with partial involvement of the anal sphincter complex. The surgical management of the injury and the early functional outcomes are discussed.

Material and Methods: Patient presented to ED with penetrating injury to the gluteal and perianal regions after slipping on a wet floor while attempting to sit on a toilet, resulting in a forceful fall onto and subsequent fracture of toilet. Physical examination revealed a 6×18 cm laceration in left gluteal region causing a defect in muscle tissue, and a 4×15 cm laceration in the presacral area partially involving fibers of the external anal sphincter. Digital rectal examination demonstrated preserved sphincter tone, and rectum assessed as intact. The patient had a recent history of AMI and was receiving dual antiplatelet therapy; however, no active arterial was observed during PE. CT with IV+rectal contrast showed no evidence of rectal contrast extravasation.

Results: Patient was taken to emergency surgery in collaboration with plastic surgery team. Irrigation removal of ceramic fragments were performed. Intraoperative evaluation demonstrated that the integrity of external anal sphincter was largely preserved, with only minimal fiber disruption. Due to the contaminated nature of the wound and the limited extent of sphincter injury, primary sphincter repair was not performed. Full-thickness lacerations of the gluteus maximus were reconstructed. Hemostasis was achieved and soft drains were placed in both compartments, and the subcutaneous tissues were approximated carefully to avoid ischemia, followed by primary skin closure. In the postoperative period, wound care was maintained with frequent dressings, and a soft diet was initiated. LMWH was started on postoperative day 0, and the patient's previous dual antiplatelet regimen was resumed on day 2. During follow-up, no hematoma, infection, wound dehiscence, fecal incontinence or additional complications were observed. Patient was discharged after receiving wound care instructions. By postoperative day 20, complete wound healing was achieved. After 6-week follow-up, Wexner score was 0, indicating full continence. The patient experienced partial functional limitation related to the gluteal muscle injury; however, symptoms regressed with physiotherapy.

Conclusion: In cases of partial external anal sphincter injury where continence and overall tissue integrity are preserved, favorable outcomes can be achieved with limited surgical intervention and meticulous wound care. This case report aims to emphasize the importance of individualized decision-making in the surgical management of penetrating trauma involving sphincter injury, highlighting that treatment strategies should be determined on a case-by-case basis.

Keywords: Penetrating trauma, gluteal injury, sphincter injury

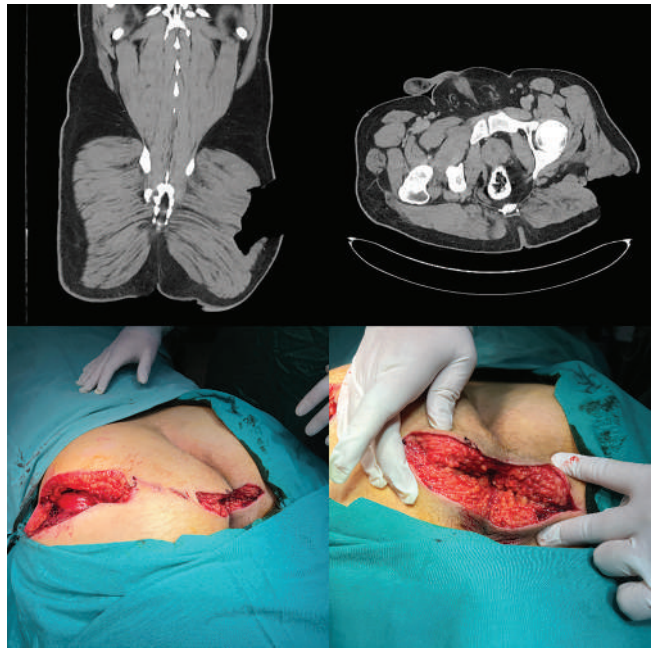

Figure 1. Computed tomography (CT)-scan and intraoperative images. On CT images, the extent of the gluteal defect is demonstrated, and no rectal contrast extravasation is observed. Intraoperative images obtained after sterile irrigation following the trauma are also presented.

Figure 2. Wound healing process. The collage demonstrates the immediate postoperative appearance on day 0 following primary repair of the gluteal and perianal lacerations, as well as well-healed wound appearance on postoperative day 25 after suture removal. No infection, wound dehiscence, or tissue necrosis was observed during the follow-up period.

Surgical management of severe blunt liver trauma unresponsive to packing: The role of liver resection

Ali Levent Işık, Ali Bekrakı

University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Severe blunt liver trauma remains one of the most challenging entities in trauma surgery. Although non-operative management has become standard in hemodynamically stable patients, high-grade (AAST IV-V) injuries accompanied by hemodynamic instability still mandate urgent operative intervention. Damage control strategies prioritize rapid hemorrhage control, prevention of the lethal triad, and staged definitive management. Perihepatic packing is widely accepted as an initial life-saving maneuver; however, persistent bleeding despite packing requires, anatomical or non-anatomical liver resection. This study evaluates surgical strategies for blunt liver trauma unresponsive to packing and the role of liver resection in hemorrhage control.

Material and Methods: This retrospective analysis included seven patients with AAST grade IV-V blunt liver injuries who underwent operative management. Demographic characteristics, injury severity (ISS, APACHE II), transfusion requirements, operative details, and postoperative outcomes were analyzed (Table 1). Surgical management followed damage control principles. Initial packing was performed in hemodynamically unstable patients, followed by planned depacking. In cases of ongoing hemorrhage, portal triad clamping (PTC), hepatic resection (segmentectomy or right hepatectomy) were undertaken in accordance with established hepatobiliary trauma techniques. Outcomes assessed included ICU stay, total hospitalization, morbidity, and mortality.

Results: The median patient age was 29 years (range 25-69), and the majority were male. Two patients had AAST grade V injuries. Hemodynamic instability on admission was common, with hypotension and elevated lactate levels (up to 7.0 mmol/L). Five required subsequent depacking and definitive procedures. Liver resections included segment 6 resection, segment 6-7 resection, segment 8 resection, and right hepatectomy (n=2). Median operative times ranged from 105 to 355 minutes. Transfusion requirements were reflecting severe hemorrhage. ICU stay ranged from 4 to 108 days, and total hospitalization up to 150 days. Postoperative complications included biliary fistula, pleural effusion, thoracostomy requirement, and reoperations for associated injuries. Notably, no mortality occurred in this series.

Conclusion: Packing effectively controls venous parenchymal bleeding; however, major hepatic vein may remain refractory. In such cases, inflow control via PTC, mobilization of the right liver lobe, resectional debridement of fragmented segments, and direct vascular repair become mandatory. Anatomical resection, including right hepatectomy, may be lifesaving when parenchymal destruction is extensive. The absence of mortality in our series suggests that timely escalation from packing to definitive resection can improve survival in selected patients. In severe blunt liver trauma early recognition of packing failure and prompt transition to anatomical or non-anatomical resection may reduce mortality and optimize outcomes in high-grade hepatic injuries.

Has non-operative management become the gold standard in blunt hepatic trauma?

Gökhan Coşkun, Uğur Özsoy

Department of General Surgery, Tokat Gaziosmanpaşa University Faculty of Medicine, Tokat

Objective: The liver is the most frequently injured solid organ in blunt abdominal trauma. Historically, surgery was the primary management strategy; however, non-operative management (NOM) has recently emerged as the standard of care for hemodynamically stable patients. This study evaluates our institutional experience with operative and non-operative approaches in the management of blunt liver injuries.

Material and Methods: We retrospectively analyzed 34 patients treated for blunt abdominal trauma and varying degrees of hepatic injury at our clinic between 2016 and 2025.

Results: The mean patient age was 39 years (range: 17-73). Radiological evaluation revealed Grade 1-2 injuries in 19 patients (55.8%), Grade 3-4 in 11 (32.3%), and Grade 5 in 4 (11.7%). NOM was initiated in 19 patients (55.8%), including 16 with isolated Grade 1-2 injuries and three stable patients with Grade 3-4 injuries. Within the NOM group, two patients required laparotomy for non-hepatic reasons (one for small bowel perforation on the 3rd day; one for hemodynamic deterioration on the 2nd day). Notably, no direct liver intervention was required in these cases as no active bleeding was observed. Furthermore, three patients undergoing splenectomy for concomitant splenic trauma required no hepatic intervention. One Grade 2 patient with a 6 cm hemangioma was successfully managed with NOM followed by elective ablation. In contrast, severe cases required intensive surgical management. One Grade 4 patient with renal avulsion died postoperatively despite complex vascular and hepatic repair. Among four Grade 5 patients, two were discharged after lobectomy, one was transferred for biliary fistula management, and one died on the 2nd postoperative day. Overall, 22 patients (64.7%) were successfully managed without direct surgical intervention to the liver.

Conclusion: In blunt liver trauma, hemodynamic stability, peritoneal signs, and concomitant organ injuries should be prioritized over radiological grading when selecting treatment modalities. Our findings suggest that NOM is a safe and effective “gold standard” for Grade 1-3 and selected Grade 4 injuries, provided there is access to high-quality intensive care and rapid diagnostic imaging.

Incidental appendiceal neuroendocrine tumor in a patient presenting with clinical acute appendicitis: Surgical approach and review of the literature

Hikmet Kadakal, Enes Şahin, Nihat Zafer Utkan

Department of General Surgery, Kocaeli University Faculty of Medicine, Kocaeli

Objective: Appendiceal neuroendocrine tumors (NETs) are rare neoplasms of the gastrointestinal system but represent the most common tumor of the appendix. They are generally asymptomatic and frequently detected incidentally during histopathological examination following appendectomies performed for acute appendicitis. Tumor size, localization, and histological stage are determinant factors in treatment planning. Although simple appendectomy is generally considered curative for tumors smaller than 1 cm, positive surgical margins or the presence of risk factors may necessitate extensive surgical resection. We present a case of a patient operated on for acute appendicitis where, despite a NET smaller than 1 cm, a right hemicolectomy was recommended due to associated risk factors.

Material and Methods: A 22-year-old male patient presented to the emergency department with right lower quadrant pain, nausea, and anorexia persisting for 24 hours. Physical examination revealed tenderness and defense at McBurney's point. Laboratory tests showed elevated CRP (24 mg/L) without leukocytosis. Upon computed tomography findings consistent with acute appendicitis, the patient underwent a laparoscopic appendectomy. No gross pathology was observed in surrounding tissues during the operation, and the patient was discharged on the first postoperative day.

Results: Histopathological examination of the specimen revealed a well-differentiated (Grade 1) neuroendocrine tumor measuring 0.7x0.5 cm in the proximal appendix. Immunohistochemical staining was positive for chromogranin and synaptophysin, with a Ki-67 proliferation index of 2%. The tumor was reported to invade the mucosa, submucosa, and muscularis propria, with no evidence of lymphovascular or perineural invasion. Critically, tumor continuity was detected at the proximal surgical margin. Although the tumor size was less than 1 cm (T1a), a right hemicolectomy was recommended in accordance with ENETS and NANETS guidelines due to risk factors including location at the appendiceal base, positive surgical margins.

Conclusion: Appendiceal NETs generally have an excellent prognosis, and simple appendectomy is sufficient for tumors smaller than 1 cm without risk factors. However, as demonstrated in this case, even with small tumor dimensions, factors such as location at the appendiceal base, positive surgical margins increase the risk of metastasis. Consequently, detailed histopathological examination is crucial for incidental tumors detected after acute appendicitis, and treatment decisions must be personalized by evaluating risk factors rather than relying solely on tumor size.

Comparison of pre-treatment and post-surgical status of the axilla in patients with locally advanced breast cancer who showed complete radiological response on positron emission tomography (PET-CT) after neoadjuvant treatment: A single-center retrospective study

Furkan Güngör, Sümeyra Emine Bölük, Gülçin Ercan, Haron Cemel, Nurper Denizoğlu, Atahan Karaaslan

University of Health Sciences Türkiye, Sultan 2. Abdülhamid Han Training and Research Hospital, İstanbul

Objective: Breast cancer is the most common cancer in women. Despite the widespread use of screening programs in our country and worldwide, advanced/locally advanced stage cancers are still being detected. The effectiveness of adjuvant and neoadjuvant therapy has increased in patient groups where it has been shown to contribute to the prognosis. Therefore, neoadjuvant therapy has become preferred not only in locally advanced stage cancer but also in patients with indications at an early stage. The complete clinical/radiological response achieved with neoadjuvant therapy has also led to deescalation in surgical treatment. This study aims to evaluate the surgical outcomes in patients with locally advanced breast cancer who achieved a complete clinical/radiological response after neoadjuvant therapy.

Material and Methods: Between 2023 and 2025, 291 patients underwent surgery for breast cancer. Of these, 54 received neoadjuvant treatment for locally advanced breast cancer and subsequently underwent surgery. Of these 54 patients, 41 with complete axillary response after treatment were included in the study. Demographic characteristics, primary tumor pathologies, axillary lymphadenopathy (LAP) involvement in preoperative and postoperative imaging studies, and the number of lymph nodes involved as a result of axillary surgery were recorded for each patient.

Results: Forty-one female patients were examined. The mean age was 53.6 (min: 34, max: 71). Tumor pathology of the patients was: 23 (56.09%) invasive ductal carcinoma, 1 (2.4%) invasive mucinous carcinoma, 3 (7.3%) invasive lobular carcinoma, 1 (2.4%) inflammatory breast cancer, and 13 (31.7%) invasive breast carcinoma. It was observed that 16 patients underwent breast-conserving surgery (BCS) and 25 patients underwent mastectomy. Sentinel lymph node biopsy (SLNB) was positive in 21 (51.2%) patients (2 micrometastases and 1 suspected LAP were evaluated as positive). SLNB was negative in 20 (48.8%) patients. Level 2 axillary lymph node dissection was performed on 15 patients who tested positive.

Conclusion: In locally advanced breast cancer, its contribution to the prognosis in the neoadjuvant period has been proven. The issue of permanent de-escalation of axillary surgery and breast surgery has also come to the fore. Complete radiological response after treatment suggests that axillary surgery may be abandoned in this patient group. In our study, we observed that SLNB positivity (after neo-adjuvant treatment) was 51.2% in patients with complete radiological response in the axillary spectrum. However, this does not mean that all SLNB-positive patients should undergo axillary dissection. Targeted axillary surgery in a selected patient group is effective in reducing comorbidities associated with axillary surgery.

Clinical course, diagnostic process, and treatment approaches in Paget's disease of the breast: A retrospective single-center study

Muhammed Hallaç[1], Duray Şeker[1], M. Salih Süer[1], Faruk Yazıcı[2], Serkan Demir[1], Melih Akıncı[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk, Ankara*

Objective: Although Paget's disease of the breast is rare, it is frequently associated with underlying ductal carcinoma *in situ* (DCIS) or invasive breast cancer, and delays in diagnosis are common. This study aimed to evaluate the demographic characteristics, clinical presentation, diagnostic process, imaging and pathological features, treatment approaches, and clinical outcomes of patients diagnosed with Paget's disease of the breast.

Material and Methods: This retrospective study included a total of 2 patients diagnosed with Paget's disease of the breast. Demographic data, symptom duration, presenting symptoms, diagnostic delay, initial point of presentation, imaging findings (mammography, ultrasonography, and magnetic resonance imaging), pathological characteristics (presence of pure Paget's disease, association with DCIS or invasive cancer, tumor type, grade, hormone receptor status, HER2, and Ki-67), surgical and adjuvant treatments, follow-up duration, and recurrence status were recorded. Descriptive statistics were presented as median (IQR) or number (percentage).

Results: The median age of the patients was 60 (50-71) years. The median symptom duration was 12 (3-18) months, and the median interval between symptom onset and biopsy was 12 (2-18) months. The most common presenting symptoms were eczema (28.6%), nipple discharge (23.8%), ulceration (23.8%), and pain (23.8%). Diagnostic delay (≥6 months) was observed in 52.4% of patients, most commonly due to dermatological manifestations in the absence of a palpable breast mass (e.g., pruritus, rash). On mammography, suspicious findings were detected in 57.1% and malignant findings in 19.0% of cases, while ultrasonography revealed malignant features in 28.6%. Magnetic resonance imaging was performed in 10 patients, of whom 60% showed findings suggestive of malignancy. Pure Paget's disease was identified in 9.0% of cases, whereas DCIS and invasive cancer were present in 66.7% and 47.6%, respectively. The most common tumor type was invasive ductal carcinoma (90.5%), and 52.4% of tumors were high grade (G3). Mastectomy was performed in 71.4% of patients, and sentinel lymph node biopsy was carried out in 76.2%. The median follow-up duration was 15 (5-24) months, and the recurrence rate during follow-up was 14.3%.

Conclusion: Paget's disease of the breast is most commonly associated with underlying DCIS and/or invasive breast cancer and is notable for diagnostic delays. In our study, the presence of a diagnostic delay of ≥6 months in more than half of the patients suggests that the risk of malignancy may be overlooked in the early stages when Paget's disease presents with dermatological symptoms. In cases where mammography and ultrasonography are limited, the detection of malignancy-suggestive findings 60% of patients who underwent MRI supports the added value of MRI in selected cases within the diagnostic algorithm. The low rate of pure Paget's disease and the high prevalence of associated DCIS and invasive cancer are consistent with the literature, reinforcing the concept that Paget's disease often represents a manifestation of underlying breast malignancy. Overall, this study contributes to the literature by quantitatively demonstrating diagnostic delay and providing a comprehensive real-world evaluation of imaging and pathological spectra. Early biopsy, appropriate imaging strategies, and a multidisciplinary approach are critical for optimal management.

Surgical and oncologic outcomes in patients with ductal carcinoma *in situ* undergoing breast-conserving surgery: A single-center experience

Baran Mollavelioğlu[1], Seza Vardar[1], Rana Günöz Cömert Bozkurt[2], Sidar Bağbudar[3], Selman Emiroğlu[1], Mustafa Tükenmez[1], Neslihan Cabıoğlu[1], Mahmut Müslümanoğlu[1]

[1]*Department of Surgery, İstanbul University, İstanbul Faculty of Medicine, İstanbul*

[2]*Department of Radiology, İstanbul University, İstanbul Faculty of Medicine, İstanbul*

[3]*Department of Pathology, İstanbul University, İstanbul Faculty of Medicine, İstanbul*

Objective: Ductal carcinoma *in situ* (DCIS) has been increasingly diagnosed with the widespread implementation of screening programs. Breast-conserving surgery (BCS) combined with adjuvant radiotherapy provides excellent long-term local control. However, the optimal surgical margin width, the need for re-excision, and particularly the indication for axillary staging remain controversial. This study aimed to evaluate the clinicopathologic characteristics and surgical and oncologic outcomes of patients with DCIS treated with BCS at our center.

Material and Methods: A total of 50 patients who underwent BCS with a diagnosis of DCIS between January 2018 and December 2023 were retrospectively analyzed. Preoperative radiologic findings, clinical characteristics, operative details, pathological results, and oncologic outcomes were reviewed.

Results: The median age was 55.5 years. Preoperative imaging included mammography (96%), ultrasonography (100%), and magnetic resonance imaging (MRI) (76%). Microcalcifications were detected in 58% of patients on mammography. Pathologic findings were identified in 74% of patients on ultrasonography and in 92% on MRI, making MRI the most sensitive imaging modality. Radiologic localization was performed in 35 patients (70%); 29 underwent wire-guided excision and 6 underwent excision based on skin projection marking. Intraoperative assessment was utilized in 15 patients (30%), and 21 patients (42%) underwent re-excision during the same surgical session. Specimen radiography or ultrasonography was performed in 26 patients (52%). Final pathology revealed pure DCIS in 37 patients (74%) and invasive carcinoma in 13 patients (26%), including 3 cases of microinvasive disease. Sentinel lymph node biopsy (SLNB) was performed in 23 patients (46%). Among these, 13 patients (56%) had high-grade, 7 (30%) had intermediate-grade, and 3 (6%) had low-grade DCIS. Estrogen receptor positivity was observed in 33 patients (66%). Despite a relatively high upstaging rate, all SLNB results were negative. Margin involvement was identified in 13 patients: 4 patients (8%) had positive margins and 9 patients (18%) had margins less than 2 mm. Six patients (12%) required a second surgery (4 mastectomies and 2 re-excisions). Adjuvant radiotherapy was administered to 44 patients (88%), endocrine therapy to 33 patients (66%), and chemotherapy to 5 patients (10%). After a median follow-up of 54 months (range: 23-96), ipsilateral local recurrence occurred in one patient (2%). Two patients (4%) died due to causes unrelated to breast cancer.

Conclusion: Breast-conserving surgery for DCIS, when planned with appropriate radiologic and clinical evaluation, achieves low reoperation rates and excellent local control. Considering the low likelihood of nodal involvement, axillary intervention should not be routine but rather tailored based on individual patient risk assessment.

High success rate in sentinel lymph node identification using the nipple traction technique

Hasan Kumru, Suat Aktaş, Fikret Ezberci, Aylin Acar, Tolga Canbak

Department of General Surgery, University of Health Sciences Türkiye, Ümraniye Training and Research Hospital, İstanbul

Objective: Breast cancer is the most common malignancy among women, and axillary lymph node status plays a critical role in staging and treatment planning. Sentinel lymph node biopsy (SLNB) is currently the standard method for staging clinically node-negative breast cancer, as it provides reliable staging with lower morbidity compared to axillary dissection. However, the sentinel lymph node identification rate using blue dye alone has been reported to range between 85% and 95% in the literature. This study aimed to evaluate the contribution of the nipple traction/massage technique to the identification rate of stained lymph nodes in SLNB performed using blue dye.

Material and Methods: Following anesthesia induction and standard surgical preparation, isosulfan blue or 1% methylene blue solution diluted with saline at a ratio of 4:2 was injected into the subareolar region. After injection, routine circular breast massage was applied for approximately 6 minutes. During this period, the nipple was repeatedly pulled upward and anteriorly and released by the surgeon to create tension (nipple traction). This maneuver was intended to increase tension in the subareolar tissue and facilitate more effective participation of the dye in lymphatic flow. The maneuver did not prolong operative time and was safely applied in all cases.

Results: Over the last three years, SLNB was performed in a total of 247 patients. The nipple traction maneuver was applied in all patients, and the sentinel lymph node was identified with a high success rate. The mean number of identified stained lymph nodes was 2 (range, 1-5). One patient developed skin necrosis related to methylene blue, and one patient experienced a non-severe allergic reaction. These findings suggest that this simple maneuver may contribute positively to increasing sentinel lymph node identification rates.

Conclusion: In the literature, the sentinel lymph node identification rate using blue dye alone has been reported as 85-95%, while the dual method (blue dye + radioisotope) achieves rates of 95-99%. In our series, using blue dye alone combined with the nipple traction technique, a success rate exceeding 98% was achieved in identifying stained sentinel lymph nodes. The technique is presumed to facilitate dye transport to the axilla by stretching the subareolar plexus. As a simple, easily learned, and safe method, the nipple traction technique may represent a valuable alternative, particularly in centers with limited access to radioisotopes. Nevertheless, as this study is retrospective in nature, the results should be confirmed by larger prospective and comparative studies.

Outpatient management of perianal fistulas with elastic seton: Clinical experience and outcomes

İbrahim Halil Öcal[1], Abdulkadir Akbaş[2]

[1]*Clinic of General Surgery, Adıyaman Training and Research Hospital, Adıyaman*

[2]*Department of General Surgery, Dicle University Faculty of Medicine, Diyarbakır*

Objective: Perianal fistulas are challenging perianal pathologies that can develop following the drainage of anal abscesses. The aim of fistula treatment is to minimise recurrence while preserving continence. Alongside surgical interventions, elastic seton placement is one of the preferred methods due to its low morbidity and high success rates. In this study, the effectiveness of elastic seton placement in outpatient settings and its effects on patient comfort were evaluated.

Material and Methods: Patients who underwent elastic seton placement in an outpatient setting for intersphincteric anal fistula at the general surgery clinic between 1 January 2021 and 31 December 2024 were prospectively evaluated. Patients diagnosed with Crohn's disease and ulcerative colitis were excluded from the study. The diagnosis of anal fistula was made based on physical examination and magnetic resonance imaging (MRI). The procedure was performed in the prone position under local anaesthesia in sterile conditions. Patients who underwent tight seton placement were recalled at 2-week intervals for seton re-tightening. Patients were provided with post-operative analgesia and hygiene recommendations. During the follow-up period, pain scores visual analogue scale (VAS), fistula closure time, and post-operative complications such as infection, bleeding, and incontinence were evaluated.

Results: Forty-one patients were included in the study. Their ages ranged from 35 to 43. The average procedure duration was 9 minutes. Post-procedure pain was assessed using the VAS and averaged 3-4. The time for the seton to separate from the tissue ranged from 1 to 6 weeks. Patients were followed up regularly at outpatient clinic appointments at 3-month intervals over a period of 3-18 months. No complications such as infection, bleeding, or incontinence were observed in any of the patients who underwent the procedure.

Conclusion: The application of elastic setons in outpatient settings is a safe, effective method for treating anal fistula that maintains a high level of patient comfort. Patients experience minimal pain and can quickly return to their daily lives, with a low-risk of serious complications. It offers a suitable treatment option, particularly for high-risk patients and those wishing to avoid surgical intervention.

Use of wound dressing products in University of Health Sciences Türkiye, Antalya City Hospital Burn Center: A retrospective clinical study

Nursen Keskin[1], Emin Türk[1], Tuğba Karabudak[1], Zeliha Akış Yıldız[1], Erdal Karagülle[2], Fazlı Aladağ[2]

[1]*University of Health Sciences Türkiye, Antalya City Hospital, Burn Center, Antalya*

[2]*University of Health Sciences Türkiye, Antalya City Hospital, Antalya*

Objective: We aimed to demonstrate the relationship between the types of wound dressing products used and the length of hospital stay (LOS) in patients hospitalized and treated at the newly established University of Health Sciences Türkiye, Antalya City Hospital, Burn Center.

Material and Methods: In this retrospective clinical study, patients hospitalized and treated at the University of Health Sciences Türkiye, Antalya City Hospital, Burn Center between March 1, 2024, and February 3, 2026, were evaluated. The types of products used, number of patients, gender distribution, mean ages, and mean LOS were recorded for patients who underwent wound dressing applications.

Results: Wound dressing products were applied to a total of 263 hospitalized patients. It was observed that multiple wound dressing products were used in some cases. •Epidermal equivalents: applied to 107 patients (72% male, 28% female). The mean age was 19.1±19.2 years, and the mean LOS was 11.9±37.2 days. •Collagen dressings: used in 16 patients; mean age was 16.9 ± 21.3 years, and mean LOS was 21.8±20.7 days. •Single-layer dermal scaffolds (polyurethane): applied to 9 patients; mean age was 42.0±14.7 years, and mean LOS was 20.8±22.6 days. •Hydrocolloid dressings: used in 10 patients; mean age was 38.9±22.9 years, and mean LOS was 15.8±13.0 days. •Double-layer dermal scaffolds (dermal matrix): Applied to 18 patients; the mean age was 41.1±23.8 years, and the mean LOS was 51.7±33.4 days, which was significantly longer compared to other product groups. •Silver-impregnated hydrofiber dressings: Used in 103 patients; mean age was 29.7±21.8 years, and mean LOS was 19.7±17.2 days. When all wound dressing products were evaluated collectively, the mean age for the 263 patients was 26.2±22.0 years, and the mean LOS was 18.3±29.7 days.

Conclusion: Wound dressing products are widely utilized in our Burn Center, and a significantly longer LOS was observed particularly in patients treated with dermal matrices. While patients were initially managed with frequent dressings using only topical creams, advancements in technology and the development of modern wound dressings have reduced the frequency of dressing changes and surgical interventions. This progress shortens treatment periods while enhancing patient comfort and aesthetic outcomes. Although these technologies may currently impact healthcare budgets in terms of cost-effectiveness, we believe that more cost-effective forms of wound dressings will improve the welfare of both patients and physicians in the future.

The experience of a surgical team new to robotic surgery: Analysis of the first year of cases

Sinan Şener, Fatih Türkoğlu, Mehmet Fatih Öztürk, Hüseyin Yılmaz

Selçuk University Faculty of Medicine, Konya

Objective: Robotic surgery gained an important role among minimally invasive surgical techniques inrecent years. Advanced 3D imaging systems, increased instrument articulation and technicalfeatures improving surgeon ergonomics have led to its widespread adoption across surgicaldisciplines. Previous studies demonstrated that robotic surgery provides precise dissection,especially in anatomically complex regions, reduces blood loss and improves surgeon comfort. However, robotic surgical procedures require a specific level oforganization, time management and coordination between surgical and anesthesiateams. During the learning process, progressive improvement in operative workflow and teamcoordination is expected, and this experience is reported to positively influence clinical outcomes. The aim of this study was to evaluate surgical and anesthetic process-related parameters, early clinical outcomes and temporal changes in robotic surgery cases performed in our clinic.

Material and Methods: Robotic surgery cases performed in our clinic were retrospectively reviewed. The total numberof cases and types of surgical procedures were recorded. Concordance between preoperativeand postoperative diagnoses was evaluated. Conversion to laparoscopic or open surgery wasanalyzed. Intraoperative blood loss and the need for blood transfusion wererecorded. Anesthesia-related processes were evaluated in detail, including anesthesia inductiontime, time to surgical handover, interval between completion of surgery and extubation, andtotal operative duration. Postoperative drain output and urine volume during the first twopostoperative days were recorded. Early postoperative complications, embolic events andmortality were assessed.

Results: A significant improvement in surgical and anesthetic timing parameters was observed overtime in robotic surgery cases. Operative durations were found to decrease in later cases,andperioperative processes were managed more efficiently. In accordance with theliterature, operative workflow became more stable as team experience increased. Conversionrates to laparoscopic or open surgery were low. Postoperative complication rates werelimited, and anastomotic leakage and embolic events were rarely observed. Mortality rateswere low in the early postoperative period.

Conclusion: The literature emphasizes that robotic surgery is a safe and effective technique, and highlights the critical role of surgical and anesthesia team experience in determining clinicaloutcomes. Our findings are consistent with previous reports, demonstrating that increasingteam experience over time contributes to shorter operative durations and improvedperioperative management. Robotic surgery was found to be a safe and feasible approach inour clinic in terms of early clinical outcomes and operational processes. It is concluded thatrobotic surgery can be effectively implemented with appropriate patient selection andexperienced multidisciplinary teams.

The initial liver transplantation experience of a surgical team: An evaluation of seven cases performed over a seven-month period

Aliya Amrahova, Feyyaz Güngör, Talha Sarıgöz, Yusuf Yunus Korkmaz, İlyas Kudaş, Birkan Bozkurt, Özgür Bostancı, Erdem Kınacı

Depar of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: Liver transplantation is the cornerstone treatment for end-stage liver disease and acute liver failure, significantly reducing mortality. This study aimed to evaluate the patient characteristics, transplantation indications, and early clinical outcomes of liver transplantations performed at our center over a seven-month period.

Material and Methods: A total of seven patients who underwent liver transplantation at our center within a seven-month period were included in the study. Demographic data, transplantation indications, urgency status (elective vs. emergency), and length of hospital stay were retrospectively analyzed.

Results: Among the patients included in the study, 43% were male (n=3) and 57% were female (n=4), with a mean age of 44 years. The mean duration of hospitalization was 30 days. Of the liver transplantations performed, 71% (n=5) were carried out electively, whereas 29% (n=2) were performed under emergency conditions. The indications for elective liver transplantation were identified as hepatocellular carcinoma arising in the context of hepatitis C–related chronic liver disease (n=1), primary sclerosing cholangitis complicated by recurrent episodes of cholangitis (n=1), liver cirrhosis secondary to hepatitis B infection (n=1), hepatocellular carcinoma developing on the background of hepatitis B infection (n=1), and hepatopulmonary syndrome (n=1). Of the patients who underwent emergency liver transplantation, one received a cadaveric graft for acute liver failure secondary to drug-induced liver injury associated with hepatitis B infection, while the other underwent cadaveric liver transplantation for acute liver failure resulting from toxic hepatitis. One of the patients who underwent surgery in an intubated state due to acute hepatic encephalopathy died of multiorgan failure during postoperative intensive care unit follow-up after transplantation, despite satisfactory graft function and the lack of recovery of cerebral function.

Conclusion: The liver transplantations performed by our newly established liver transplantation unit over a limited time period for different etiological indications demonstrate that liver transplantation is an effective and feasible treatment modality for both chronic liver diseases and acute liver failure.

Keywords: Liver, transplantation, urgent, elective

Retrospective analysis of 347 patients: Effectiveness of a synchronized model in preoperative evaluation with joint surgeon and anesthesiologist visit

Orhan Birdal[1], Artoghrul Mammadli[2]

[1]*Clinic of General Surgery, University of Health Sciences Türkiye, Ankara Training and Research Hospital, Ankara*

[2]*Clinic of Anesthesiology and Reanimation, University of Health Sciences Türkiye, Ankara Training and Research Hospital, Ankara*

Objective: Preoperative preparation is a significant determinant of surgical outcomes. Separate evaluations by the surgeon and anesthesiologist can lead to communication gaps and oversight of uncontrolled comorbidities. In this study, we aimed to assess the impact of a synchronized preoperative visit mode conducted jointly by the surgeon and anesthesiologist on surgery cancellation/postponement rates, detection and optimization of uncontrolled comorbidities, time efficiency, and stakeholder satisfaction.

Material and Methods: This retrospective study included 347 patients scheduled for elective general surgery between December 1, 2025, and January 5, 2026. The patients were divided into two groups: The Joint Visit Group (n=150) and the traditional Separate Visit Group (n=197). Patients in the Joint Visit Group were evaluated simultaneously by both specialists during designated afternoon hours on three days per week. The two groups were compared regarding demographic characteristics, surgery cancellation/postponement rates and reasons, detected uncontrolled comorbidities [hypertension (HT), diabetes mellitus (DM)], visit durations, and satisfaction scores of patients, surgeons, and anesthesiologists measured on a 5-point Likert scale.

Results: No significant difference existed between the groups in terms of age and gender distribution. In the Joint Visit Group, a total of 21 patients (14%) experienced cancellation/postponement in the preoperative period (11 mutual decision, 5 patient refusal, 3 upper respiratory tract infection, 2 uncontrolled HT/DM). In the Separate Visit Group, this number was 41 patients (20.8%) (19 anesthesiology deferral, 7 patient refusal, 5 no-show, 10 intraoperative postponement). The most significant finding was the difference in the management of uncontrolled comorbidities. In the Joint Visit Group, uncontrolled HT/DM was detected in 33 patients (22%), allowing for complete preoperative optimization. In the Separate Visit Group, despite a similar prevalence of comorbidities, uncontrolled disease was present in 26 patients (13.2%). Optimization was incomplete in a significant portion of these patients, which was observed as the primary reason for intraoperative postponements (24.4%) in this group.The joint visit model saved 5-6 minutes per patient. All satisfaction scores were significantly higher in the Joint Visit Group (4.4, 4.3, 4.6 vs. 3.9, 4.1, 4.0, respectively).

Conclusion: The joint surgeon-anesthesiologist visit model stands out due to its capacity to proactively screen for the control status of these conditions and optimize them in the preoperative period within a population with a similar comorbidity burden. This approach has the potential to reduce intraoperative surprises and postponements, increases time efficiency, and enhances satisfaction among all stakeholders. This model presents a viable multidisciplinary strategy for improving the safety and quality of elective surgical programs.

Keywords: Multidisciplinary team, patient satisfaction, preoperative evaluation, surgery cancellation

Co-occurrence of acute appendicitis and urinary tract infection: Prevalence and clinical characteristics

Levent Bolat[1], Murat Aba[2], Alper Çalışkan[2], Tarık Sırça[2]

[1]*Osmaniye State Hospital, Osmaniye*

[2]*Selahaddin Eyyubi State Hospital, Diyarbakır*

Objective: This study aimed to evaluate urinary system findings in patients with acute appendicitis, particularly their association with perforation, diabetes mellitus (DM), age, and gender.

Material and Methods: A retrospective analysis was performed on 100 patients who underwent appendectomy with a diagnosis of acute appendicitis. Demographic data, comorbidities [(especially DM), laboratory tests white blood cell (WBC), C-reactive protein (CRP)], urinalysis parameters (urine WBC, red blood cell, squamous epithelium), and intraoperative perforation status were recorded. Patients were divided into perforated and non-perforated groups. Mann-Whitney U and chi-square tests were used for statistical analysis, and $p<0.05$ was considered significant.

Results: A total of 100 patients diagnosed with acute appendicitis were included in the study. The mean age of the cohort was 37.8±14.6 years, and 47.2% of the patients were female. Perforation was detected in 18 patients (18.0%), while DM was present in 13 patients (13.0%). Comparison of laboratory parameters between perforated and non-perforated cases revealed significant differences. The mean WBC count was 16.1±4.3 $\times 10^3/\mu L$ in the perforated group compared with 12.6±3.4 $\times 10^3/\mu L$ in the non-perforated group ($p<0.05$). Similarly, mean CRP levels were markedly higher among patients with perforated appendicitis (73.1±56.3 mg/L) compared with those without perforation (21.0±21.3 mg/L, $p<0.05$). Urinary abnormalities were also evaluated according to DM status. Hematuria was more frequently observed in patients with DM (69.2%) compared to non-diabetic patients (41.4%); however, this difference did not reach statistical significance ($p=0.113$). The prevalence of leukocyturia was similar between DM-positive (30.8%) and DM-negative (27.6%) groups ($p>0.05$). Female patients demonstrated a higher prevalence of hematuria (56.9%) than male patients, who exhibited lower rates. Leukocyturia was also more common in women (31.4%). Age-stratified analysis showed that patients younger than 40 years presented with urinary abnormalities more frequently compared to those aged 40 years or older.

Conclusion: Urinary abnormalities such as hematuria and leukocyturia are common in acute appendicitis and can mimic urinary tract infections. These findings are significantly more pronounced in perforated cases. The presence of DM further increases both perforation risk and hematuria frequency. Clinicians should therefore consider appendicitis in patients presenting with acute abdomen and urinary abnormalities.

Keywords: Appendicitis, urinary tract, hematuria

To do or not to do: Primary anastomosis in emergency colorectal tumors

Eda Gül Doğan, Ramazan Onuş, Turgay Sayın

Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Colorectal cancer is a common disease that can be found in emergency and daily clinics. They can be admitted with obstruction, perforation or bleeding. They can undergo emergency surgery. In emergency surgeries major challenges are less evaluation time, lack of bowel preparation and intestinal distention due to obstruction. Because of these factors surgeons may be tentative to perform primary anastomosis. Anastomosis leakage is a major problem especially with patients which have age greater than 70 and American Society of Anesthesiologists physical status score–Grade III to V, cardiorespiratory comorbidities, poor nutritional status. In our study, we evaluate emergency colorectal surgeries with primary anastomosis in our clinic within selected time period.

Material and Methods: This retrospective study has 37 patients who underwent colorectal surgery and primary anastomosis at University of Health Sciences Türkiye, Ankara Etlik City Hospital between August, 2024 and December, 2025. Demographically, there are 23 (62.2%) male and 14 (37.8%) female patients and their mean age is 67.1 (min-max, 39-89). When we evaluate them according to tumor localisation 22 left colon tumors and 15 right colon tumors present. All of them are T3 or T4 locally-extensive tumors. After following suitable oncological resection, primary anastomosis has been performed via circular/lineer stapler or manuel. Leakage status, distribution and management have been evaluated.

Results: Anastomosis leak has been seen in 10 (27%) patients. Six of them are clinically stable, have Clavien-Dindo Class I-II leakage and resulted in successful closure without any additional complication. Four of these 10 leak patients need additional surgery for diverting stoma but they have no further complications and successfully discharged. There is no statistical difference between anastomosis with circular stapler, linear stapler or manual anastomosis according to leak status. Tumor localisation is statistically significant, left colon tumors have higher risk for leak ($p=0.016$; $p<0.05$). Proximal intestinal dilation in diameter is also analysed for leak but there is no statistical difference according to diameter of intestine. Length of hospitalisation is longer and statistically significant in leak patients. (Without leak min-max: 5-23; leak min-max: 12-52; $p=0.006$; $p<0.01$) There was one mortality among patients without leak due to comorbidities.

Conclusion: Colorectal tumoral obstructions can be challenged in emergency surgeries but as in elective procedures, patients have a chance of primary anastomosis without additional morbidity or mortality. In experienced centers, patient follow-up has a key role in leak management. Our study shows, primary anastomosis in emergency colorectal tumors can be preferable in suitable patients and should not be a taboo.

Laser surgery in recurrent proctological cases: Early results and clinical experience

Emre Furkan Kırkan, Osman Akdoğan, Aydın Eray Tufan, Elif Tufan

Yalova Training and Research Hospital, Yalova

Objective: Recurrent proctologic diseases constitute a challenging patient population due to fibrosis and distorted anatomy resulting from previous surgical interventions. Conventional surgical approaches in these cases often require wider dissection and may increase the risk of sphincter injury, particularly in anal fistula patients. In recent years, laser surgery has gained increasing attention in proctologic practice because of its minimally invasive and sphincter-preserving characteristics. The aim of this study was to evaluate the early clinical outcomes and feasibility of laser surgery in patients with recurrent hemorrhoidal disease, anal fistula, and pilonidal sinus.

Material and Methods: This retrospective, single-center pilot study included patients who underwent laser surgery for recurrent proctologic disease. A total of 20 patients with recurrent hemorrhoids, recurrent anal fistula, or recurrent pilonidal sinus were analyzed. Early outcomes were assessed within the first two months of follow-up. Demographic characteristics, previous surgical history, laser technique applied, operative time, length of hospital stay, postoperative complications, early clinical improvement, and early recurrence were evaluated using descriptive statistics.

Results: Among the included patients, 10 had recurrent pilonidal sinus, 4 had recurrent hemorrhoidal disease, and 4 had recurrent anal fistula. The mean operative time was approximately 16 minutes, and 90% of patients were discharged on the same day or within 24 hours. No major postoperative complications were observed, while minor complications occurred in 20% of patients. The overall early clinical improvement rate was 80%. In the recurrent pilonidal sinus group, the healing rate was 80% with an early recurrence rate of 10%. In the hemorrhoid group, early recurrence was observed only in a patient with Grade IV disease. In the anal fistula group, complete healing was achieved in 50% of patients. One patient underwent a staged approach with loose seton placement followed by laser ablation during a second session, resulting in marked symptom relief. No permanent continence impairment was observed during the early follow-up period.

Conclusion: Laser surgery appears to be a safe and feasible treatment option for recurrent proctologic diseases, offering low morbidity, short hospital stay, and acceptable early recurrence rates. Particularly in recurrent anal fistula, laser treatment may serve as a valuable component of a sphincter-preserving, stepwise treatment strategy. However, careful patient selection remains essential, especially in advanced hemorrhoidal disease and complex recurrent cases. Larger studies with long-term follow-up are required to define the durable efficacy of laser surgery in recurrent proctologic disorders.

Keywords: Recurrent proctologic diseases, laser surgery, sphincter-preserving treatment

Table 1. Disease-based early clinical outcomes

Disease group	Number of patients (n)	Early recovery	Early recurrence	Minor complication	Reoperation
Recurrent hemorrhoids	4	100%	25% (grade IV)	25%	0
Recurrent anal fistula	4	50%*	50%	25%	0
Recurrent pilonidal cyst	10	80%	10%	20%	10%
Total	20	80%	20%	20%	5%

*In one patient in the anal fistula group, laser treatment was applied during the second session after a loose seton application. Although complete anatomical closure was not achieved, a significant reduction in symptoms was observed. No loss of continence was observed in any patient during the early period.

[P-582]

The overlooked etiology behind renal stone disease: Delayed diagnosis of parathyroid adenoma in a young adult

Özlem Özaydın[1], Serkan Teksöz[1], Tülin Öztürk[2]

[1]Department of General Surgery, Cerrahpaşa Faculty of Medicine Hospital, İstanbul
[2]Department of Pathology, Cerrahpaşa Faculty of Medicine Hospital, İstanbul

Objective: Parathyroid adenoma is a benign endocrine tumor and represents the most common cause of primary hyperparathyroidism, accounting for approximately 80-85% of cases. Although many patients are currently diagnosed through incidental detection of asymptomatic hypercalcemia, some present with end-organ complications such as nephrolithiasis. In young adults, recurrent renal stone disease without comprehensive metabolic evaluation may lead to delayed recognition of the underlying endocrine etiology. In this case, we wanted to present our case both to ensure that patients receive early treatment with accurate diagnosis, and to facilitate the functioning of the healthcare system in our country without burdening different branches and resources.

Material and Methods: This study presents a retrospective evaluation of a young patient who was managed symptomatically for recurrent nephrolithiasis and was subsequently diagnosed with parathyroid adenoma. Clinical records, laboratory findings, imaging studies, surgical details, and postoperative outcomes were reviewed. Biochemical assessment included measurement of serum calcium and parathyroid hormone (PTH) levels. Lesion localization was performed using cervical ultrasonography. Surgical treatment consisted of focused parathyroidectomy. Postoperative biochemical response and follow-up outcomes were analyzed.

Results: A 28-year-old male with no known comorbidities was evaluated in multiple urology clinics over a two-year period due to recurrent nephrolithiasis and received medical treatment. During this time, no comprehensive metabolic investigation was performed, and management focused solely on urinary tract pathology. Upon referral to our center, laboratory analysis revealed persistent hypercalcemia and markedly elevated PTH levels. Neck ultrasonography demonstrated a hypoechoic lesion located posterior to the inferior pole of the thyroid gland, consistent with parathyroid adenoma. Following localization studies, the patient underwent focused parathyroidectomy. Histopathological examination confirmed the diagnosis. In the early postoperative period, serum calcium and PTH levels returned to normal ranges. No recurrence of nephrolithiasis was observed during follow-up.

Conclusion: Hypercalcemia secondary to parathyroid adenoma promotes increased bone resorption and renal calcium excretion, predisposing patients to nephrolithiasis. In young patients, exclusive focus on symptomatic urinary management may obscure the underlying endocrine etiology. Diagnostic delay can result in prolonged morbidity, repeated hospital visits, and unnecessary interventions. Surgical excision remains the definitive and curative treatment. Early diagnosis and timely surgical intervention not only normalize biochemical parameters but also significantly reduce the risk of recurrent renal stone formation. Recurrent nephrolithiasis in young adults should prompt evaluation for parathyroid adenoma as a potential underlying cause. Simple biochemical screening may prevent delayed diagnosis and avoidable morbidity. Early multidisciplinary assessment and definitive surgical management are essential for optimal clinical outcomes.

Keywords: Parathyroid adenoma, nephrolithiasis, endocrine surgery

Early clinical, metabolic, and nutritional outcomes following mini gastric bypass: A single-center early experience

Süleyman Kuşcu[1], Muhammed Salih Süer[1], Serkan Demir[1], Şener Balas[1], Harun Karabacak[2], Faruk Yazıcı[3]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Lokman Hekim İstanbul Hospital, İstanbul*

[3]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Mini-gastric bypass (MGB) is an effective surgical treatment for morbid obesity, providing significant weight loss and metabolic improvement; however, it requires careful postoperative follow-up because of potential complications and nutritional consequences. This study aimed to evaluate the demographic, clinical, operative, and postoperative outcomes of patients who underwent MGB for obesity and to assess early safety and nutritional results.

Material and Methods: In this retrospective observational study, data from six patients who underwent MGB for obesity were analyzed. Demographic characteristics, preoperative clinical status, comorbidities, operative and perioperative data, as well as early and late postoperative complications were evaluated. Metabolic and nutritional outcomes during follow-up were also assessed. Continuous variables were presented as median (IQR) and minimum–maximum values, and categorical variables as numbers and percentages.

Results: All patients were female, with a median age of 48.5 years (33-55). The median preoperative body mass index was 43.8 kg/m² (26.7-49.4), and most patients were in the class III obesity group. Type 2 diabetes was present in 33.3% of patients, with a median disease duration of 10 years. MGB was successfully completed in all cases. No major perioperative complications, blood transfusions, or intensive care requirements were observed. The median length of hospital stay was 3 days. During postoperative follow-up, one patient developed a marginal ulcer and one developed dumping syndrome, while no reactive hypoglycemia was observed. Cholelithiasis was detected in two patients during follow-up, and cholecystectomy was performed in these cases. No anastomotic leaks, reoperations, or mortality occurred. Evaluation of the lowest albumin levels during follow-up showed that no patient developed severe hypoalbuminemia. Metabolic remission was achieved in all patients with type 2 diabetes.

Conclusion: This small series demonstrates that MGB is a safe and effective option for obesity treatment in the early period. The absence of major perioperative complications, intensive care need, reoperation, or mortality indicates a high safety profile in appropriately selected patients. Marginal ulcer and dumping syndrome were rare, and no severe nutritional deficiency was observed. All patients with type 2 diabetes achieved metabolic remission, supporting the metabolic benefits of the procedure. Despite the limited sample size, these findings suggest that MGB provides favorable clinical and nutritional outcomes, which should be confirmed in larger studies with long-term follow-up.

Discriminatory performance of systemic inflammatory indices in identifying tumor stage in gastric cancer: A retrospective study

Turan Pehlivan, Merve Tokoçin, Candaş Erçetin, Erkan Yavuz, Osman Bilgin Gülçiçek, Hakan Yiğitbaş

Department of General Surgery, University of Health Sciences Türkiye, Bağcılar Training and Research Hospital, İstanbul

Objective: Systemic inflammatory biomarkers have emerged as accessible indicators of tumor biology in gastric cancer. However, their ability to reliably discriminate tumor stage remains incompletely elucidated. This study aimed to evaluate the discriminatory performance of commonly used systemic inflammatory indices for identifying advanced-stage gastric cancer using both group-based and classification-oriented analytical approaches.

Material and Methods: This retrospective observational study included 151 patients with histologically confirmed gastric cancer, categorized into early-stage and advanced-stage disease according to pathological staging criteria. The neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), lymphocyte-to-monocyte ratio, mean platelet volume, systemic immune-inflammation index (SII), and systemic inflammation response index (SIRI) were calculated from pre-treatment complete blood count data.

Results: Group-level comparisons revealed no statistically significant differences in median values of any inflammatory indices between early- and advanced-stage disease (all $p>0.05$). However, classification-oriented analyses demonstrated preserved discriminatory performance for selected markers. Receiver operating characteristic analysis showed good discrimination for both NLR and PLR, with areas under the curve exceeding 0.85, whereas composite indices including SII and SIRI exhibited limited discriminatory ability. In multivariable logistic regression analysis, both NLR and PLR remained independently associated with advanced-stage disease after mutual adjustment, confirming their preserved discriminatory value despite overlapping group distributions.

Conclusion: Despite the absence of statistically significant group-level differences, NLR and PLR demonstrated preserved discriminatory capacity and independent associations with advanced-stage gastric cancer when evaluated using classification-oriented analytical approaches. These findings support the role of systemic inflammatory indices as accessible adjunctive biomarkers when interpreted within multimodal staging and risk stratification frameworks rather than as standalone staging tools.

The evolution of HALP score literature: A global bibliometric perspective

Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Yılmaz Türk[1]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: The hemoglobin, albumin, lymphocyte, and platelet (HALP) score is an emerging immune-nutritional biomarker that integrates systemic inflammation, nutritional status, and immune competence. While clinical studies have associated low HALP scores with poor survival outcomes in multiple malignancies, the global research landscape of HALP remains unmapped.

Material and Methods: A comprehensive literature search was conducted in the Web of Science Core Collection without language or time restrictions. Eligible publications explicitly mentioning HALP were analyzed using the Bibliometrix R package and Biblioshiny interface. Descriptive indicators, citation metrics, and source-level analyses were reported in line with BIBLIO guidelines. Co-authorship networks, keyword co-occurrence, thematic maps, and trend analyses were employed to examine the intellectual structure and evolution of the field.

Results: A total of HALP-related publications showed a sharp rise after 2020, reaching their highest output in 2025. China dominated in publication volume, while the United States led in citation impact. Institutional productivity was concentrated in a limited group of centers, particularly the University of Health Sciences and Qingdao University (Figure 1). Co-citation and keyword network analyses revealed three major thematic clusters, anchored by a foundational core of early studies and a rapidly expanding new research wave. The conceptual structure of the field consistently revolved around inflammation, nutrition, and oncologic outcomes (Figure 2). Despite rapid growth, international collaboration remained limited and methodological heterogeneity was pronounced.

Conclusion: HALP research is expanding quickly but remains in an early developmental stage, characterized by uneven global distribution, inconsistent cut-off values, and fragmented methodological approaches. This bibliometric analysis clarifies the current landscape, identifies research gaps, and highlights the need for standardized methods and broader collaborative networks. Strengthening multicenter studies and harmonizing analytical frameworks will be essential for advancing the clinical utility and global adoption of the HALP score.

The value of computed tomography findings in predicting perforation and malignancy in acute appendicitis: A single-center retrospective cohort study

Mehmet Selim Yağmur[1], Mert Ercan[1], Özgür İbiş[1], Murat Güner[2], Erdinç Kamer[2]

[1]*Department of General Surgery, University of Health Sciences Türkiye, İzmir City Hospital, İzmir*

[2]*Department of General Surgery, University of Health Sciences Türkiye, İzmir Faculty of Medicine, İzmir City Hospital, İzmir*

Objective: Acute appendicitis is one of the most common indications for emergency surgical intervention. Accurate preoperative prediction of complications such as perforation and underlying malignancy is critical for clinical decision-making and surgical timing. Although computed tomography (CT) is widely used in the diagnostic evaluation of acute appendicitis, the diagnostic performance of standalone radiological interpretation remains limited, particularly in complicated cases. Moreover, the relative value of CT-based composite scoring systems compared with direct CT interpretation in predicting pathological outcomes has not been clearly established. This study aimed to evaluate the diagnostic performance of CT findings and composite CT scores in predicting perforation and malignancy in patients with acute appendicitis.

Material and Methods: Between January 1, 2024, and December 31, 2025, histopathological reports of 1,187 adult patients (≥18 years) who underwent appendectomy with a diagnosis of acute appendicitis established solely by CT were retrospectively reviewed. Among these, 212 patients with pathological findings consistent with complicated appendicitis and/or neoplastic or malignant lesions (Table 1) constituted the study cohort (Figure 1). Patients were analyzed in three cohorts based on pathological perforation (n=92), presence of neoplasia (n=37), and presence of malignancy (n=17). Because individual CT findings of complicated appendicitis demonstrate high specificity but limited sensitivity, composite scoring systems were developed to reduce false-negative results. A composite CT perforation score based on 8 imaging parameters and a composite CT neoplasia/malignancy score based on 5 parameters were constructed according to previously reported imaging features (Table 2). Demographic, clinical, laboratory, and CT findings were recorded. Standalone CT interpretations and composite scores were evaluated using pathology as the reference standard (Figure 4).

Results: The mean age of the patients was 45.9 years, and 49.5% were female. The mean symptom duration was 60.1 hours, and the mean Alvarado score was 7.71. Patients with intraoperative and pathological perforation had significantly higher age, symptom duration, Alvarado scores, white blood cell count, C-reactive protein levels, and length of hospital stay ($p<0.001$) (Figure 2). The perforation detection rate on CT was 25.5%, where as the pathological perforation rate was 43.4%. Wall defect, extraluminal air, periappendiceal fat stranding, free intraperitoneal fluid, and signs of peritonitis were significantly associated with perforation ($p<0.001$). Patients with pathological perforation had significantly larger appendiceal diameters and higher composite CT perforation scores ($p<0.001$) (Figure 3). While standalone CT interpretation of perforation showed a sensitivity of 41.3% and specificity of 86.7%, the composite perforation score (V≥2) increased sensitivity to 82.6%. In cases with neoplasia and malignancy, suspected mass, suspected mucocele, mural calcification, and periappendiceal lymphadenopathy were significant. The composite malignancy score (W≥1) demonstrated a sensitivity of 82.4% and a negative predictive value of 98.0.

Conclusion: Although standalone CT interpretation in acute appendicitis demonstrates high specificity, its sensitivity for predicting perforation and malignancy is limited. The composite CT scores developed in this study significantly reduce false-negative rates and provide a more balanced and clinically reliable risk stratification.

Predictors of recurrence in the management of breast abscesses

Zekeriya Pelen

University of Health Sciences Türkiye, Gaziosmanpaşa Training and Research Hospital, İstanbul

Objective: Inflammatory breast pathologies represent a significant clinical challenge in general surgery, profoundly impacting patient morbidity and quality of life due to their high propensity for recurrence. Mastitis and breast abscesses constitute the majority of these cases. While the current therapeutic paradigm prioritizes conservative measures—specifically targeted antibiotherapy and ultrasound-guided needle aspiration—surgical intervention remains the definitive recourse for refractory cases. This study seeks to elucidate the clinicopathological predictors of recurrence in patients who transitioned to surgical drainage following the failure of primary conservative management.

Material and Methods: A retrospective cohort of 196 patients diagnosed with breast abscesses between 2021 and 2025 was reviewed. Analysis focused on 109 patients who exhibited clinical persistence despite initial intervention, subsequently requiring surgical drainage. Multiple variables, including anatomical localization, microbiological profiles, systemic inflammatory markers (WBC and CRP), smoking status, diabetes mellitus, and the presence of underlying granulomatous mastitis, were analyzed to determine their association with disease recurrence.

Results: The mean age of the cohort was 35.95 years (range: 21–52), with a predominant distribution of non-puerperal cases (n=107) over puerperal ones (n=2). Statistical modeling demonstrated that positive microbiological cultures and non-granulomatous etiologies were significantly associated with reduced recurrence rates ($p<0.05$). Conversely, granulomatous mastitis, active smoking, and diabetes mellitus emerged as potent independent predictors of recurrence ($p<0.05$). Notably, neither leukocytosis nor elevated CRP levels demonstrated sufficient sensitivity as predictors for recurrence ($p>0.05$).

Conclusion: Conservative management via needle aspiration and antibiotherapy remains the cornerstone of breast abscess treatment. However, when these measures prove insufficient, surgical drainage becomes mandatory. In such instances, routine microbiological and histopathological sampling is paramount to delineate the underlying etiology. A precise diagnosis facilitates a tailored therapeutic approach, which is critical for mitigating the risk of chronicity and minimizing the necessity for repeated surgical interventions. In summary while aspiration is our first line of defense, understanding the underlying pathology is what ultimately prevents the scalpel from being needed a second time.

Reducing incorrect home interventions and unregistered topical product use in burn treatment: A multilevel roadmap for evidence-based first aid and risk communication

Gülsüm Tozlu Bindal

Isparta City Hospital, Isparta

Objective: Common "home/alternative" remedies (oil, yogurt, toothpaste, ice, etc.) used in the community after thermal burns, and the recent increase in the availability of unregistered, unidentified topical preparations (so-called "burn creams") in some rural areas, can increase the risk of burn depth, wound infection, allergic/irritant reactions, delayed treatment, and ultimately sepsis, extensive scarring, and tissue loss. The aim of this report is to discuss the reasons for the continuation of these incorrect practices and to propose an awareness-behavioral change-access program that can be implemented, particularly in rural communities.

Material and Methods: Evidence-based burn first aid recommendations and application barriers are compiled within a "multi-level" intervention framework involving stakeholders such as primary care, emergency services (112), pharmacies, schools, local government, and the tourism sector. The text also discusses the risks of "unregistered products" based on anonymized field observations encountered in clinical practice.

Results: Many guidelines emphasize that the first approach in burns is to safely remove heat; cooling the burn with cool running tap water for 20 minutes, removing constricting jewelry/clothing, covering the burn with a clean dressing, and seeking medical attention. Applying ice and oily/creamy substances is not recommended; excessive/prolonged cooling may increase the risk of hypothermia. There is clinical data reporting that topical "traditional material" applications can increase infection and mortality in acute burns. Infection and subsequent sepsis in burn wounds are significant determinants of morbidity/mortality. Safety issues such as microbial contamination and heavy metal content have been reported in unregistered/community-produced topical products; additionally, herbal/topical preparations may cause allergic contact dermatitis.

Conclusion: One-off informational campaigns are insufficient to reduce harmful home care practices in burn treatment. An effective approach should include: (i) simple and repetitive messaging ("20 min water"), (ii) culturally appropriate communication with local opinion leaders, (iii) care pathways that facilitate access in rural areas, and (iv) risk communication and feedback loops targeting the use of unregistered products.

Keywords: Burn, unregistered topical product, traditional treatment, infection

Bibliometric analysis of general surgery, emergency surgery, and trauma surgery literature in the context of Gaza (2023–2026)

Faruk Yazıcı[1], Serkan Demir[2], M. Salih Süer[2], Şener Balas[2]

[1]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[2]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Armed conflicts cause devastating health outcomes for civilians, and surgical care is vital in managing these crises. This study aims to analyze the scientific literature on general, emergency, and trauma surgery in the context of Gaza (2023-2026) using bibliometric methods to reveal publication trends, geographical contributions, and thematic evolution.

Material and Methods: A search was conducted in the PubMed database using keywords such as "Gaza", "Gaza Strip", "General Surgery", "Trauma", and "Armed Conflict". Studies published between 2024 and 2026 were included. Bibliometric analyses were performed via Bibliometrix/Biblioshiny software, evaluating annual production, author/institutional productivity, core journals (Bradford's Law), keyword co-occurrence, and thematic maps.

Results: Thirty publications indexed in PubMed across 12 journals were analyzed, involving 217 authors. The literature showed a highly collaborative structure (10.2 co-authors per document) with a 13.33% international co-authorship rate. Scientific production peaked in 2025 before a relative decline in 2026. While institutional contributions centered on Gaza-based entities, India, Pakistan, Türkiye, and the USA provided significant global contributions. Thematic analysis indicated that studies primarily focused on demographics, risk factors, and global disease burden. These emerged as "basic themes" with high centrality, whereas themes regarding specific surgical interventions and clinical outcomes remained limited.

Conclusion: This bibliometric analysis reveals that while literature concerning general surgery, emergency surgery, and trauma surgery in the context of Gaza has shown a quantitative increase in the post-2023 period, it remains largely descriptive and demographically focused in terms of content. It is noteworthy that systematic and high-level evidence regarding surgical clinical decision-making, intervention outcomes, and care strategies under conflict conditions is limited. The thematic findings demonstrate that the impacts of war on the civilian population are primarily addressed through the concepts of human and disease burden, while surgical practice is mostly reflected indirectly as a consequence of this humanitarian load. This situation highlights that the events in Gaza are not only a humanitarian crisis but also a surgical care problem that is insufficiently documented scientifically. In conclusion, although the existing literature makes the vital role of surgery in conflict environments quantitatively visible, it fails to sufficiently reflect the actual clinical needs and ethical responsibilities on the ground. By emphasizing that surgical care in wartime is not merely technical but a field of scientific responsibility centered on human dignity, this study provides an objective framework for future patient-centered and systematic research.

Keywords: Gaza, general surgery, humanitarian crisis

Fundoplication preferences and early outcomes in laparoscopic hiatal hernia repair: A single-center retrospective analysis

Ulvi Mecidli, Habip Sarı, Mert Çöl

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: The choice of fundoplication technique during laparoscopic hiatal hernia repair remains individualized, particularly in patients with esophageal motility disorders. This study aimed to evaluate the distribution of fundoplication types and assess early clinical outcomes in our center.

Material and Methods: A retrospective analysis was performed on 117 consecutive patients who underwent laparoscopic hiatal hernia repair in 2025. Demographic characteristics, surgical indications, type of fundoplication, concomitant procedures, and early postoperative outcomes were analyzed. The mean age was 46.7 years, with the majority of patients in the middle-aged group. A 360° Nissen fundoplication was the preferred technique in most cases. Posterior partial (Toupet) fundoplication was performed in patients with documented esophageal motility disorders or increased risk of postoperative dysphagia. In selected cases, additional procedures such as Heller myotomy, revisional surgery, or simultaneous cholecystectomy were performed. Patients were evaluated at 1-, 3-, and 6-month follow-up visits.

Results: Primary hiatal repair and fundoplication were successfully completed in all patients. Nissen fundoplication was the most commonly performed procedure, followed by Toupet fundoplication. Early postoperative morbidity was low, and the rate of major complications was minimal. Reoperation was rarely required. Concomitant procedures did not significantly increase complication rates. Symptomatic improvement was observed in the majority of patients during early follow-up.

Conclusion: Laparoscopic hiatal hernia repair is a safe and effective procedure in our center. The type of fundoplication should be individualized according to patient characteristics and esophageal motility findings. Long-term functional outcomes are required to better define the optimal fundoplication strategy.

Structured communication models in surgical intensive care units: The effect of SBAR and current protocols on team awareness

Onur Turhan, Ayça Elmaderesi Aydın, Emine Bayat

Hacettepe University Hospitals, Adult Hospital, Ankara

Objective: Surgical intensive care units (SICUs) are high-risk areas where patient care is complex and continuous information flow is required among multidisciplinary team members. When the root causes of medical errors are examined in the literature, it is seen that communication deficiencies and errors rank first with a rate of over 60%, and approximately half of these errors occur during patient handovers. Traditional and unstructured communication paves the way for information loss. The aim of this study is; this study aims to evaluate the effects of current structured communication protocols, primarily Situation, Background, Assessment, Recommendation (SBAR), but also I-PASS and Introduction, Situation, Background, Assessment, and Recommendation (ISBAR), on team awareness and patient safety in the CYCU (SICU) in light of literature data.

Material and Methods: This study is a systematic review of national and international literature published between 2015 and 2024 examining the use of structured communication models in surgical and intensive care settings. Studies using SBAR, ISBAR, and related checklists were included by searching PubMed, CINAHL, Medline, and National Databases. Data were analyzed in terms of communication clarity, omission rates, team collaboration, and adverse event frequency parameters.

Results: In the studies reviewed, it was found that the use of standard protocols such as SBAR increased the accuracy of the information conveyed. In the study by Wang et al., it was determined that the use of SBAR-based checklists reduced the rate of "missing information" in patient handover in SICUs from 7.26% to 2.02%. A recent study in Türkiye reported that 66.7% of nurses stated that the SBAR model positively contributed to the handover process. Furthermore, it was observed that the SBAR model reduced hierarchical barriers among team members and increased nurses' confidence in offering "suggestions." Looking at clinical outcomes, it was found that unexpected deaths decreased after the use of structured communication, and communication-related incident reporting decreased from 31% to 11%.

Conclusion: The use of SBAR and similar structured communication protocols in SICUs not only standardizes information transfer but also improves team awareness and patient safety culture. It is recommended that institutions adapt these protocols to their own dynamics, support them with simulation training, and integrate them into electronic health records.

The importance of clinical decision-making processes in resident education: The necrotizing course of mild-onset biliary pancreatitis

Yunushan Furkan Aydoğdu, Murtaza Kaan Özdemir, Enes Faruk Belen

University of Health Sciences Türkiye, Ankara Training and Research Hospital, Ankara

Objective: In the surgical training process, decision-making competence in patient management is shaped not only by theoretical knowledge but also by clinical intuition, multifaceted assessment, and repetitive observation skills. Diseases such as acute pancreatitis, which initially present mildly but can rapidly worsen, are of high educational value in surgical assistant training. In this presentation, the dynamic structure and educational importance of the "safe discharge" decision in assistant training will be discussed using the example of a patient who was initially diagnosed with mild biliary pancreatitis but quickly developed a necrotizing course, resulting in the need for intensive care.

Material and Methods: A 57-year-old man presented with right upper quadrant pain and nausea. Laboratory tests showed amylase levels more than three times the normal limit, and imaging findings were consistent with biliary pancreatitis. He was admitted with mild acute pancreatitis and treated with intravenous fluids and empirical broad-spectrum antibiotics. Although initially stable and evaluated for discharge on day four after tolerating oral intake, the patient developed fever, tachycardia, hypoxia, and leukocytosis on day five. Contrast-enhanced CT revealed necrotizing pancreatitis, and the patient was transferred to the intensive care unit due to sepsis. Two percutaneous drainage catheters were placed under interventional radiology guidance on separate days, and antibiotic therapy was adjusted according to culture results. The patient gradually improved and was discharged on day 46.

Results: This case highlights three key concepts in surgical assistant training: 1. The relativity of clinical stability: the patient showed signs of improvement on the 4th day but experienced a significant deterioration on the 5th day, illustrating how sensitive an assessment is required for the concept of "early discharge." 2. Multidisciplinary patient management: the coordinated approach of the surgical, intensive care, infectious diseases, and interventional radiology units provides an ideal example for residents to develop their clinical leadership and communication skills in such patients. Clinical intuition and continuous observation: the fluctuating course observed in this case emphasizes the need to teach residents not only clinical algorithms but also decision-making based on individualized observation.

Conclusion: Even in cases of mild biliary pancreatitis, residents must be cautious when making early discharge decisions due to the dynamic clinical course and must develop the habit of performing multidimensional patient assessments, not just laboratory and imaging tests. This case highlights the educational value of incorporating patient monitoring processes into surgical training curricula not only based on complications but also on decision-making processes.

Health care quality literacy scale

Murat Yıldırım, Alper Yavuz

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: With the launch of the Health Transformation Program by the Ministry of Health in 2003, a healthcare delivery model emphasizing efficiency, effectiveness, patient safety, and patient satisfaction was adopted, and performance- and quality-based evaluation mechanisms were systematically developed. Currently, quality practices in Türkiye are conducted on the basis of patient safety, clinical quality indicators, accreditation processes, and continuous quality improvement cycles, aiming to institutionalize a sustainable and measurable culture of quality within healthcare services. Nevertheless, the failure to fully internalize and embed a quality culture at the hospital level remains a significant challenge. In this study, we aim to evaluate the level of quality culture implementation in healthcare institutions and to highlight existing gaps, thereby contributing to the growing body of literature on healthcare quality management.

Material and Methods: This study was conducted to assess the quality literacy levels of residents working in the General Surgery Clinic of University of Health Sciences Türkiye, Ankara Etlik City Hospital in the context of healthcare service delivery. A standardized questionnaire was administered for this purpose. In addition, five supplementary questions were incorporated into the introductory section of the survey to evaluate physicians' perspectives on quality (Tables 1 and 2). Quality literacy scores were calculated on a scale ranging from 0 to 100 based on participants' responses to the questionnaire. Furthermore, the distribution and proportions of responses to the questions assessing attitudes toward quality were analyzed.

Results: Analysis of the first five items showed that 88.1% (n=52) of residents answered "yes" and 11.9% (n=7) "no" to the question "Are quality practices necessary in healthcare?" To "Have you received training on quality practices?", 57.6% (n=34) responded "yes" and 42.4% (n=25) "no." Regarding their perspective, 69.5% (n=41) reported a positive view and 30.5% (n=18) a negative view. To "How do you define quality practices?", 59.3% (n=35) described them as a "loss of workforce," while 40.7% (n=24) considered them "necessary." Concerning primary responsibility, 45.8% (n=27) indicated physicians and 54.2% (n=32) nurses. Descriptive statistics showed a mean score of 63.09±22.71. According to the evaluation criteria, this value falls within the 50–75 range, indicating a good level on the scale.

Conclusion: Although the residents achieved high scores in quality literacy, their perception of quality practices as a source of workforce burden and as primarily a nursing responsibility may indicate that a fully institutionalized culture of quality has not yet been established.

Keywords: Health, quality

Table 1. Physicians' perspectives on quality practices

Age:	**Year of residency:**	
Are quality practices necessary in healthcare?	Yes	No
Have you received training on quality practices?	Yes	No
What is your perspective on quality practices?	Positive	Negative
How do you define quality practices?	Loss of workforce	Necessary
Who do you think holds primary responsibility for quality practices?	Physician	Nurse

The role of preoperative laboratory parameters in predicting complicated acute appendicitis: A single-center experience

Semih Yolcu, Ferudun Kaya, Serkan Ademoğlu, Ercan Korkut

University of Health Sciences Türkiye, Gaziantep City Hospital, Gaziantep

Objective: Acute appendicitis is one of the most common causes of acute abdomen requiring emergency surgical intervention. Delayed diagnosis may lead to the development of complicated forms such as gangrenous or perforated appendicitis, resulting in increased morbidity. Early prediction of complicated acute appendicitis is therefore essential for determining appropriate surgical timing and optimizing perioperative management. Although computed tomography has high diagnostic accuracy, its use may be limited by radiation exposure and accessibility. Recently, simple and readily available preoperative laboratory parameters have been suggested as useful tools for predicting disease severity and complicated appendicitis. This study aimed to evaluate the role of preoperative laboratory parameters in predicting complicated acute appendicitis.

Material and Methods: This single-center retrospective study included patients who underwent surgery for acute appendicitis between September 16, 2025, and January 8, 2026. Demographic characteristics, preoperative laboratory parameters, and pathological findings were reviewed retrospectively. Patients with incomplete data were excluded from the statistical analysis. Based on pathological evaluation, patients were classified as having complicated appendicitis (gangrenous, perforated, or plastron appendicitis) or uncomplicated appendicitis. Preoperative white blood cell count (WBC), C-reactive protein (CRP), albumin levels, and neutrophil-to-lymphocyte ratio (NLR) were compared between the groups. Statistical analyses were performed using appropriate tests according to data distribution. A p-value of <0.05 was considered statistically significant.

Results: A total of 99 patients were included in the final analysis. Preoperative WBC and CRP levels were significantly higher in the complicated appendicitis group compared with the uncomplicated group ($p=0.024$ and $p=0.035$, respectively). No statistically significant differences were observed between the groups in terms of albumin levels or NLR ($p>0.05$).

Conclusion: Preoperative laboratory parameters, particularly WBC count and CRP levels, may be useful in predicting complicated disease in patients with acute appendicitis. The integration of these readily available markers with clinical assessment may contribute to improved risk stratification and optimization of surgical decision-making.

Laser ablation for pilonidal sinus: Initial experience from a single center

Mehmet Fatih Yiğit[1], Muratcan Fırat[2], Server Sezgin Uludağ[2], Nazım Güreş[1]

[1]*Balıkesir Atatürk City Hospital, Balıkesir*

[2]*İstanbul University-Cerrahpaşa, Cerrahpaşa Faculty of Medicine, İstanbul*

Objective: Pilonidal sinus disease (PSD) is a chronic condition involving hair ingrowth and infection in the sacrococcygeal region, primarily affecting young adults. It significantly impacts quality of life due to pain, discomfort, and recurrent infections. Traditional surgical methods often require extensive excisions and prolonged healing, whereas laser ablation has emerged as a minimally invasive alternative. Laser ablation destroys sinus tract inner surfaces using laser energy, offering less tissue damage, shorter recovery, and reduced postoperative pain. Initial success rates range from 73–94%, but long-term (≥60 months) recurrence rates may reach 14-36%, potentially higher than excision techniques like the Karydakis flap. This study evaluates laser ablation effectiveness and spinal anesthesia advantages in a single-center experience. Spinal anesthesia enhances muscle relaxation, improves operative field control, aids postoperative pain management, and increases patient comfort. It also offers fewer complications and shorter hospital stays compared to general anesthesia. This study focuses on the role of spinal anesthesia in laser ablation procedures.

Material and Methods: In this single-center retrospective study, outcomes of 42 patients undergoing laser ablation for PSD between January 2023 and October 2024 were analyzed. All procedures used spinal anesthesia. Demographic data, clinical characteristics, operative details, complication rates, recurrence rates, and pain scores were recorded.

Results: The mean patient age was 28.5±7.2 years (range: 18-45). Of the patients, 33 (78.6%) were male, and 9 (21.4%) were female. Mean operative time was 25±8.5 minutes. Complications included abscess (2 patients), hematoma (1 patient), and seroma (8 patients). Two seroma cases required debridement and open surgery, while spontaneous resolution occurred in approximately 28 days for others. No recurrences were observed. Mean hospital stay was 1 day, return to daily activities was 3 days, and mean satisfaction level (VAS scale) was 8.5. Postoperative pain scores (VAS) were significantly lower than preoperative scores.

Conclusion: Laser ablation is a minimally invasive, effective, and safe treatment for PSD. Further research is needed on long-term recurrence rates and factors such as obesity and multiple sinus tracts.

Keywords: Laser ablation, minimally invasive surgery, pilonidal sinus

Table 1.

Parameter	Results

[2]*Department of General Surgery, Trabzon Faculty of Medicine, University of Health Sciences Türkiye, Trabzon Kanuni Training and Research Hospital, Trabzon*

[3]*Department of Medical Pathology, Karadeniz Technical University Faculty of Medicine, Trabzon*

Objective: Parathyroid cancer accounts for less than 1% of primary hyperparathyroidism cases. It is a rare endocrine pathology. Most patients present with markedly elevated serum calcium (Ca) and parathyroid hormone (PTH). Surgery is the gold standard treatment. Definitive diagnosis is by histopathology. Although Ca and PTH generally normalize after surgery, persistent or recurrent hypercalcemia—or persistent hypocalcemia—may develop. We aimed to draw attention to this rare entity by presenting our patient who developed persistent hypocalcemia following parathyroid cancer surgery.

Material and Methods: An 89-year-old male patient presenting to the neurology department with forgetfulness and dizziness was referred to the endocrinology outpatient clinic after labs revealed serum Ca 11.3 mg/dL. The patient was diagnosed with primary hyperparathyroidism and referred to our department for surgical management. During the operation, multiple nodules were observed in both thyroid lobes, as well as a soft tissue mass at the mid-upper level of the left thyroid lobe, whose borders could not be clearly distinguished from the thyroid (invasion) (Figure 1). An incisional biopsy specimen was obtained from this area and evaluated by frozen section, which reported oncocytic cells invading the thyroid. Thereupon, a bilateral total thyroidectomy with right central lymph node dissection was performed en bloc, including the aforementioned soft tissue mass.

Results: The patient's preoperative serum Ca was 12.3 mg/dL and PTH was 263 pg/mL. Neck ultrasonography showed bilateral isoechoic solid nodules (largest 2 cm in the left lobe) and a 18×14 mm irregular nodular lesion in the posterior mid-portion of the left lobe (parathyroid lesion). Parathyroid scintigraphy demonstrated focal uptake in the upper pole of the left thyroid lobe, consistent with hyperfunctioning parathyroid tissue. En bloc left superior parathyroidectomy and bilateral total thyroidectomy were performed. Postoperative Ca and PTH levels on day 1, month 1, and month 6 were 7.3 mg/dL and <1 pg/mL; 8 mg/dL and 23 pg/mL; and 8.1 mg/dL and 22 pg/mL, respectively. The patient was discharged on postoperative day 4 with oral Ca and vitamin D (1000 mg/880 IU) three times daily. Pathology revealed "parathyroid carcinoma infiltrating the thyroid" (Figure 2). He remains under close endocrinology follow-up, and the Ca dose was reduced to twice daily at month 6.

Conclusion: Parathyroid carcinoma is a rare endocrine malignancy diagnosed definitively by histopathology. Imaging findings and markedly elevated serum Ca and PTH levels may raise suspicion. Although these levels usually normalize postoperatively, hungry bone syndrome and persistent hypocalcemia may rarely occur. Close multidisciplinary follow-up is recommended.

Inflammatory breast cancer: A single-center experience

Kübra Ergin Karabalık, Firdevs Melike Onuktav, Gülay Özbölük, Ebru Şen

Department of General Surgery, University of Health Sciences Türkiye, Başakşehir Çam and Sakura City Hospital, İstanbul

Objective: This retrospective study included a total of 24 patients diagnosed with inflammatory breast cancer (IBC) between 2023 and 2025 who underwent surgical treatment following neoadjuvant chemotherapy (NAC). The patients' demographic characteristics, tumor biology, response to neoadjuvant therapy, type of surgical intervention, axillary surgical approach, and pathological response rates were examined. Pathological complete response (pCR) was defined as the absence of invasive tumor in both the primary tumor site and the axilla. Disease course and survival data were evaluated retrospectively.

Material and Methods: Patients diagnosed with IBC between 2023 and 2025 were included in this retrospective study. Demographic data, clinical and pathological features, treatments administered, disease progression, recurrence, metastasis status, and survival data were retrieved from patient medical records. Overall survival and progression-free survival were analyzed using the Kaplan-Meier method. Data were evaluated using descriptive statistics.

Results: All patients received trimodality therapy consisting of surgery and adjuvant radiotherapy after NAC. pCR was achieved in 6 patients (25%). In the axillary evaluation, node negativity was detected in 62.5% of the patients. Among the 16 patients who underwent Sentinel Lymph Node Biopsy (SLNB), 8 (50%) were found to be axilla-negative. It was observed that axillary involvement rates were lower in patients who achieved pCR. Local recurrence in the axilla was observed in one patient, and brain metastasis was detected in another patient during the first postoperative year.

Conclusion: Trimodality therapy provides significant pathological response rates in patients with IBC. The 25% pCR rate obtained in our series is consistent with the literature and supports the efficacy of neoadjuvant therapy. The high rates of axillary node negativity support current discussions in the literature suggesting that axillary surgery may be limited in selected patients. The axillary approach in IBC may be re-evaluated, subject to confirmation by larger series.

Keyword: Inflammatory breast cancer

Table 1. Clinical outcomes and pathological responses

Characteristic/finding	n	Percentage (%)
Pathological complete response (pCR)	6	25.0%
Axillary status		
Overall node negativity	15	62.5%
Sentinel lymph node biopsy (SLNB) performed	16	66.7%
Negative SLNB (among SLNB group)	8	50.0%

Fournier gangrene in a tertiary surgical center: Patterns of microbiology, antibiotic resistance, and risk stratification

Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Şener Balas[1], İrfan Şencan[3]

[1]*Department of General Surgery, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Clinic of General Surgery, Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

[3]*Department of Infectious Diseases, University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

Objective: Fournier gangrene represents one of the most fulminant soft-tissue infections, originating in the perineal and genital regions and spreading rapidly along fascial planes. Identifying causative microorganisms and their antimicrobial susceptibility is essential to guide empirical therapy and improve outcomes.

Material and Methods: This retrospective study was conducted at University of Health Sciences Türkiye, Ankara Etlik City Hospital, General Surgery Clinic between October 2022 and May 2025. Of 59 operated patients, 30 with complete clinical and microbiological data and available wound cultures were included. Demographic features, microbiological profiles, antibiotic susceptibility, and fournier's gangrene severity index (FGSI) scores were analyzed.

Results: The mean age was 59.2 years (range: 45-84), with male predominance (56.7%). Nearly half of the patients were aged 50-59 years (46.7%). Wound cultures demonstrated monomicrobial growth in 50.0%, polymicrobial in 26.7%, and no growth in 23.3% (Figure 1). *Escherichia coli* was the most common pathogen (52.9%), followed by *Klebsiella pneumoniae* (8.8%), while anaerobes were rarely isolated. Resistance rates reached 41.4% in Gram-positive and 38.3% in Gram-negative organisms. Amikacin (100%) and carbapenems (>80%) exhibited the highest susceptibility, whereas fluoroquinolones and aminopenicillins showed resistance above 40% (Figure 2). Based on FGSI, 93.3% of patients were classified as low risk (FGSI <9) and 6.7% as high risk (FGSI ≥9).

Conclusion: *E. coli* was the predominant pathogen in Fournier gangrene, accompanied by considerable resistance to widely used antibiotics. Aminoglycosides and carbapenems remain the most reliable empirical options. Although most patients presented with low FGSI scores, the presence of resistant isolates emphasizes the need for region-specific antibiotic stewardship and comprehensive multidisciplinary management.

An overlooked risk factor for anastomotic leakage in colorectal surgery: Vascular calcifications and mesenteric artery stenosis

Osman Gökhan Gökdere, Bilal Aydoğmuş, Zeynep Arda Acar, Burhan Hakan Kanat, Gökhan Söğütlü, Furkan Yazıcıoğlu

Malatya Turgut Özal University Faculty of Medicine, Malatya

Objective: Anastomotic leakage (AL) is one of the most serious complications following colorectal surgery, significantly increasing postoperative morbidity and mortality. Although adequate tissue perfusion is essential for anastomotic healing, reliable and easily accessible preoperative risk predictors remain limited. Mesenteric artery stenosis and vascular calcifications detectable on routine preoperative computed tomography (CT) imaging are potential factors that may impair anastomotic perfusion but are often overlooked in clinical practice. The aim of this systematic review and meta-analysis was to evaluate the association between vascular pathologies assessed on preoperative CT and the risk of clinically relevant anastomotic leakage.

Material and Methods: This study was conducted as a systematic review and meta-analysis in accordance with PRISMA guidelines. Observational studies evaluating mesenteric artery stenosis (inferior and/or superior mesenteric artery) and abdominal aortic or aortoiliac calcification on preoperative CT imaging, and reporting anastomotic leakage after colorectal surgery, were included. Only clinically relevant anastomotic leaks classified as Grade B or C according to the International Study Group of Rectal Cancer (ISREC) were analyzed. Effect estimates were extracted as odds ratios (ORs) with 95% confidence intervals, and pooled using a random-effects model due to inter-study heterogeneity. Methodological quality was assessed using the Newcastle-Ottawa scale. PRISMA flow diagram illustrating the identification, screening, eligibility assessment, and inclusion of studies evaluating vascular calcification and anastomotic leakage following colorectal surgery.

Results: Seven observational studies involving more than 3.000 patients were included in the analysis. Mesenteric artery stenosis was significantly associated with an increased risk of anastomotic leakage. Inferior mesenteric artery stenosis was associated with more than a twofold increase in the risk of anastomotic leakage. Although superior mesenteric artery stenosis was evaluated in a smaller number of studies, the available data indicated a strong association with increased leakage risk. The presence of abdominal aortic and aortoiliac calcification was also significantly associated with a higher risk of anastomotic leakage. In studies using the Aortic Calcification Index, increased calcification burden was identified as an independent risk factor for anastomotic leakage. Despite methodological heterogeneity, the direction of effect was consistent across studies.

Conclusion: Mesenteric artery stenosis and vascular calcifications detected on preoperative CT imaging are associated with an increased risk of clinically relevant anastomotic leakage following colorectal surgery. Systematic evaluation of vascular structures on routine preoperative imaging may enhance risk stratification and support surgical decision-making. This approach may facilitate individualized surgical strategies, particularly in patients at high risk for anastomotic leakage.

A rare pathology in patients operated with a pre-diagnosis of acute appendicitis: Analysis of our cases of appendiceal endometriosis

Mehmet Hasan Cam, Metin Yüksel, Serkan Demir, Mehmet Salih Süer, Ender Ergüder, Şener Balas

University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara

Objective: Appendiceal endometriosis is a rare pathology, particularly observed in women of reproductive age, which frequently mimics the clinical presentation of acute appendicitis. Preoperative diagnosis is often not feasible, and the definitive diagnosis is established through histopathological examination. In this study, we aimed to evaluate the clinical, radiological, and histopathological characteristics of cases operated with a preliminary diagnosis of acute appendicitis and subsequently diagnosed with appendiceal endometriosis based on pathology results.

Material and Methods: Ten female patients who underwent surgery with a preliminary diagnosis of acute appendicitis and were histopathologically diagnosed with appendiceal endometriosis at our clinic between October 2022 and October 2025 were retrospectively reviewed. Demographic data, presenting complaints, imaging findings, intraoperative observations, and histopathological results were analyzed.

Results: The mean age of the patients was 37.1 years (range: 21-57). All cases presented with right lower quadrant pain; anorexia and nausea were recorded as the most common associated symptoms. In imaging studies, findings consistent with acute appendicitis were observed in the majority of cases, while pelvic inflammatory disease or cystic lesions were additionally detected in two cases. Histopathological examination identified endometriosis foci in all cases, and ER, PR, and CD10 positivity was determined immunohistochemically. In the majority of cases, significant inflammatory changes accompanying acute appendicitis and edema in the periappendiceal adipose tissue were observed.

Conclusion: Appendiceal endometriosis, although rare, is a significant pathology that can clinically mimic acute appendicitis in women of reproductive age and is often indistinguishable during the preoperative period. Especially in the presence of accompanying pelvic inflammatory findings or suspected gynecological pathology, keeping it in mind for the differential diagnosis of acute appendicitis may reduce unnecessary diagnostic delays and potential recurrent admissions. Careful histopathological evaluation of the appendectomy specimen, and confirmation with immunohistochemical markers such as ER, PR, and CD10 when necessary, is of critical importance for a definitive diagnosis and for guiding the management of the potential associated endometriosis burden. Therefore, adopting a standardized assessment approach between surgical and pathology teams will strengthen clinical management.

[4]*Department of Internal Medicine, Division of Gastroenterology, Acıbadem Atakent Hospital, İstanbul*

Objective: The liver is the most frequent site for colorectal cancer metastasis, and various management options exist for these patients. While surgical resection is the curative standard for resectable metastases, ablation techniques have emerged as a significant alternative in selected cases. Guidelines recommend ablation for small lesions (<3 cm). In this way, ablation serves as an alternative approach that may protect the patient from major surgery and its associated risks. Radiofrequency ablation (RFA) is a widely utilized method among these techniques. Although RFA is commonly performed percutaneously, EUS-guided application for pancreatic, adrenal, and liver lesions is considered as a safe alternative. This method can be considered an effective treatment option for metastatic liver lesions, as well as primary hepatobiliary malignancies. Here we share our experience with EUS-guided RFA for a metastatic liver focus that showed regression after systemic therapy.

Material and Methods: A 65-year-old-male presented with abdominal pain and difficulty in defecation. Examinations revealed 28 cm rectosigmoid lesion circumferentially narrowing the lumen. Biopsy confirmed adenocarcinoma. Contrast-enhanced CT detected wall thickening in the rectosigmoid region, suspicious pericolic lymph nodes, and 21x17mm metastatic lesion in liver segments 8 and 4a (cT3N2bM1a) (Figure 1). No pulmonary metastases were observed. Systemic therapy was initiated. After 6 cycles of FOLFIRINOX + bevacizumab, imaging showed near-complete regression in the liver and partial regression in the primary mass. The multidisciplinary tumor board planned primary tumor resection and RFA for the liver lesion.

Results: In the patient scheduled for laparoscopic low anterior resection (LAR) and intraoperative RFA, the liver lesion—undetected on preoperative USG—was localized with difficulty using intraoperative laparoscopic USG. However, since the posterior right lobe lesion was technically unsuitable for percutaneous or laparoscopic intervention, ablation was postponed to the postoperative period. The LAR procedure was completed without complications. Postoperative pathology reported adenocarcinoma, ypT3N1bMx, Grade 2. On the 6th postoperative day, the patient underwent ablation with RFA at 50W for 10 seconds on an 11x10 mm hypoechoic lesion observed in liver segment 8 via transgastric EUS guidance (Figure 2). The patient was discharged on day 7 without complications. After completing a total of 12 cycles of adjuvant FOLFIRINOX treatment, capecitabine + bevacizumab was initiated as maintenance therapy.

Conclusion: EUS-assisted RFA is a valuable alternative for liver metastases that could not be reached intraoperatively due to anatomical locations. As in this case, when percutaneous or intraoperative ablation is unfeasible, postoperative EUS-RFA may be a viable treatment option.

Bibliometric analysis of the Turkish publications on the inflammatory bowel disease surgery

Ali Cihat Yıldırım, Sezgin Zeren, Yalçın Sönmez

Department of General Surgery, Kütahya Health Sciences University Faculty of Medicine, Kütahya

Objective: Inflammatory bowel disease (IBD), which includes ulcerative colitis and Crohn's disease, frequently requires surgical intervention due to complications or the ineffectiveness of medical therapy during disease course. Recently, Türkiye has become a notable contributor to the global literature on IBD surgery; however, a comprehensive analysis of the characteristics and impact of these publications is lacking. This study aims to systematically explore the publication trends, research focus, and institutional contributions of Turkish authors in the field of IBD surgery.

Material and Methods: A bibliometric analysis was conducted using data extracted from the Scopus database, specifically targeting publications related to IBD surgery with at least one author affiliated with a Turkish institution. The dataset comprised detailed metadata, including author names, full affiliations, article titles, publication years, document types, keywords, citation counts and journal information. Data cleaning and preprocessing were performed in Python, involving the normalization of author and institution names and the extraction of pertinent keywords.

Results: The analysis revealed that the majority of Turkish-authored publications on IBD surgery were original research articles, with "inflammatory bowel disease," "ulcerative colitis," and "Crohn's disease" being the most common keywords. The annual publication output has steadily increased, indicating growing research activity. The most productive authors were affiliated with major academic centers in Türkiye, particularly İstanbul and Ankara. Institutional analysis indicated that Turkish universities and departments of gastroenterology and general surgery were the primary contributors to this research. Collaboration networks demonstrated both strong intra-national and notable international partnerships, especially with the United Kingdom and Italy. Research topics have extended beyond surgical techniques to encompass management, pregnancy, colonoscopy, and comorbid conditions such as familial Mediterranean fever.

Conclusion: This bibliometric study provides a detailed characterization of Turkish contributions to the literature on IBD surgery. The findings underscore Türkiye's prominent and expanding role in this field, the diversity of research topics, and the significance of national and international collaboration. These insights can inform future research strategies and foster advancements in IBD surgery.

The relationship between clinical, radiological, and laboratory findings and clinical course in Ogilvie syndrome: A single-center case series

Ahmetcan Atmaca[1], Gürkan Değirmencioğlu[1], Muhammed Salih Süer[1], Serkan Demir[1], Faruk Yazıcı[2], Şener Balas[1]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Etimesgut Martyr Sait Ertürk State Hospital, Ankara*

Objective: Acute colonic pseudo-obstruction (ogilvie syndrome) is a clinical condition that often developes under advanced age, severe comorbidities, and systemic stress. In cases of delayed diagnosis and treatment, it can lead to significant morbidity and mortality. This study aimed to evaluate the demographic characteristics, triggering factors, clinical-radiological findings, laboratory parameters, treatment approaches, and short-term clinical outcomes of patients diagnosed with ogilvie syndrome.

Material and Methods: A total of 5 patients diagnosed with ogilvie syndrome who were followed up in the general surgery clinic of etlik city hospital were included in this retrospective observational study. Demographic data, ASA score, Charlson comorbidity index categories, possible triggering factors, and medication use were recorded. Clinical presentation findings, cecum diameter measurements in radiological evaluation, and imaging findings for excluding mechanical obstruction were examined. Laboratory parameters, including serum electrolyte levels, albumin, and lactate values, were used to assess metabolic status. Treatment approaches (conservative monitoring, neostigmine administration, colonoscopic decompression, and surgical intervention), recurrence rates, and 30-day mortality were analyzed. The data were presented using descriptive statistics.

Results: A total of 5 patients with ogilvie syndrome were included. Median age was 88 (46-93), 60% male. All had high-risk profiles (ASA ≥3: 100%), distributed asa 3 (40%) and ASA 4 (60%). Charlson comorbidity index: 0 (1 patient), 4 (2 patients), 5 (2 patients). ICU/immobilization was a trigger in 20% of cases; others were in "other" category (80%). All had abdominal distention, pain, and constipation, with vomiting in 80%. Laboratory results: median WBC 10.2/mm^3, CRP 85 mg/L, lactate 2.04 mmol/L, albumin 38.6. No electrolyte disturbances. Radiological exam: median cecum diameter 10.0 cm, transverse colon 7.5 cm; mechanical obstruction excluded. Conservative treatment in 40%, decompression tubes in 80%, colonoscopic decompression in 20%, surgery in 20%. 60% responded in 24 hours. No recurrence at 72 hours or 7 days. 30-day mortality 60%.

Conclusion: This study confirms that ogilvie syndrome occurs in elderly patients with high comorbidity, but can also present with severe clinical course without classic triggering factors like electrolyte imbalances. Systematic exclusion of mechanical obstruction, careful evaluation of cecum diameter, and interpretation with clinical presentation were decisive in diagnosis and treatment. Laboratory parameters such as albumin and lactate reflected disease severity and systemic stress. Treatment approaches were individualized, and while no recurrence was found, the high mortality rate was more related to the heavy comorbidity burden than ogilvie syndrome itself. These findings support the importance of early diagnosis, close monitoring, and a comprehensive approach with clinical, radiological, and laboratory data.

FISSURE-CD (FISSUre in cRohn's disEase): International prospective multicentre observational study on the management and outcomes of anal fissure in Crohn's disease

Semra Demirli Atıcı[1], Aras Emre Canda[2], Mustafa Cem Terzi[2]

[1]*Clinic of General Surgery, Acıbadem Kent Hospital, İzmir*

[2]*KRC Clinic for Colorectal Surgery and Peritoneal Surface Malignancies, İzmir*

Objective: Perianal Crohn's disease research has predominantly focused on anal fistulas. However, in clinical practice, the first perianal manifestation is frequently an anal fissure. Current management strategies for Crohn's-related fissures are largely extrapolated from idiopathic fissure algorithms, despite fundamental differences in inflammatory pathobiology, tissue healing dynamics, and disease course. Existing guidelines provide safety frameworks for idiopathic fissures but offer no phenotype-driven strategy for Crohn's-associated fissures. This study aims to develop the first biology-centred, phenotype-based treatment selection model, shifting decision-making from procedure-orientated paradigms toward disease-specific stratification.

Material and Methods: This international prospective multicentre observational cohort study includes adult Crohn's disease patients diagnosed with anal fissures between June 2026 and June 2027 who meet the inclusion criteria. Patients will be followed for at least 6 months (optionally 12 months). Continuous variables will be summarised as mean ± SD or median (IQR); categorical variables as absolute and relative frequencies. Multilevel mixed-effects logistic regression and Cox frailty models will identify independent predictors, accounting for center clustering. Confounding will be addressed through prespecified adjustment and IPTW sensitivity analyses. Sample size was planned to provide ~80% power to detect a clinically meaningful difference in healing at α=0.05.

Results: The primary endpoint is clinical fissure healing rate and time following index fissure-directed treatment. Clinical healing is defined ASA documented macroscopic epithelialisation or absence of visible fissure on examination, with patient-reported pain ≤ 2/10 on the visual analogue scale (VAS) without analgesic use for ≥7 days. Resolution or minimal pain (VAS ≤ 2/10 or equivalent clinical documentation), c) No requirement for escalation within 12 weeks for medical therapy. The secondary endpoint is to evaluate symptom improvement, time to healing, treatment escalation, recurrence, and complications, HR-QoL change (IBDQ-short or EQ-5D-5L), and continence (Vaizey/Wexner score), as well as identify clinical and disease-related predictors of treatment success or failure.

Conclusion: This study aims to identify independent determinants of clinical improvement and the need for treatment escalation in anal fissures associated with Crohn's disease. Based on the findings, the goal is to develop a risk-based and phenotype-focused management algorithm for CD-related anal fissures. This will reveal the biological and clinical differences between this clinical presentation and idiopathic anal fissures; treatment strategies for patients with concomitant CD and anal fissures can be restructured according to disease activity and involvement characteristics.

Can the surgery-to-resident ratio be used to determine the ideal number of residents in a general surgery training clinic? Single-center experience

Ahmet Can Koyuncuoğlu[1], Çağrı Büyükkasap[2], Aydın Yavuz[2], Hüseyin Göbüt[2], Kürşat Dikmen[2]

[1]*University of Health Sciences Türkiye, Ankara Etlik City Hospital, Ankara*

[2]*Gazi University Hospital, Ankara*

Objective: General surgery training requires significant clinical exposure for residents to acquire essential skills, knowledge, and experience. Successfully navigating the surgical learning curve and preparing for independent practice strongly depend on the volume of procedures residents actively perform. In our country, resident numbers are determined centrally; however, evaluating a clinic's educational carrying capacity objectively is crucial. Although adding residents can distribute workloads, it risks diluting the surgical cases available per resident if clinical capacity remains unchanged, ultimately compromising education quality. This study aims to examine the impact of resident numbers on surgical training quality and evaluate the surgery-to-resident ratio (SRR) as a systematic metric to determine the optimal number of residents.

Material and Methods: A retrospective analysis was conducted at the General Surgery Department of Gazi University Faculty of Medicine between 2012 and 2023. Data were evaluated across 48 three-month quarterly periods. The analysis included total surgeries under general anesthesia, appendectomies, upper endoscopies, and colonoscopies. Procedures under local anesthesia and residents serving less than three months were strictly excluded. The surgery-to-resident ratio (SRR) was calculated by dividing the total number of surgical procedures by the total number of active residents. To prevent statistical bias from the suspension of elective procedures, periods heavily affected by the COVID-19 pandemic were entirely excluded from the ideal number calculations

Results: Over the 48 periods, the resident count fluctuated between 12 and 26, averaging 18.69. As the number of residents increased, a steady, significant decline in total surgical cases per resident was observed. During the COVID-19 pandemic, total surgeries decreased significantly due to the restriction of elective cases (p=0.038). After excluding the pandemic periods, the SRR and resident totals were overlaid on a 3-axis chart. Statistical comparisons revealed that the SRR decreased significantly when the resident count exceeded 18 (p=0.032). This drop became even more pronounced when the resident count reached 21 (p=0.036). Based on these statistical intersection points and the current surgical volume, the ideal number of residents for our clinic was accurately determined to be 18.

Conclusion: Expanding the surgical resident workforce without concurrent enhancements to clinical resources—such as hospital beds and operating rooms—inevitably leads to educational inefficiencies. The SRR method provides an objective, evidence-based approach to determine the optimal number of residents, ensuring adequate case exposure. While 18 is unique to our specific institutional data, the SRR methodology can be readily adapted by other surgical training centers to maintain rigorous, high-quality surgical education standards globally.

Keywords: Surgery education, surgery-to-resident ratio, resident case exposure
